Organic Reagents[1] in Qualitative Analysis.
I. The Separation of Iron, Chromium and Aluminum

BY LEO LEHRMAN, ELVIN A. KABAT AND HAROLD WEISBERG

In the usual methods of analysis of the ammonium sulfide group a mixture of sodium hydroxide and sodium peroxide is employed to separate the iron and aluminum groups.[2,3] It is a well known fact that these reagents, especially the former, due to its action on glass, introduce small amounts of aluminum and silica into the solution.[4,5] In the final precipitation of aluminum ion by ammonium hydroxide any silica originally present will also be precipitated as silicic acid. This precipitate may be mistaken for aluminum hydroxide, though the use of aluminon will overcome this possible error.[6] However, it would be preferable to separate and detect aluminum ion without the use of sodium hydroxide and sodium peroxide or at least before they are added.

The problem would be simplified considerably if it were possible to separate the trivalent from the divalent metallic ions. Ammonium hydroxide in the presence of ammonium salts has been shown to be unreliable[7] even when the *P*H of the solution has been controlled.[8] Recently the separation of ferric ion from the divalent metallic ions was reported by using hexamethylenetetramine which, it is stated, acts as a very weak base in acid solution and precipitates ferric hydroxide.[9] The authors claim that from a study of the *P*H's at which chromic hydroxide and the hydroxides of the divalent metallic ions form, it would be impossible to make a separation. However, experimentation sho [illegible] iling [illegible] of each metallic ion containing a [illegible] trivalent [illegible] are

precipitated by hexamethylenetetramine. This fact suggested a possible method of separation when the metallic ions are present together. Further work confirmed this possibility.

Experimental

Reactions of the Metallic Ions with Hexamethylenetetramine.—To 100 mg. separately of each of the metallic ions in 10 cc. of solution, excess 10% $(CH_2)_6N_4$ in water solution was added. If precipitation took place the reagent was added until complete and the mixture filtered. To both the filtrates and the solutions in which there was no precipitation, concentrated ammonia was added to distinct alkalinity and then hydrogen sulfide passed in. The experiments were repeated only boiling after the addition of $(CH_2)_6N_4$ and in a third group 1 g. ammonium nitrate was added first. Table I shows the results of these experiments.

TABLE I

REACTIONS OF METALLIC IONS WITH $(CH_2)_6N_4$

Metallic ion	$(CH_2)_6N_4$, precipitation	$(CH_2)_6N_4$ + boiling, precipitation	1 g. NH_4NO_3 + $(CH_2)_6N_4$, precipitation	1 g. NH_4NO_3 + $(CH_2)_6N_4$ + boiling, precipitation
Fe^{+++}	Complete	Complete	Complete	Complete
Al^{+++}	None	Complete	Complete	Complete
Cr^{+++}	None	Complete	None	Complete
Ni^{++}	None	Partial	None	None
Co^{++}	None	Partial	None	None
Mn^{++}	None	Partial	None	None
Zn^{++}	Partial	Complete	None	None
Fe^{++}	Partial	Partial	Partial	Partial

Separation of Trivalent Metallic Ions from Divalent.—To a mixture of 100 mg. of Fe^{++} and 5 mg. of Mn^{++} in a solution of 75 cc. of 0.3 *N* hydrochloric acid containing 1 g. of ammonium nitrate, comparable to the filtrate from the previous group after the hydrogen sulfide has been boiled out, 5 cc. of 3% hydrogen peroxide was added and boiled for five minutes in order to oxidize the Fe^{++} to Fe^{+++}; 10% $(CH_2)_6N_4$ solution was then added to the boiling solution until no more precipitation took place. The filtrate was concentrated to 20 cc. and divided in half. Both solutions were treated with ammonium sulfide, the precipitates filtered and washed. One precipitate was tested for Mn^{++} by the sodium bismuthate method and the other by a sodium carbonate bead and potassium chlorate. Both methods gave positive results. The experiment was repeated using 100 mg. of each of the other trivalent metallic ions separately and 5 mg. of Mn^{++}. Positive tests for Mn^{++} were obtained. Further experiments showed that 1 mg. of Mn^{++} originally in the presence of 100 mg. of each of the trivalent metallic ions together could be detected by the sodium bismuthate method and 2 mg. by the bead test. A solution of 100 mg. of each of the trivalent metallic ions together was carried through the same procedure. The filtrate after the addition of $(CH_2)_6N_4$ yielded no precipitate with ammonium sulfide, showing complete precipitation by $(CH_2)_6N_4$.

The above experiments were repeated using Zn^{++} instead of Mn^{++}. The filtrates from the $(CH_2)_6N_4$ precipitation were evaporated to 10 cc., cooled, filtered if salts crystallized out, and the filtrates tested for Zn^{++} with freshly prepared potassium ferrocyanide solution. The results showed that 1 mg. of Zn^{++} originally in the presence of 100 mg. of each of the trivalent metallic ions together could be detected.

The same experiments were carried out separately with Ni^{++} and Co^{++} and gave similar results, the Ni^{++} being detected with dimethylglyoxime and the Co^{++} by α-nitroso-β-naphthol.

A solution containing 100 mg. each of the trivalent metallic ions, 2 mg. of Mn^{++} and 1 mg. each of the other divalent metallic ions was used in the next experiment. The filtrate from the $(CH_2)_6N_4$ precipitation was analyzed for each divalent metallic ion, positive tests resulting.

Before the procedure could be tried to find out if small amounts of the trivalent metallic ions in the presence of large amounts of the divalent could be separated, an adequate method of detecting the trivalent metallic ions when together was necessary. The method finally developed precipitates Fe^{+++} with cupferron,[10] oxidizes Cr^{+++} to $CrO_4^{=}$ with ammonium persulfate in the presence of silver ion[11,12] and detects Al^{+++} in a weakly acid solution with $(CH_2)_6N_4$. Experiments showed that 1 mg. of each of the trivalent metallic ions together in the presence of 100 mg. of each of the divalent together were effectively separated and detected. Furthermore, it was shown that 1 mg. of each trivalent metallic ion in the presence of 100 mg. of each of the other metallic ions of this group together could be separated and detected.

In order to determine whether or not any Al^{+++} is introduced from the metallic ions of previous groups, a 50-cc. solution containing 100 mg. of each of these metallic ions was made. The silver group was precipitated with Cl^- and filtered, the Cl^- in the filtrate removed by evaporation with HNO_3[13] and after adjustment of the acidity to 0.3 N hydrochloric acid completely precipitated with hydrogen sulfide. The filtrate, after removal of the hydrogen sulfide, was concentrated and divided into three portions. One portion was treated with ammonium hydroxide, the second with ammonium sulfide and the third with $(CH_2)_6N_4$ and boiled. No precipitate formed in any case, showing that no Al^{+++} had been introduced.

Summary

1. The reactions of the metallic ions of the ammonium sulfide group with hexamethylenetetramine under varying conditions have been investigated.

2. A separation of the trivalent from the divalent metallic ions, based on these reactions, has been effected.

Preparation and Properties of Silver Sols by Reduction of Silver Halides with Formaldehyde

BY T. IVAN TAYLOR AND WM. H. CONE

An analysis of some Bredig silver sols showed them to be unsuitable for some investigations recently begun. The precipitated colloid was found to contain from 26 to 44% of silver oxide depending, among other things, on the amount and kind of electrolyte used for stabilizing. Approximately a liter of the gases given off during the preparation of Bredig silver sols was collected and analyzed. The gases consisted of 22.1% oxygen and 77.9% hydrogen by volume. There was, therefore, an equivalent of 11.2% oxygen united with the silver to form silver oxide.

A silver colloid comparable in constitution and properties to Zsigmondy gold sols seemed desirable, so a method of reduction with formaldehyde without the use of a protective colloid was developed.

Experimental

It is well known that silver halides formed in excess of silver nitrate or alkali halide form stable positive and negative colloids, respectively. The angle of attack chosen was the reduction of these colloidal silver halides. The halide sols prepared with excess silver nitrate were reduced immediately forming a stable negative sol while those with excess halide were reduced only slowly and formed no stable sol.

Though the amounts of the reagents theoretically necessary were calculated, the solution to the problem was best found by trial and error

TABLE I

EFFECT OF VARYING AMOUNTS OF REAGENTS ON STABILITY AND PROPERTIES OF THE SILVER SOLS

Cc. of 0.1 *N* $AgNO_3$ (diluted to 250 cc.)	Cc. of 0.1 *N* KBr (diluted to 250 cc.)	Cc. of 2% Formaldehyde	Cc. of 0.3 *N* NaOH	Stability and properties of sol

	1.0			Reddish-yellow, stable
	5.0			Reddish-yellow, stable
	9.0			Ruby-red, stable

methods. Table I gives a brief summary of the results as the amounts of the different substances were varied.

The procedure finally adopted for the preparation of a highly dispersed silver sol by this method is briefly summarized as follows. Dilute 10 cc. of 0.1 *N* silver nitrate to 250 cc. and add slowly with vigorous stirring 1 cc. of 0.1 *N* potassium bromide diluted to 250 cc. Add to the resulting mixture 10 cc. of 2% solution of formaldehyde; then add quickly with vigorous stirring 100 cc. of 0.03 *N* sodium hydroxide. Reduction takes place immediately after addition of the sodium hydroxide and the sol changes from a brownish-yellow by reflected light to a straw-yellow in about an hour. It then has a clear reddish-yellow color by transmitted light.

Hydroquinone was used with equal success but it has the disadvantage of giving a brown-colored oxidation product. A stable sol could not be prepared by replacing potassium bromide with potassium chloride, but potassium iodide worked equally well. A comparison of the properties of these sols, all prepared by the same method, is best given in Table II.

TABLE II

ANALYSIS AND PROPERTIES OF SOLS PREPARED FROM HALIDES

Halide salt,	cc.	Color of sol	Stability	Silver, %	Precipitation value mml. $NaNO_3$ per liter	Cataphoretic velocity $\times 10^5$ cm./sec./volt/cm.
KCl	1	Bluish-gray	Unstable	99.44	..	..
	9	Bluish-gray	Unstable	99.46	..	..
KBr	1	Reddish-yellow	Stable	99.03	40.0	42.2
	9	Ruby-red	Stable	98.26	12.0	41.7
KI	1	Brownish-red	Stable	82.75	44.0	41.7
	9	Bright ruby-red	Stable	4.32	88.0	39.9

The percentage of silver was determined by dissolving the silver in the precipitated sol with warm nitric acid. The residues in the cases of potassium bromide and potassium chloride were completely soluble in ammonia. Silver iodide is insoluble in ammonia. Warm ammonia poured over another precipitated sol made with 1 cc. of potassium bromide dissolved only 0.46%, indicating that silver bromide was dissolving from the surface, but may have been some silver oxide or silver hydroxide. At most, then, there is only very little, if any, silver oxide in the sol.

The precipitation values were made by diluting varying volumes of 0.1 *N* sodium nitrate to 15 cc. and mixing quickly with 10 cc. of the sol. The color change at the precipitation point is almost as marked as it is with Zsigmondy gold sols. The amount of electrolyte which causes complete precipitation within twelve hours causes the sols to change to a definite green within three to five minutes. The color changes by transmitted light after addition of precipitating electrolyte are as follows: orange-yellow ⟶ reddish-yellow ⟶ ruby-red ⟶ greenish-yellow ⟶ green ⟶ bluish-green ⟶ blue ⟶ bluish-lavender ⟶ purple ⟶ purple-gray ⟶ gray.

A sol prepared according to the above directions was dialyzed in cellophane bags for 108 hours in running distilled water (average conductance, 4.2×10^{-6}). The effect of the dialysis is given in Table III.

TABLE III

EFFECT OF DIALYSIS ON SILVER SOL

Sol	Cataphoretic velocity cm./sec./volt/cm.	Conductance, mhos	Precipitation value, millimoles of $NaNO_3$ per liter
Undialyzed	42.2×10^{-5}	5.14×10^{-4}	40.0
Dialyzed	40.7×10^{-5}	5.0×10^{-6}	24.0

Further tests on the properties and structure of these silver sols were made by diluting 10 cc. of 0.1 *N* silver nitrate to 500 cc. and reducing with formaldehyde and sodium hydroxide as before. Just as the color reached a milky purple, 2 cc. of 0.1 *N* solutions of various salts were added and their effect on the stability of the silver particles noted at various times. Some settled out comparatively rapidly while others settled only slowly, and some not at all. The apparent order of their stabilizing effect as judged from rate of settling and appearance after twenty-four hours is: unstable, NaOH, K_2CO_3, K_2SO_4, KCl, $K_2C_2O_4$, $KMnO_4$, $NaNO_2$; slightly precipitated, K_2CrO_4, Na_2SiO_3, $Na_2HPO_4(PO_4^{\equiv})$, $K_2Cr_2O_7(CrO_4^{=})$, KCN, KCNS; completely stable, KBr, $K_3Fe(CN)_6$, $K_4Fe(CN)_6$, $Na_2S_2O_3(S^{=})$, Na_2S, K ethyl xanthate, KI.

The order is essentially that of the solubility of the silver salt normally formed with the anion. Most all anions which normally form a silver salt with a solubility of 0.002 g. per 100 g. of water or less stabilize the silver particles. Apparently at low concentrations of the anion, the more insoluble the silver salt, the greater is its stabilizing effect. The one most definitely out of place is the chloride ion. The true ionic radius of the chloride ion according to Goldschmidt is 1.33 Å. compared with 2.02 Å. for the iodide ion. In general, the smaller the ionic radius, the greater the hydration of the ion. Thus the moles of water per mole of chloride ion is two while for the iodide ion it is only one-half. The greater the hydration of the ion, the less will be the electrochemical attraction of the silver atoms in the crystal surface for that ion. The greater insolubility of the chloride ion is apparently overbalanced by its hydration, thus preventing adsorption of enough ions to give the required potential for stability.

Six liters of sols stabilized as above by chloride, bromide and iodide were prepared and precipitated. The washed and dried coagulum of each was analyzed as before. The warm nitric acid dissolved and carried through the crucible all the silver but enough to react with the halide carried down. The results are given in Table IV.

TABLE IV

ADSORPTION OF HALIDES BY SILVER

Halide sol	Pptd. colloid, g.	Undissolved residue of AgX, g.	Halogen, g.	Total weight of silver, g.	G. atoms of halogen per gram atom silver	Ratio of halogens adsorbed
AgCl	0.8733	0.0026	0.00064	0.8727	0.002243	1
AgBr	.9025	.0076	.0030	.8995	.004478	1.997
AgI	1.0383	.3738	.1604	.8779	.1293	57.66

If a regular stoichiometric chemical reaction of the simple double decomposition or replacement type had taken place on the surface, one would expect equivalent amounts to be carried down after allowing for the differences in solubility. This is definitely not the case. The process seems to be one governed more by the principles of electrochemical adsorption. The differences are readily explainable on the basis of hydration of the ions and insolubility as a measure of the electrochemical attraction between the atoms of the crystal surface and the ion adsorbed. Similar observations were made by Beckley and Taylor[1] on the adsorption of various substances on silver iodide. Besides adsorption in this type of system, however, one must not fail to recognize other types where the system is fundamentally different.[2]

There is a difference in the appearance, stability, and apparent degree of dispersion obtained when the stabilizing substance is added before reduction rather than after. For example, a sol prepared with 1 cc. of potassium bromide added before reduction is a clear reddish-yellow, while it is a milky, brownish-yellow when added after reduction. On adding the potassium bromide to the silver nitrate as directed above, no precipitate or coloration can be seen, but very minute particles of silver bromide must be present which act as reduction and condensation centers. The bromide ions liberated on the reduction of these silver bromide nuclei can then act as stabilizing ions on the surface of the reduced silver.

Summary

1. A method of preparing comparatively pure silver colloids by a reduction process has been described.

2. The properties and probable structure of these sols with analyses of sols prepared with different halides at varying concentrations have been given.

Ammonium Trinitride[1]

BY W. S. FROST, J. C. COTHRAN AND A. W. BROWNE

In connection with a current investigation of the nitridizing action of ammonium trinitride in solution and in the vapor state, determinations have been made of various properties of this substance, including (1) its solubility in water, methanol, ethanol, benzene and ether, (2) its qualitative behavior toward numerous organic liquids, (3) its specific gravity and the specific gravity of its saturated solutions and (4) its vapor tension at temperatures from 15 to 134°.

Preparation of Ammonium Trinitride.—The ammonium trinitride used throughout the present investigation was prepared either by the method of Browne and Houlehan,[2] or by the following procedure: 65 g. of sodium trinitride was placed in a 500-cc. round-bottomed flask connected through a Reitmeier bulb with a suitable condenser and a receiver containing 200 cc. of ether and cooled with ice. Two hundred cc. of water and 200 cc. of ether were added, and 60 cc. of concentrated sulfuric acid was slowly introduced, from a dropping funnel, beneath the surface of the solution. The greater part of the hydrogen trinitride, diluted with ether vapor, passed over into the receiver during this operation. The remainder was distilled by heating the flask for a short time over the steam-bath. The ethereal distillate was refluxed for thirty minutes over calcium chloride, and was finally redistilled from the desiccant. Dry ammonia gas was bubbled through the ethereal hydrogen trinitride until complete precipitation of the ammonium salt had been effected. The final product was readily freed from residual ether by storage over sulfuric acid.

Solubility of Ammonium Trinitride.—Curtius[3] observed that ammonium trinitride is soluble in water and in 80% ethanol, slightly soluble in 100% ethanol, and insoluble in ether and in benzene. Qualitative experiments have been performed by the authors with a number of other liquids at room temperature, including methanol, pyridine and glycerol, in which the salt is soluble; allyl, butyl and isobutyl alcohols, in which it is slightly soluble; and acetone, aniline, benzaldehyde, carbon disulfide, chlorobenzene, chloroform, ethyl acetate, ethyl methyl ketone, isoamyl alcohol, methyl acetate, nitrobenzene, tetrachloroethane, toluene and xylene, in which it is insoluble.

Quantitative determinations of the solubility of ammonium trinitride in carefully purified benzene, ether, ethanol, methanol and water have been made by a method and with an apparatus especially designed for systems in which both solvent and solute are

[1] This article is based upon parts of the theses presented by Walter Sprague Frost and John Cleveland Cothran to the Faculty of the Graduate School of Cornell University in partial fulfilment of the requirements for the degree of Doctor of Philosophy.

[2] Browne and Houlehan, THIS JOURNAL, 33, 1742 (1911).

[3] Curtius, *Ber.*, 24, 3341 (1891).

volatile.[4] The results are summarized in Table I. Each datum is the average of at least two satisfactorily concordant determinations.

Specific Gravity of Solid Ammonium Trinitride.—Determinations of the specific gravity made with the aid of a pycnometer containing a saturated solution of the salt in benzene yielded the result d_{20} (compared with water at 4°) = 1.3459.

Vapor Tension of Ammonium Trinitride.—Curtius[3,5] and his co-workers have repeatedly called attention to the volatility of ammonium trinitride. From vapor density determinations Curtius and Rissom[5c] concluded that the vapor was completely dissociated at 100°.

The results of a series of measurements of the vapor tension of freshly sublimed ammonium trinitride at temperatures ranging from 15 to 134° are recorded in Table II. For this work a constant volume tensimeter with compact, completely immersible cell was designed.[6]

TABLE II

VAPOR TENSION OF AMMONIUM TRINITRIDE

Temp., °C.	Pressure Obs., mm.	Pressure Calcd., mm.	Diff., mm.	Temp., °C.	Pressure Obs., mm.	Pressure Calcd., mm.	Diff., mm.
15.0	0.2	0.3	−0.1	77.9	38.5	35.8	2.7
27.5	.6	.8	− .2	85.0	55.1	56.0	− 0.9
32.5	1.0	1.3	− .3	91.0	80.1	80.5	− .4
37.5	1.9	1.9	.0	96.0	108.3	107.9	.4
42.0	2.9	2.8	.1	102.9	160.9	160.0	.9
48.0	4.5	4.4	.1	109.0	222.7	223.9	− 1.2
54.0	6.7	6.9	− .2	114.0	292.3	291.8	0.5
58.4	9.5	9.5	.0	119.0	377.9	379.3	− 1.4
61.9	12.0	12.2	− .2	125.0	508.1	512.9	− 4.8
67.5	18.5	18.0	.5	132.1	709.9	727.8	−17.9
71.9	24.4	24.2	.2	134.2	782.1	803.5	−21.4

The equation used in calculating the pressures was: $\text{Log } p = -(3428.6/T) + 11.325$.

The rectilinear character of the logarithmic curve indicates the nonexistence of isomeric forms[7] of ammonium trinitride under the conditions prevailing in the experiments. This negative conclusion was strongly substantiated by the identity of the vapor tension curves successively obtained with samples of ammonium trinitride that had been (1) freshly prepared, but not sublimed, (2) stored for five months over calcium chloride, (3) stored for eight months in dry air containing ammonia gas and (4) freshly sublimed.

---

(4) A detailed description of the method and apparatus used in this work will be found in the thesis, "A Study of Ammonium Trinitride," by W. S. Frost, of which a typewritten copy has been deposited in the Library of Cornell University, Ithaca, N. Y.

(6) Thesis, "A Study of Certain Compounds Containing Chains of Four Nitrogen Atoms," by J. C. Cothran. A typewritten copy is on file in the Library of Cornell University, Ithaca, N. Y.

(7) Mendeléeff, *Ber.*, **23**, 3464 (1890).

When samples that had been stored for a long time over phosphorus pentoxide were sublimed, however, appreciable amounts of a white, vesicular, relatively non-volatile residue were obtained. This may be identical with the residual traces noted by Curtius and Rissom.[5c] It was at first surmised that this residue might be the long-sought isomer predicted by Mendeléeff.[7] Analysis by the Pregl method, however, proved that the substance was not a hydronitrogen, but rather, in all probability, an ammonium salt of hypophosphorous acid. It is interesting to note, further, that storage of ammonium trinitride over phosphorus pentoxide, calcium chloride or any other desiccant capable of absorbing ammonia but not hydrogen trinitride, soon results in the accumulation of considerable amounts of the latter substance in the vapor phase. The reverse is true for alkaline desiccants that selectively absorb hydrogen trinitride.

Summary

The solubility of ammonium trinitride (1) in water, methanol, ethanol, benzene and ether has been determined quantitatively and (2) in numerous organic liquids has been studied qualitatively. The specific gravity of solid ammonium trinitride and of various saturated solutions has been determined. The vapor tension of the solid has been measured over a temperature range of 15 to 134°.

Solid–Liquid–Air Contact Angles and their Dependence upon the Surface Condition of the Solid

By F. E. Bartell and Allan D. Wooley

Introduction

Several investigators[1] have observed that the angle formed when a contact angle forming liquid has advanced to rest over a dry solid surface is larger than the angle formed when the liquid has receded to rest from a wetted surface. Sulman[1d] called this phenomenon "hysteresis of contact angle," which term was used to imply that advancing and receding contact angles are unstable forms of a definite equilibrium contact angle. Later workers,[1e,2] holding similar views, have attempted to evaluate equilibrium contact angles by relating them mathematically to the advancing and receding contact angles. Thus Ablett, believing that the so-called hysteresis of contact angle is due to adsorption of the liquid by the solid, concluded that the "stationary angle" is the arithmetical mean of the dynamic advancing and receding contact angles. Adam and Jessop consider that the difference between advancing and receding contact angles lies in a "simple friction" effect between the liquid and the solid, and assume that the cosine of the equilibrium angle is equal to the mean of the cosines of the advancing and receding angles. Others have expressed the view that with proper precautions "equilibrium" contact angles can be obtained directly and measured as such.[3] Proof of the existence of a single and definite equilibrium contact angle, however, has not been given, nor has any definite relationship between the theoretical equilibrium contact angle and the observed static advancing and receding angles been established.

(2) Ablett, *Phil. Mag.*, **46**, 244 (1923); Nietz, *J. Phys. Chem.*, **32**, 255 (1928).

The purpose of the present investigation was to study the characteristics of static advancing and receding contact angles and to determine if possible their relation to the "equilibrium" contact angle. The results obtained indicate that both the advancing contact angle and the receding contact angle may exist as stable and characteristic angles for the precise system in question.

Experimental

The general capillary formulation used for calculation of surface tension values in cases in which the liquids form a contact angle with the walls of the capillary is $S = rhdg/2 \cos \Theta$, in which S represents the surface tension of the liquid, r the radius of the capillary, h the height of liquid ascension, d the density of the liquid, g the gravitational constant, and Θ the contact angle. Thus, by measurement of the capillary rise of a liquid forming a contact angle in a capillary of known radius, the contact angle can be calculated if the true surface tension of the liquid can be obtained by some method which gives true values independent of the contact angle. The only method independent of contact angle which seemed sufficiently accurate for this purpose was the drop weight method as developed and standardized by Harkins and co-workers. Accordingly, that method was adopted for this investigation. The liquids selected were α-bromonaphthalene and acetylene tetrabromide. The solids selected were "Pyrex" and silica.

Apparatus

The Capillary Height Method.—The details of apparatus and operation necessary to obtain results of high accuracy with the capillary height method are fully discussed by Richards and Coombs,[4] Richards and

Carver[5] and Harkins and Brown.[6] The apparatus used by us is illustrated in Fig. 1.

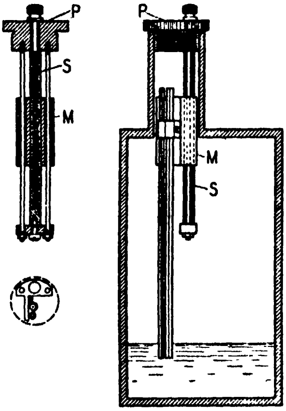

Fig. 1.—Capillary height apparatus.

The apparatus used for the determination of the drop weight was modeled, in its essential details, after that described by Harkins and Brown.[6] It was used in an air thermostat which made some minor alterations advisable (see Fig. 2).

The air thermostat was used with both methods. During the time of a series of observations the temperature of the liquid under measurement never varied more than 0.03°.

Density Determinations.—The density data appearing in the literature for α-bromonaphthalene and acetylene tetrabromide show such discrepancies[7] that densities of these liquids were determined. Values were determined over small temperature ranges so that the density at the working temperature could be obtained by linear interpolation. A new pycnometer was devised which greatly reduced the labor necessary in determining a series of densities over a given temperature range.

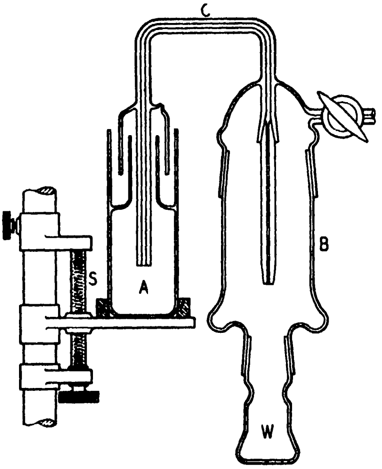

Fig. 2.—Drop-weight apparatus.

The details of the pycnometer are shown in Fig. 3. The new feature of the pycnometer is that it can be tightly closed so as to eliminate evaporation losses. This is effected by the use of copper-to-glass seals upon the inlet and outlet tubes which makes it possible to use screw-caps fitted with lead gaskets. The pycnometer is used as a constant-weight volume-determining apparatus.

Procedure and Measurements.—It was our belief that in former investigations the pretreatment of the solid surface upon which contact angle measurements were made had not been sufficiently investigated, and that the cause of apparent anomalies and of the so-called "hysteresis contact angle" might lie therein.

The preliminary work indicated that although the magnitude of the advancing contact angle was dependent upon the precise pretreatment of the solid surface upon which it was measured, the magnitude of the receding contact angle was largely independent of the pretreatment of the solid surface. This suggested that it might be possible by proper pretreatment to obtain a solid surface

upon which the advancing contact angle would be equal to the receding contact angle. Such surfaces were finally produced.

The capillaries used were first given a rigorous acid cleaning with concentrated nitric acid, were then washed with a large quantity of distilled water (steamed with water for at least three hours), dried and calibrated, again treated with nitric acid and washed. After this second acid cleaning, acid was never used again in recleaning the capillaries. After use the capillaries were cleaned each time by drawing liquids through them. The order of treatment was first, ether or benzene, then benzene and then acetone. Usually about 100 cc. of each liquid was used, after which a quantity of distilled water was drawn through.

After being cleaned as described above, the capillaries were given one of the following pretreatments: (1) steamed with water for one hour. Heated in a current of clean, dry air at a certain temperature (shown in the data) for a given time. (2) Flushed with benzene vapor for one hour. Heat treated at a known temperature for a given time in a current of clean, dry air.

After the capillaries had been heat treated at an elevated temperature (425°),[8] the furnace was slowly cooled over a period of one hour (to 300°), after which it was disconnected and allowed to cool fairly rapidly. As soon as the capillary had reached the temperature of the thermostat (one-half to one hour) it was lowered into the liquid very slowly to avoid wetting above the meniscus. The height of the large meniscus was taken and subsequently the height of the lowest point of the small meniscus. The capillary was then lowered further into the liquid and the meniscus caused to advance up the dry capillary. Again, after equilibrium had been reached, the capillary height was measured. Usually six such advancing heights, and then a series of six receding heights, were measured. Each series of six measurements was averaged to give a single advancing or receding capillary height. At least three series of measurements were run for both advancing and receding heights for each method of pretreatment. Corrections were made for meniscus effects when determining capillary height values.

Before confidence could be placed in the values of the contact angles calculated by comparison of the apparent surface tension

[8] Careful investigation showed that the radii of both Pyrex and silica capillaries remained unchanged even after heating the capillary for one hour at 450°.

as measured by the capillary height method with the true surface tension as measured by the drop-weight method, it was necessary to prove that the two apparatuses gave the same surface tension value when a zero contact angle liquid was used. For this purpose benzene was selected.

The surface tension at 25.23° of very carefully purified benzene was determined by the capillary height method using both Pyrex and silica capillaries. The capillaries were carefully cleaned, flushed with benzene vapor for one hour and finally heated for one hour at 425°. Advancing and receding capillary heights were measured. The values obtained in the Pyrex capillary were as follows: the average of all the advancing heights gave 28.165 dynes/cm.; the average of receding heights gave 28.16 dynes/cm.; the average of advancing heights in the silica capillary gave the value 28.18 dynes/cm., and the average of receding heights gave 28.16. The mean of these values gives the surface tension of benzene at 25.23° as 28.166. The drop-weight method using a dropping tip having a radius of 0.29835 cm. gave 28.175 dynes/cm. as an average value of the surface tension of the same sample of benzene at 25.23°.

Discussion of Results

Influence of Pretreatment.—Tables II and III give, respectively, the advancing and receding contact angle values obtained for the systems α-bromonaphthalene–Pyrex (and silica)–air, and acetylene tetrabromide–Pyrex (and silica)–air by measurements in capillaries treated in the manner indicated in the tables as "Pretreatment." Inspection of the tables shows that for a particular vapor treatment such as steaming with water, the magnitude of the advancing contact angle depends upon the temperature and duration of heat treatment. Taking the results in Table II as typical, it is seen that the advancing contact angle of α-bromonaphthalene in a Pyrex capillary which had been steamed with water and heat treated at 115° for fifteen minutes is 24°. If during pretreatment the capillary is heated at 125° for one hour, an angle of 18° is obtained. Heating for twenty-four hours at 125° gives an angle of 16°. With longer heating of the capillary at 125° during pretreatment, the contact angle remains sensibly constant. If the capillary is pretreated by heating for one hour at 425°, the advancing angle becomes zero. The calculated cosine of the angle (0.99946) is equivalent to an angle of 1°53′, but since the error of measurement for an angle of zero degrees magnitude is equivalent to a 3° angle, the angle 1°53′ is sensibly zero. The advancing contact angle of α-bromonaphthalene on a Pyrex surface pretreated by steaming with water and subsequently by heat treating at 425° for one hour has been proved by us (using the Richards and Carver test) to be a zero contact angle. Pretreatment of the capillary at elevated temperatures tends to cause a decrease of the advancing contact angle. Heat treatment of a capillary at a given temperature lowers the advancing contact angle rapidly during the first hour, after which longer times of heating leave it sensibly constant.

The same generalizations apply if the capillary is vapor-flushed with benzene rather than with water. It should be noted, however, that a Pyrex capillary steamed with water and heated at 125° for one hour gives

an advancing contact angle of 18° with α-bromonaphthalene, while an angle of 15° is obtained if the capillary is flushed with benzene and heated under the same conditions. The data show similar results for the systems α-bromonaphthalene–silica–air, acetylene tetrabromide–Pyrex–air and acetylene tetrabromide–silica–air.

The receding contact angles for the same systems and for the same pretreatments are also given in the tables. Taking the data for the receding contact angles of α-bromonaphthalene–silica–air as typical (Table II), one observes that the receding contact angle is largely independent of the pretreatment. Even insufficient drying (25°) was shown to have comparatively small effect upon the magnitude of the receding contact angle.

The data show that for the system α-bromonaphthalene–Pyrex (and silica)–air the same or very nearly the same advancing and receding contact angles are obtained, if the capillaries are pretreated by steaming with water or flushing with benzene and heat treated at 425° for one hour. This contact angle must be characteristic of the system, for it fulfils the most rigid requirement for an equilibrium contact angle—namely, that the same angle be obtained when the liquid advances to, and recedes to, equilibrium. The advancing contact angle of a system can, then, become equal to the receding contact angle, which is independent (apparently) of pretreatment; the receding contact angle must, therefore, be the most characteristic contact angle of a system.

Table III shows that for the systems acetylene tetrabromide–Pyrex (or silica)–air, the advancing and receding contact angles are not quite equal when the capillaries are heated during pretreatment for one hour at 425°. Subsequent experiments, in which silica tubes were heated to 600° for one hour in their pretreatment, gave for advancing and receding contact angles for the system silica–acetylene tetrabromide–air values which were sensibly the same.

The dependence of the advancing contact angle upon the treatment history of the solid surface suggests that in an advancing contact angle we have a very sensitive criterion of the surface condition of a solid.

During the course of the investigation the question arose—will a capillary which has been well wetted with a liquid and then drained by gravity, give an advancing height with that liquid equivalent to the receding height in the wetted capillary? This was tested for the systems α-bromonaphthalene–Pyrex–air and α-bromonaphthalene–silica–air as follows. The capillaries were cleaned in the usual manner, steamed for one hour with water, heated at 125° for one hour, cooled and then wetted with α-bromonaphthalene. The capillaries were then allowed to drain for twelve hours in an atmosphere saturated with α-bromonaphthalene. The advancing height of the liquid was then measured in the capillaries. It was found that advancing heights in capillaries treated in this manner were easily reproducible. The advancing contact angle for α-bromonaphthalene in a

Pyrex capillary treated as described was found to be 13°, and for α-bromonaphthalene in a silica capillary treated in an identical manner, 21°. Comparison with the corresponding receding contact angles, 0 and 5°, respectively, shows the advancing contact angles to be considerably larger in magnitude.

Theoretical Considerations.—The magnitude of the contact angle which a given liquid will form with a solid surface depends upon the relative values of the existing interfacial tension forces of the system. For any given set of interfacial energies there is a corresponding equilibrium configuration for the system; the contact angle formed may be either zero or finite. If any one of the free surface energies be changed, the contact angle (if finite) will change to a new characteristic value. This will be readily understood by considering Young's[9] equation[10] $S_1 - S_{12} = S_2 \cos \Theta$, for a drop at rest and in equilibrium upon a solid surface. It is seen that the magnitude of the contact angle is dependent upon the relation of the interfacial tensions at the solid-air (S_1), liquid-air (S_2) and solid-liquid (S_{12}) interfaces. If contamination of the system is prevented, the interfacial tensions of the solid-liquid and liquid-air interfaces remain constant. A difference in magnitude between an advancing contact angle and receding contact angle for two different samples of the same uncontaminated system is indicative that the free surface energy of the solid (against air) is different in the two cases.

In explanation of the results obtained in this investigation the problem to be dealt with seems to be the cause of the free surface energy changes in the solid-air interface. The particular pretreatment methods used in preparation of the solid surfaces were of such nature that two closely related processes undoubtedly contributed to the final state of the solid surface, namely, sorption and change in surface structure. By the term "sorption" is meant the collective result of the processes of adsorption and persorption. There is evidence that the processes of adsorption and persorption are accompanied by a change in structure of the sorbent solid.[11] Moreover, there can be little doubt that solids subjected to heat treatment at elevated temperatures undergo a change in surface structure.[12] The precise condition of a solid surface depends in fact upon every process to which it has been subjected during its preparation.

Penetration of gases or liquids to a finite distance into a solid surface (termed "persorption"[13]) must result in a change in the free surface energy of the solid–air interface by alteration of the forces of adhesion and by modification of the intermolecular cohesive forces existing between the molecules of the solid. The processes of sorption and of structural change are in most cases so intimately related that the individual effects cannot be isolated.

---

[9] Young, *Phil. Mag.*, 165 (1805).

[10] The symbols S_1, S_{12} and S_2 represent, respectively, the surface and interfacial tension values of the solid-air, solid-liquid and liquid-air interfaces. Since free surface energy values are numerically equal to surface tension values, the relations of the equation are fulfilled equally well by free surface energy values.

[11] McBain, "The Sorption of Gases by Solids," Routledge, London, 1932; Bangham, *Phil. Mag.*, [7] **5**, 737 (1928).

[12] Beilby, "Aggregation and Flow of Solids," The Macmillan Company, New York, 1921.

[13] McBain and Britton, THIS JOURNAL, **52**, 2198 (1930).

It has been shown,[14] by investigations on the adsorption of gases, that the surface of a solid in the amorphous form possesses a more intense field of surface force and a greater free surface energy than a crystalline form of the solid. Further, Beilby[12] has shown that the condition of a solid surface can be altered greatly by very simple treatments, such as heat treatment and subjection to solvents.

An advancing contact angle formed by a given liquid upon such an amorphous surface of a given solid would tend toward a minimum value for that solid–liquid system. A silica or Pyrex surface which has been subjected to sorption processes possesses a lower free surface energy, and as a result the advancing contact angle formed upon it by a given liquid would tend toward a maximum value.

The solid surface upon which a receding contact angle is formed is one which has had, in effect, an additional (and final) pretreatment process included in its preparation, namely, it has been wetted by the liquid under measurement. The independence of the receding contact angle from the initial pretreatment of the solid surface becomes more readily understood by consideration of this fact, for the final pretreatment process of a surface upon which a receding contact angle is formed is always the same. Wetting a solid surface by a liquid is apparently a very powerful pretreatment process, for it alters the effects of such other pretreatment processes as vapor flushing and low temperature heat treatment. Sorption and change in surface structure processes may occur when the solid surface is wetted by the liquid. The wetting liquid probably causes desorption of previously sorbed molecules. Likewise, the wetting liquid may cause a change in surface structure of the solid by exerting orientational and adhesional forces upon the surface molecules of the solid. The constancy of the receding contact angle of a given solid–liquid–air system suggests that a solid surface which has been wetted by a liquid is left in a definite condition with its characteristics determined by the wetting liquid used.

To account for the difference between advancing and receding angles in a single system one may conclude then that the advancing angle is dependent upon the precise condition (*i. e.*, the pretreatment) of the unwetted solid surface upon which the liquid is advancing, while the receding angle is largely independent of the pretreatment (*i. e.*, of the type described herein) of the solid surface. The liquid as it recedes leaves the solid surface in a definite and characteristic condition.

(14) Langmuir, *Phys. Rev.*, **8**, 149 (1916); Kuster, "Lehrbuch d. allg. Physik," 1916, p. 189, Pawlow, *Z. physik. Chem.*, **88**, 316 (1920).

When the advancing and receding angles in a system are found to be the same, it must be that the pretreatment of the surface has been so adjusted (through changes in sorption and orientation) as to give to the solid surface approximately the same characteristic condition as that imparted to it by wetting by the liquid in question.

The apparent anomalies and the so-called hysteresis of contact angles have caused certain investigators to propose concepts which describe the contact angle as an unstable configuration of a solid-liquid-air system. To the authors it seems that a careful consideration of the free surface energy relationships of such a system (particularly of the changes which may occur in the existing value of the solid-air interfacial free surface energy) explains the phenomena which seem to present anomalies and "hysteresis effects." To us it seems that a contact angle formed by a system whether advancing or receding is in effect an equilibrium contact angle and is characteristic of the system precisely as it then exists.[15] The contact angle formed by a system is then an extremely sensitive criterion of the energy relations existing in the system. Any variation in its magnitude points to the occurrence of some process which has caused a change in one or more of the interfacial energy values.

Summary

Certain conclusions which seem justifiable can be drawn from the data obtained in this investigation.

1. The magnitude of the advancing contact angle is intimately related to the treatment history of the solid surface upon which it is measured. A standard method of treatment of a solid surface results in a characteristic reproducible advancing contact angle with a given liquid. Because of the reproducibility and apparent stability of such contact angles they are in effect equilibrium angles. Advancing contact angles are very sensitive criteria of the condition of a solid surface.

2. The magnitude of receding contact angles is largely independent of the treatment history of the solid surface upon which they are formed. Receding contact angles are equilibrium angles and are the most characteristic of contact angles for a given solid-liquid pair.

3. A characteristic equilibrium contact angle exists for the system α-bromonaphthalene-silica-air and acetylene tetrabromide-Pyrex (or silica)-air which can be approached from either direction, *i. e.*, advancing liquid or receding liquid. This is the most characteristic contact angle for a given solid-liquid pair and is equivalent to the receding contact angle.

(15) The advancing contact angle may not represent a true equilibrium angle in the strict sense of that term, but does represent a relatively stable angle which will not change appreciably with time. Its tendency to change is dependent upon the tendency of the solid phase (or surface) to pass to a more stable form (or condition) which can exist at a lower energy level.

Liquid Ammonia as a Solvent. III. The Solubility of Inorganic Salts at 25°

BY HERSCHEL HUNT AND L. BONCYK

In order to investigate the behavior of strong electrolytes in liquid ammonia it is advantageous to know their solubilities. It is the purpose of this article to report the solubilities of some inorganic salts in liquid ammonia at 25°.

Experimental

The same methods of measuring solubilities were used as described in the first paper of this series.[1] In the meantime, the vapor pressures of ammonia solutions of the salts of ammonia were determined and the following agreement between the two methods of measuring solubilities was found.

	NH_4NO_3	NH_4I
Solubility by vapor pressure	390.0 g.	368.5 g./100 g. NH_3
Solubility by methods of Paper I	390.0 g.	368.5 g./100 g. NH_3

M. Linard and M. Stephan[2] criticized our values as being too low because a vapor correction was not applied. The solubilities of the alkali halide salts were checked by weighing the amount of salt previously reported into a 25-mm. tube with the reported amount of ammonia, drawing the tube down to a long narrow capillary, sealing, and, when the salt had dissolved, weighing the tube. Then the tube was cooled, the tip broken and a few milligrams of ammonia allowed to escape. The tube was then placed in the 25° bath. Crystals always came out with this smaller amount of ammonia. The tubes were sealed as close to the liquid as possible. Using our method we found a value of 12.85 g./100 g. NH_3 for the solubility of sodium chloride at 0°. Linard's data show that we have a great variation in solubility with change in temperature. G. Patscheke[3] has shown that sodium chloride has a wide variation in solubility at various temperatures. Linard's results show that the vapor phase correction is no greater than was explained in Paper I.

We have taken special precautions to have all our materials extremely dry. Reagent grade chemicals were recrystallized three times from water and then from a suitable anhydrous solvent. They were dried to constant weight in a vacuum oven.

The formulas for ammonium oxalate, ammonium sulfate and sodium sulfate were incorrectly printed in the first paper of this series, subscripts of three being given instead of four. The solubility of sodium sulfate was incorrect also.

KNH_2	3.6	H_3BO_3	1.92		

$SbBr_3$, $BiCl_3$, $Bi(NO_3)_3$, $Cd(NO_3)_2$, $Co(NO_3)_2$, $FeBr_3$, $Pb(C_2H_3O_2)_2$, Mg_3N_2, $Hg(NO_3)_2$, $Ni(NO_3)_2$, S, $SnCl_4$ appear to be insoluble, while $Cu(NO_3)_2$, I_2, $Pb(NO_3)_2$, and HgI_2 were very soluble in liquid ammonia but all reacted with ammonia.

If salts are ionized in ammonia as in water, salts with common ions should decrease each other's solubility and salts without common ions should increase the solubility of each other. This point was verified by determining the solubilities of the mixtures given in Table II: 0.2500 g. of the less soluble salt was mixed with variable amounts of the more soluble salt and ammonia added in excess. Ammonia was allowed to escape from the solution until a single small crystal of one salt came out of solution. Identical results were obtained by approaching the saturation point from opposite sides. The various experiments indicate the ratio of the two salts present in the solution when the solution was saturated with respect to one salt.

Discussion of Results

In general, the solubility of the halides increases as the atomic weight of the halogen increases. The salts of ammonia are the most soluble, salts of lithium are more soluble than salts of sodium, salts of sodium are more soluble than salts of potassium, and the solubilities of the nitrates of the alkaline earths decrease as the atomic weight of the metal increases. The halides of silver diverge the most radically of any salts from the aqueous solubilities, the iodide being 7.5 × 10^8 times as soluble in ammonia as in water. Silver iodide reacts with silver nitrate so that the solubility of mixtures of the two salts could not be determined. Mixtures of sodium nitrate and ammonium chloride react with explosive violence. All sulfates, phosphates, carbonates and oxides tested were insoluble. On comparing the solubilities of silver halides or any sulfates, one sees no correlation between physical properties and solvent power of the two solvents. As a general rule, the inorganic salts studied are more soluble in ammonia than in the aliphatic alcohols.

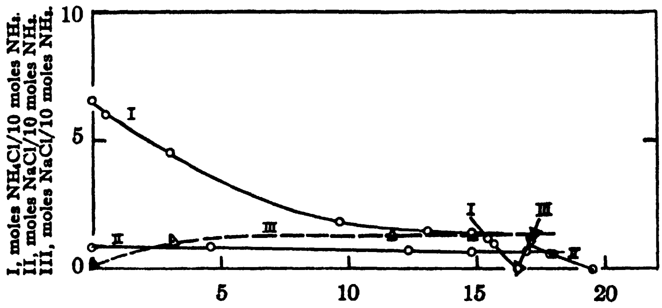

Fig. 1.—Solubilities of mixed salts: I, moles NH_4NO_3/10 moles NH_3 (scale 1 mole = 2 cm.); II, moles $NaNO_3$/10 moles NH_3 (scale 1 mole = 1 decimeter); III, moles NH_4NO_3/10 moles NH_3 (scale 1 mole = 2 cm.).

Some salts are very soluble but are unstable in liquid ammonia, as lead nitrate, while others, as nickelous nitrate, react only after a certain concentration is reached. The difference in solubility between similar salts, as potassium iodide and potassium iodate, makes this solvent a possible one to use for extractions in the preparation of pure chemicals. Compounds of the metals of groups I and II of the periodic table show the least tendency toward reaction with ammonia in liquid ammonia.

Figure 1 shows that the presence of a common ion decreases the solubility of a salt in ammonia. Curve III shows that salts without a common ion increase the solubility of each other. The solubility curves have the same general shape in ammonia as in water, indicating ionization of the salts.

Summary

1. The solubilities of twenty-six inorganic compounds in liquid ammonia have been determined quantitatively at 25°.

2. The solubilities for three sets of mixed salts, NH_4Cl–NH_4NO_3, NaCl–$NaNO_3$, and NaCl–NH_4N[illegible] have been determined.

Further Studies on Acetic Acid–Acetate Solutions

BY ARTHUR W. DAVIDSON AND WILBERT CHAPPELL

Introduction

The purpose of this investigation was to supplement the existing data on the solubility of acetates in anhydrous acetic acid[1] by the study of two additional acetates, namely, those of strontium and nickel, each of which presented certain points of interest.

It was to be expected,[1b] in the case of strontium acetate, that the solid phase in equilibrium with the solutions at ordinary temperatures would be a solvate, and that the solubility of this compound would be intermediate between that of barium and that of calcium acetate. In the case of nickel acetate, previous statements as to solubility have been extremely conflicting. Spaeth[2] stated that this salt was easily soluble in acetic acid, but Adler[3] reported its solubility as only 0.44 mole per cent. even at 140°, and Schall and Markgraf[4] gave a figure of 0.1971 normal (0.60 mole per cent.) for the concentration of a solution which they apparently considered saturated at 65°.

A study was made also of the effect of ammonium acetate upon the solubility of nickel acetate, in the expectation that this ternary system would be analogous to the ammonium acetate–cupric acetate–acetic acid solutions previously described.[1c]

Method

Preparation of Materials.—Acetic acid (m. p. 16.55–16.62°) and ammonium acetate were prepared as described in previous papers. Strontium acetate prepared from strontium carbonate was recrystallized from dilute acetic acid and the product kept at 165° for four days. Nickel acetate was prepared similarly. The recrystallized tetrahydrate was dehydrated at 90°, the product moistened with pure acetic acid and again heated at the same temperature to constant weight. The pale green anhydrous salt was analyzed for nickel by means of dimethyglyoxime, giving 33.11% as compared with the calculated 33.21%.

Strontium Acetate–Acetic Acid System.—Freezing points were determined by the synthetic method described in previous articles. The freezing points of the acetic acid are believed to be correct to ±0.2°, other equilibrium temperatures to ±0.5°.

Nickel Acetate–Acetic Acid System.—It soon became apparent why the recorded data for the solubility of nickel acetate had been so discordant. The salt dissolved fairly readily on gentle heating, the solutions showing a faint turbidity which did not disappear at higher temperatures. When the concentration of solute was less than 12 mole per cent., only acetic acid was obtained as solid phase on cooling. Solutions containing 12 to 13 mole per cent. of solute, however, deposited abundant quantities of a finely

divided greenish-white solid, which did not redissolve even on heating to the boiling point. The extreme slowness with which equilibrium was attained in these solutions (if, indeed, it was a true equilibrium) eliminated all possibility of employing the synthetic method for determining solubility. There remained as an alternative the analysis of solutions apparently saturated at a fixed temperature. Accordingly, a 13 to 14% solution was prepared at 100°; on slow cooling, a solid phase appeared. The mixture was then kept at 30° in a thermostat, with frequent stirring, for twelve hours, after which some of the solution was drawn off through a Gooch crucible provided with a thick mat of asbestos. The filtering device remained immersed in the thermostat throughout the filtration, precautions being taken to exclude moisture. The concentration of the filtrate was determined by analysis for nickel by the dimethylglyoxime method.

Ammonium Acetate–Nickel Acetate–Acetic Acid System.—The same difficulty was encountered here as in the case of the binary solutions just referred to, namely, that the solid phase, although it separated readily enough from supersaturated solutions, redissolved only extremely slowly. The same procedure was therefore employed as in the binary system. Solutions containing both ammonium and nickel acetates were prepared at elevated temperatures and allowed to come to equilibrium at 30°. After filtration, the nickel content of the solution was determined as before, while another portion of the filtrate was analyzed for ammonium by making it alkaline with sodium hydroxide solution and distilling the ammonia into standard hydrochloric acid. The concentration of acetic acid could then be found by difference.

Analysis of Solid Phases.—The desired solid having been obtained by the cooling of a solution of suitable concentration, the mother liquor was filtered off by suction, and the crystals rapidly dried between porous tiles. In the case of strontium acetate, the product was analyzed for acetic acid by titration with sodium hydroxide solution. In the product containing nickel acetate, nickel was determined by means of dimethylglyoxime, and in the ternary system the solid was analyzed for both nickel and ammonium, as in the case of the corresponding solutions.

Results

I. System $Sr(C_2H_3O_2)_2$–$HC_2H_3O_2$.—Concentrations in mole per cent. of solute, and the corresponding equilibrium temperatures, *T*, are tabulated.

(a) SOLID PHASE $HC_2H_3O_2$

T	118.5	121.8

The freezing point curve for this system is shown in Fig. 1. Three analyses of the solid phase (b) gave a mean value of 50.08 mole per cent.

$HC_2H_3O_2$, corresponding to the compound $Sr(C_2H_3O_2)_2 \cdot HC_2H_3O_2$, which has not previously been reported. In the neighborhood of 113° this compound undergoes transition to another substance (c) which could not be obtained in sufficient quantity for analysis, but which appears to be unsolvated $Sr(C_2H_3O_2)_2$.

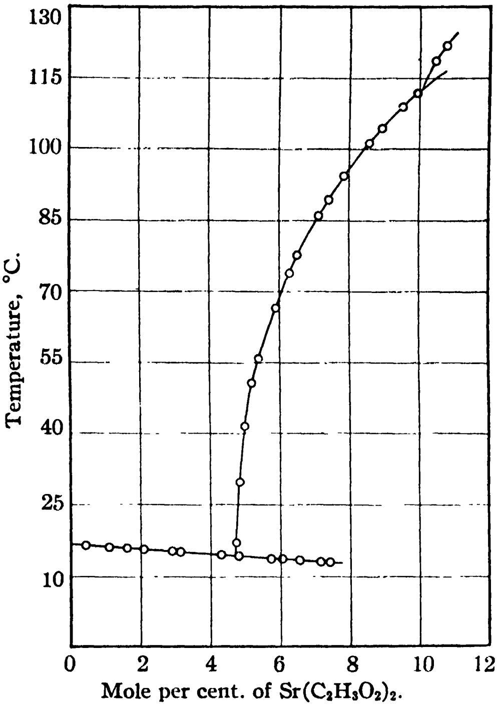

Fig. 1.—System $Sr(C_2H_3O_2)_2$–$HC_2H_3O_2$.

II. System $Ni(C_2H_3O_2)_2$–$HC_2H_3O_2$.—These solutions were green at ordinary temperatures, changing to olive-green at 115 to 120°; the most concentrated solutions were very viscous. Freezing point depression data are tabulated below.

Four solubility determinations at 30° gave values of 11.87, 13.15, 12.06 and 12.39 mole per cent., mean 12.37 mole per cent. The wide divergence among these values seems to indicate that we had here no true equilibrium between solution and crystalline solid, but that colloidal phenomena were involved. This conclusion is supported by the high viscosity of these solutions, by the marked Tyndall effect exhibited by them, and by the nature of the solid phase. This was a very finely divided greenish-white substance, which had very little tendency to redissolve in acetic acid. It showed no detectable crystalline structure upon microscopic examination, and analyses of three samples gave results varying from 54 to 66 mole per cent. of $Ni(C_2H_3O_2)_2$. This range is far in excess of any possible experimental error, and indicates that the solid is not a definite crystalline compound, but a solvated product of variable composition.

$Ni(C_2H_3O_2)_2$, %	0.0	0.32	0.61	1.00	1.73	2.47	3.22	
T	16.55	16.45	16.40	16.30	16.15	16.00	15.85	
$Ni(C_2H_3O_2)_2$, %	4.47	5.68	7.32	8.90	10.57	12.19	13.67	14.89
T	15.60	15.35	15.10	14.90	14.55	14.15	13.80	13.55

III. System $NH_4C_2H_3O_2$–$Ni(C_2H_3O_2)_2$–$HC_2H_3O_2$.—These solutions were green with a slight olive tinge at ordinary temperatures; at the boiling point the color was distinctly yellow-green.

At low concentrations of ammonium acetate the saturated solutions were viscous and of high nickel acetate content; in general, the solubility of the nickel compound decreased with increasing concentration of ammonium salt, but no consistent quantitative data were obtainable, nor was the solid phase even approximately constant in composition, although it always contained all three components. However, when the concentration of ammonium acetate exceeded 15 mole per cent., true equilibrium was apparently attained, concordant solubility values were found, and the solid phase appeared to be a definite compound.

The compositions of saturated solutions at 30°, in mole per cent., are

$NH_4C_2H_3O_2$, %	15.13	17.44	19.67	22.79	24.79
$Ni(C_2H_3O_2)_2$, %	0.214	0.111	0.071	0.039	0.028

The solid phase was a finely divided greenish-white substance which showed under the microscope a distinctly crystalline structure; accurate analysis was difficult because of its instability on exposure to the atmosphere. Nine analyses gave the following mean values in mole per cent.: $NH_4C_2H_3O_2$, 25.49; $Ni(C_2H_3O_2)_2$, 25.62; $HC_2H_3O_2$, 48.89. This composition was confirmed by the analysis of several wet residues; it corresponds to the compound $Ni(C_2H_3O_2)_2 \cdot NH_4C_2H_3O_2 \cdot 2HC_2H_3O_2$.

Discussion

Solubility Data.—The solubility of the monosolvate of strontium acetate in pure acetic acid at 25° was found to be 0.842 mole per 1000 g. of solvent, or 4.81 mole per cent. Comparison of this figure with the previously determined value[1b] of 0.068% for the corresponding calcium compound, and 6.40% (by extrapolation) for disolvated barium acetate,[5] shows that the solubility of these bases increases in the order of increasing atomic weight of the metal, just as in the case of the corresponding hydroxides in aqueous solution.

In the case of nickel acetate we can scarcely avoid the conclusion that the binary solutions are, at least in part, colloidal in nature. The concentration of an apparently saturated solution might then be expected to vary with particle size, conditions of stirring, temperature at which solution occurs, and other factors. Although this difficulty has not arisen in any of the previous work on acetic acid solutions in this Laboratory, phenomena of the same nature were apparently encountered by Seward and Hamblet[6] in attempting to determine the solubility of sodium iodate in this solvent, while McBain and Kistler[7] concluded that "colloidal constituents are of very common occurrence in non-aqueous solutions of electro-

---

(5) The solubility of a monosolvate of barium acetate at this temperature would undoubtedly be even greater than that of the disolvate. See Kendall, Davidson and Adler, THIS JOURNAL, 43, 1489 (1921).

lytes that are usually regarded as quite simple." This case should perhaps be regarded as parallel to the behavior of nickelous hydroxide in water. The latter compound, although known to have a crystalline structure, may, of course, be precipitated in an apparently amorphous form of variable composition (hydrous nickel oxide), and colloidal solutions of this substance are readily obtained.

Ternary solutions containing moderate concentrations of ammonium acetate show anomalies similar to those of the binary system. While the tendency toward colloidal behavior is apparently somewhat reduced by the presence of the third component,[6b] it nevertheless persists to so high a concentration of the latter as to prevent the observation of any similarity between this case and the corresponding copper system, except that at very high concentrations of ammonium acetate a solvated double salt is formed whose solubility decreases with further increase in ammonium acetate concentration. The color of the ternary nickel solutions, on heating, undergoes a pronounced reversible change toward the yellow; but since the same change occurs in similar solutions containing potassium acetate instead of ammonium, it cannot be attributed, as in the case of cupric acetate,[1c] to the formation of a complex cation containing ammonia.

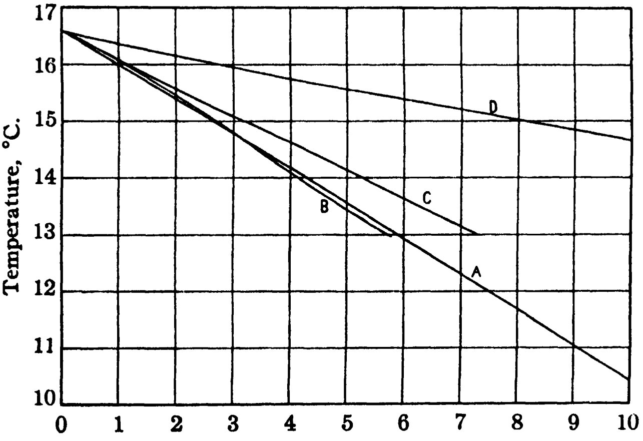

Fig. 2.—Freezing point depression curves, acetic acid as solvent: A, ideal solute; B, sodium acetate; C, strontium acetate; D, nickel acetate.

Freezing Point Depression Data.—The freezing point depression curves for the two acetates which have been studied in this work are shown in Fig. 2; for purposes of comparison we have included also the curve for sodium acetate[1a,8] and the ideal curve for a perfect *undissociated* solute. It will be noted that, in spite of the fact that all these acetates

---

(8) Webb, THIS JOURNAL, 48, 2263 (1926).

are known to be ionized, and might therefore be expected to show freezing point depressions greater than the ideal values, the sodium acetate curve approaches the ideal rather closely, while the other two lie far *above* it. Now, although it is obviously impossible to determine quantitatively the molecular state of an electrolyte from freezing point data, yet valid qualitative conclusions as to the molecular complexity or type of ionization of solutes have been reached, in certain cases, by means of a simple interpretation of such data, not only for aqueous solutions, but also for such solvents as formic[9] and sulfuric[10] acids. In the case of the acetic acid solutions here considered, however, it is evident that such an interpretation might well be entirely misleading. The reason for the difficulty lies, of course, in the very low dielectric constant of acetic acid, in consequence of which interionic forces are far greater than in the other solvents mentioned, and may even become the predominant factor causing deviation from the behavior of an ideal ionized solute throughout the entire concentration range in which experimental data are obtainable. Sharply conflicting opinions as to the molecular state of simple electrolytes in acetic acid have resulted from varying interpretations of the facts just mentioned. Sodium acetate, for instance, has been regarded at one extreme as being associated to some extent into polymeric molecules,[11] at the other, as being practically completely dissociated into ions.[8,12]

Thermodynamic treatment of freezing point data, which does not demand any particular theory as to the molecular state of the solute, yields values of the mean activity coefficient of sodium acetate varying from 0.37 at $m = 0.001$ to 0.010 at $m = 1$. In the case of strontium acetate the activity coefficients cannot be determined satisfactorily, both because of the lack of data at high dilutions and because of uncertainty as to the type of dissociation of this electrolyte, but it is evident from Fig. 2 that the values must be even smaller than those for sodium acetate.

Our knowledge of acetic acid solutions is as yet scarcely adequate to permit a decision as to whether the low values of the freezing point depressions, observed even in dilute solutions of these typical electrolytes, are due to polymerization or to incomplete dissociation, or merely to the very large interionic forces prevailing in this solvent.[13] In the case of nickel acetate, however, the extremely small slope of the freezing point

(12) For an intermediate viewpoint, see Hall and Werner, THIS JOURNAL, 50, 2367 (1928).

(13) It is true that several authors [Refs. 6a, 8; also Conant and Werner, THIS JOURNAL, 52, 4436 (1930); Hutchison and Chandlee, *ibid.*, 53, 2887 (1931); and La Mer and Eichelberger, *ibid.*, 54, 2763 (1932); have been fairly successful in calculating various properties of electrolytes in acetic acid on the basis of the Debye–Hückel theory and its modifications. Various arbitrary values of the parameter "*a*" are employed, however, in these calculations, as well as other hypotheses on which the several writers are not always in accord, so that experimental results may scarcely be said to have been accounted for on an entirely theoretical basis.

depression curve, as compared to that of the corresponding strontium compound, is in accord with the hypothesis advanced above that the solute is at least partially in the form of aggregates of considerably larger than molecular dimensions.

Summary

1. The solubility of strontium acetate in pure acetic acid has been determined over a wide range of temperatures, and is found to be intermediate between those of the corresponding barium and calcium salts.

2. The solubility of nickel acetate in acetic acid at 30°, as well as the composition of the solid phase in equilibrium with the solution, is found to be variable. This anomalous behavior is attributed to the presence of colloidal constituents.

3. In the presence of high concentrations of ammonium acetate, the solubility of nickel acetate is found to decrease with increasing concentration of ammonium salt.

4. Two new compounds, $Sr(C_2H_3O_2)_2 \cdot HC_2H_3O_2$ and $Ni(C_2H_3O_2)_2 \cdot NH_4C_2H_3O_2 \cdot 2HC_2H_3O_2$, have been isolated and analyzed.

5. The freezing point depression curves of several acetates in acetic acid have been compared with the curve for an ideal solute, and their deviations therefrom have been discussed.

Properties of Electrolytic Solutions. VI. Conductance of Sodium Triphenylstannide, Sodium Triphenylgermanide and Sodium Triphenylmethide in Liquid Ammonia[1]

BY CHARLES A. KRAUS AND W. HARLOW KAHLER[2]

I. Introduction

In the preceding paper of this series, values were given for the conductance of various salts in which nitrogen functioned as central element of the negative ion. The constitution of such ions may be modified by means of two substituent groups attached to the nitrogen atom. It seemed of interest to study corresponding ions of the elements of the fourth group, which form anions of the type R_3A^-, where R is an organic group or hydrogen. The salts of these ions are readily soluble in liquid ammonia and are appreciably soluble in ether and other similar solvents. Excepting the derivatives of tin and lead, the salts are stable in the pure state. Since an ion of this type has a very weak affinity for its charge electron, it is readily oxidized by more electronegative elements, including oxygen.

---

[1] This and the preceding paper of this series formed the subject matter of the Edgar F. Smith Birthday Lecture delivered by the senior author at the University of Pennsylvania, May 23, 1930.

[2] Metcalf Fellow in Chemistry in Brown University.

The salts may be looked upon as derivatives of extremely weak acids, R_3AH, and they, therefore, react readily with most protonic solvents. Fortunately, liquid ammonia is a very weak ammonolyzing agent and solutions of these salts are usually stable in this solvent. With the exception of silicon, salts of the type of sodium triphenylmethide are not ammonolyzed under ordinary conditions.

Sodium triphenylmethide is most conveniently prepared by the action of the sodium amide upon triphenylmethane. Reaction takes place according to the equation $(C_6H_5)_3CH + NaNH_2 = (C_6H_5)_3CNa + NH_3$. A similar reaction does not take place in the case of the corresponding derivatives of silicon, germanium or tin. The alkali metal salts of triphenylgermanium and triphenyltin may be prepared by the direct action of the metal upon the corresponding free groups in liquid ammonia.

Schlenk and Marcus[3] have shown that sodium triphenylmethide is a conductor in ethereal solution. Foster[4] carried out preliminary measurements of the conductance of sodium triphenylgermanide in liquid ammonia. Wooster[5] carried out similar measurements with sodium triphenylgermanide, triphenylmethide, and triphenylstannide. These measurements indicated that salts of this type are exceptionally good electrolytes.

We have measured the conductance of these salts in liquid ammonia in the hope of obtaining data that would be sufficiently accurate to enable us to calculate their dissociation constants. Unfortunately, solutions of these salts show signs of instability at low concentrations. Of the three salts, sodium triphenylstannide proved the most stable and sodium triphenylmethide the least. From our measurements we have been able to approximate the dissociation constant of sodium triphenylstannide.

II. Apparatus and Procedure

The general procedure was much the same as that of Kraus and Hawes.[6] The solutions were made up in the conductivity cell, the materials being sealed in fragile glass bulbs which were broken as needed. The ammonia introduced into the cell was measured in a pipet, and the amount of solution withdrawn from the cell was determined by weight after evaporation and absorption in water. The conductance cell differed from that of Kraus and Hawes and is described below.

The cell consisted of a cylindrical tube A (Fig. 1), which was closed at the top by means of a ground-glass stopper through which passed the stem B, carrying the electrode system C. The stem was movable through the slip-joint D. The platinum wire leads EE (Figs. 1a and 1b) were sealed through the end of the stem and were soldered to copper wire leads passing up through the stem B. In order to render the constant of the electrodes independent of their position in the cell, they were surrounded by a housing F, which was provided with small openings GG at top and bottom to allow free flow of the solution past the electrodes. The cell was emptied by withdrawing the solution through the capillary tube H. This tube also served as stirring tube, ammonia vapor being passed through it by means of a modified Toepler pump I, similar to that used by Kraus and Hawes. Solution was withdrawn through the capillary J, which left a determinable quantity of solution in the cell. The solution passed through a special stopcock K into the receiver as described by Kraus and Hawes. Stopcocks L and M were used to equalize the pressure between the withdrawing tube and the interior of the cell.

---

[3] Schlenk and Marcus, *Ber.*, **47**, 1678 (1914).

[4] Foster, Thesis, Brown University, 1926.

[5] Wooster, Thesis, Brown University, 1928.

[6] Kraus and Hawes, THIS JOURNAL, **55**, 2776 (1933).

The materials used in preparing the salts were sealed in weighed glass bulbs N and O. One of these, containing the metal, was placed immediately under the electrode housing, while the other was placed in the pocket P. The housing at the bottom was made sufficiently heavy so that the bulbs could be crushed by bearing down on the stem of the electrode system, which was movable in the slip-joint D.

After washing the cell repeatedly with liquid ammonia until the desired specific conductance was obtained, a measured quantity of ammonia was condensed in the cell, the bulbs were crushed under the liquid, and the contents of the cell were stirred. Only a few minutes were required to complete the reaction. In the case of sodium triphenylmethide, the sodium bulb was first crushed and the metal converted to amide, the reaction being accelerated by a bit of iron oxide.

The cell constant was determined by intercomparison with a standardized cell. Three different sets of electrodes were used whose constants were approximately 0.36, 0.13 and 0.06. The electrical measuring apparatus was the same as that used by Kraus and Hawes. Triphenyltin and triphenylgermanium were products that had been prepared in this Laboratory, and were purified by recrystallization from benzene. Triphenylmethane was purified by recrystallization. Sodium was introduced into weighed bulbs as described by Kraus and Hawes. Ammonia was purified as usual by means of metallic sodium. A correction of 2 × 10^{-7} has been applied for the conductance of the solvent.

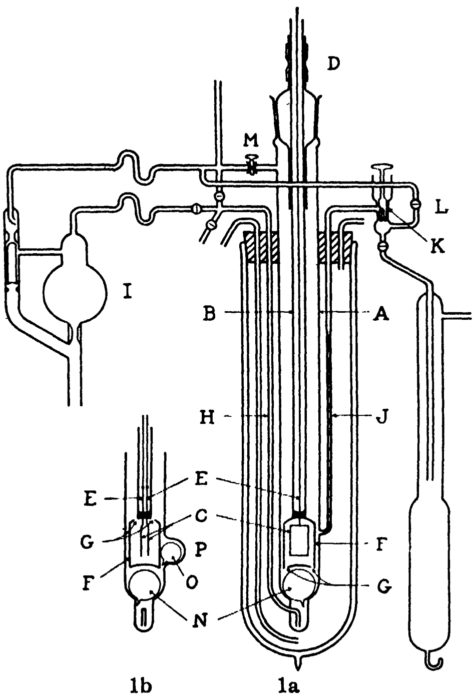

Fig. 1.—Conductance cell.

III. Experimental Results

Conductance values of sodium triphenylstannide, sodium triphenylgermanide and sodium triphenylmethide are given in the following table. In the case of all three salts, measurements were made at concentrations much lower than the lowest given in the table. The values, however, were manifestly unreliable, since the conductance changed with time and the conductance curve showed a marked change in curvature. The difficulty was overcome to some extent by carrying the measurements out very rapidly. In the case of tin, fairly satisfactory results were obtained down to relatively low concentrations. In the case of germanium and carbon, however, satisfactory results could not be obtained at low concentrations. With sodium triphenylstannide, the conductance curve tended to rise abruptly at low concentrations, while, in the case of the triphenylmethide, the conductance curve fell consistently at concentrations below 0.001 *N*. The germanium salt exhibited an intermediate behavior. In some respects, sodium triphenylmethide behaved as though it were undergoing ammonolysis. In this connection it may be noted that, according to Kraus and Kawamura,[7] sodium triphenylmethide is completely ammonolyzed when an ammonia solution of this salt is evaporated at −33°.

TABLE I

CONDUCTANCE OF SALTS IN LIQUID AMMONIA AT −33°

V	Λ	*V*	Λ	*V*	Λ

26580	218.3				
58350	219.4				

IV. Discussion

The conductance curves of the three salts are shown graphically in Fig. 2, values of the equivalent conductance being plotted as ordinates and logarithms of concentrations as abscissas. Inspection of the figure will show that all three salts are very strong electrolytes in liquid ammonia. Although the mobilities of the negative ions are relatively low because of their large size, at higher concentrations these salts are, nevertheless, much better conductors than are the ordinary salts. For the purpose of comparison, the conductance curve for sodium bromate, which is one of the stronger inorganic salts, is likewise plotted in Fig. 2. It will be noted that, although the limiting conductance of sodium bromate (278) is much higher than that of the three salts which we have measured, it is a markedly poorer conductor at concentrations above 0.01 *N*. The conductance curves for the three salts are very nearly parallel at higher concentrations, the conductance of the tin salt being highest and that of the carbon salt lowest. It was found that, toward lower concentrations, the curve for sodium triphenylmethide falls off rapidly and that of sodium triphenylgermanide less rapidly. The solutions are evidently unstable at lower concentrations. The curve for sodium triphenylstannide appears to be normal and resembles

---

(7) Kraus and Kawamura, THIS JOURNAL, 45, 2756 (1923).

that of sodium triphenylboron ammide.[8] It is of interest to note that the triphenylstannide and the triphenylboron ammide ions are of about the same size and have much the same symmetry.

The determination of precise values of Λ_0 and of K is not possible, even in the case of sodium triphenylstannide. Indeed, this salt is so highly ionized that a satisfactory evaluation of K cannot be made except with highly precise data. Nevertheless, Λ_0 and K could be approximated fairly closely. The values found are: $\Lambda_0 = 226$ and $K = 0.013$. Sodium triphenylstannide is a salt having about the same strength as sodium triphenylboron ammide, and its limiting conductance has nearly the same value.

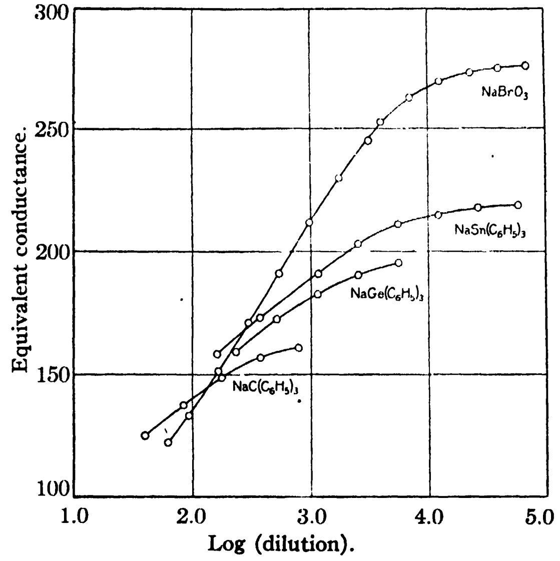

Fig. 2.—Conductance of salts in liquid ammonia.

It may be of interest to point out that familiar inorganic salts, which are usually considered to be typical electrolytes, are, in fact, much weaker electrolytes than the compounds here investigated. Thus, the dissociation constant of sodium bromate is 35×10^{-4}, while that of sodium triphenylstannide is about four times as great. The dissociation of a salt is primarily determined by the size of its ions, or, in other words, by the work necessary to separate a pair of ions from their position of minimum energy. When the ions are small, the energy of separation is large and the dissociation constant is correspondingly small.[9] It is also evident that the affinity of the negative ion for its electron has no influence on the dissociation of its salts. Thus, the affinity of an ion such as triphenylmethide or triphenylstannide for its electron is exceedingly small in comparison with that of the chloride or the bromate ion. While it is true that, in the case of the acids, ionization is the greater the more electronegative the ion, this is not true generally for salts in solvents of lower dielectric constant, where ion association is appreciable.

V. Summary

The conductances of solutions of the sodium salts of triphenyltin, triphenylgermanium and triphenylmethyl in liquid ammonia have been measured.

All three salts are very strong electrolytes. The dissociation constant of sodium triphenylstannide is approximately four times that of sodium bromate.

Properties of Electrolytic Solutions. VII. Conductance of Sodium Trimethylstannide and of the Sodium Salts of Certain Phenols and Thiols in Liquid Ammonia

BY CHARLES A. KRAUS AND EDMUND G. JOHNSON

I. Introduction

In the two preceding papers of this series, conductance values were given for electrolytes in which the charge of the negative ion was localized on nitrogen,[1] tin, germanium or carbon,[2] the remaining valences of these elements being satisfied by organic groups. The purpose of these investigations has been to study the influence of ion size and constitution on the properties of the electrolyte, particularly its dissociation constant. The results already presented lend support to the view that the dissociation of an electrolyte is primarily determined by the size of its ions and, to a lesser degree, by their configuration. Electrolytes with large ions, which cannot approach each other very closely, have a lower energy of dissociation and, consequently, a higher dissociation constant. Where the ions are unsymmetrical, constitutional factors have a marked influence and it may be expected that the salts of such ions will be the more highly ionized the more the charge is screened by neutral atoms of the ion complex.

It seemed of interest to determine the dissociation constants of salts of simple oxygen and sulfur acids of the type RAH, which give ions of the type RA^-. The salts of the ordinary alcohols are not sufficiently soluble in liquid ammonia to permit of conductance measurements, but the salts of the aromatic alcohols are readily soluble and are well suited to the purpose of the present investigation. In the case of sulfur, both the alkyl and the aryl substituted thiols yield readily soluble salts. It was to be expected that, owing to the larger diameter of the sulfur atom, the salts of thio alcohols would prove to be markedly better electrolytes than their oxygen analogs. In the salts of alpha and beta naphthol, we have the interesting case where the oxygen atom, which presumably carries the charge electron, is located in different positions on the naphthalene nucleus, and we should expect a somewhat higher dissociation constant in the case of the α-naphtholate because of the somewhat greater screening due to the remainder of the molecule.

---

[1] Kraus and Hawes, THIS JOURNAL, 55, 2776 (1933).

[2] Kraus and Kahler, *ibid.*, 55, 3537 (1933).

Sodium trimethylstannide was measured for the purpose of comparison with sodium triphenylstannide.[2] Unfortunately, this salt, like the corresponding phenyl derivative, yields solutions that are not entirely stable at low concentrations. Nevertheless, it was possible to carry out measurements to concentrations sufficiently low to show that, as was to be expected, this salt is a markedly weaker electrolyte than sodium triphenylstannide.

II. Experimental

Apparatus and Procedure.—The apparatus employed in the present investigation was very similar to that of Kraus and Kahler and need not be described, except for a few minor variations. Instead of stirring the solution by means of vapor withdrawn from the cell with a Toepler pump, the electrode system was moved up and down in the slip-joint through which the stem of the electrode system passed. An improved three-way stopcock was employed for withdrawing the ammonia, which made it possible to equalize the pressure between the cell and the withdrawal capillary without use of an additional stopcock. The electrical measuring apparatus was the same as that used by Kraus and Kahler.

Excepting sodium phenolate, all solutions were prepared by the action of sodium or sodium amide on the proper compounds in the cell itself. Sodium phenolate was prepared by the action of metallic sodium on phenol in liquid ammonia. It was washed with ether to remove traces of phenol and was sealed in weighed glass bulbs, the bulbs being broken in the cell as described by Kraus and Kahler. The naphtholates were prepared in the cell by the action of sodium amide on the corresponding naphthols. The naphtholates cannot be prepared by the action of metallic sodium on the naphthols because of the reducing action of the resulting hydrogen.[3] The thiophenolate and ethyl mercaptide were prepared by the action of sodium on the corresponding thiols. Ethyl mercaptan was introduced into the cell with a stream of ammonia vapor, a weighed bulb of sodium having been crushed under ammonia previous to introducing the mercaptan. In this case, the cell was exhausted after preparation of the salt in order to remove traces of excess mercaptan. Sodium trimethylstannide was prepared by the direct action of metallic sodium on an equivalent amount of trimethyltin in the cell.

In measuring the conductance of sodium trimethylstannide, the cell electrodes had a constant of 0.1299 and were lightly platinized. For the remaining salts, the electrodes had a constant of 4.682 and were heavily platinized.

All the solutions excepting those of sodium trimethylstannide were stable down to the lowest concentrations measured. The solutions of the sodium naphtholates were strongly fluorescent, the color being yellow by transmitted light and a deep violet by reflected light.

III. Results

The conductance values for sodium phenolate, sodium α-naphtholate, sodium β-naphtholate, sodium ethyl mercaptide, sodium thiophenolate and sodium trimethylstannide are given in Table I. The conductance values have been corrected for the conductance of the pure solvent, which was determined just prior to preparation of the solution in the case of each salt. This value l is given at the head of each table of values. Check measurements, made in the case of the phenolate, the α-naphtholate and trimethylstannide, were in agreement with previous values and are not tabulated.

IV. Discussion

The values of Λ_0 and K for the different salts have been evaluated by the method of Fuoss and Kraus.[4] In the figure, values of the ratio Λ/Λ_0 are plotted as ordinates against the square root of concentrations as abscissas. This plot is more convenient than a plot of the conductance in comparing different salts with one another. The straight line as drawn in the figure is the limiting Debye–Hückel–Onsager slope averaged for the different salts. Actually, this slope varies slightly with Λ_0, but the variation is so small that it seemed unnecessary to introduce the limiting tangent for each electrolyte.

---

(4) Fuoss and Kraus, THIS JOURNAL, 55, 476 (1933).

The curves as drawn are the calculated curves based upon the values of the constants Λ_0 and K as computed. In evaluating these constants, the following values of constants were assumed for the solvent medium: dielectric constant 22, viscosity 0.00256, temperature 240°. From the figure, it is evident that the measured values of the conductance are satisfactorily accounted for by a combination of ionic dissociation and the usual interionic effects. The deviations from the limiting Debye–Hückel slope, due to the mass action effect, is marked in all cases and is the greater, the lower the dissociation constant of the electrolyte. None of the salts are sufficiently strong to approximate the limiting curve closely.

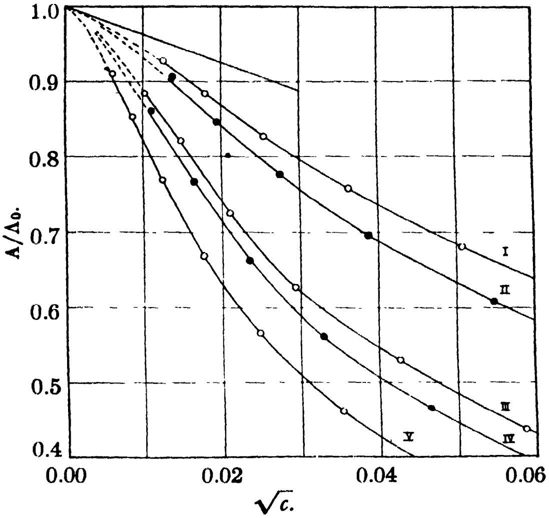

Fig. 1.—Conductance of sodium phenolates and thiolates in liquid ammonia: I, C_6H_5SNa; II, C_2H_5SNa; III, α-$C_{10}H_7ONa$; IV, β-$C_{10}H_7ONa$; V, C_6H_5ONa.

In Table II are given values of Λ_0, the limiting conductance, K, the dissociation constant, and a, which may be looked upon as the minimum distance between ion centers in the ion pairs. The quantity a was computed from the data according to the method of Fuoss and Kraus.[5]

TABLE II

CONSTANTS OF ELECTROLYTES IN LIQUID AMMONIA

Electrolyte	Λ_0	$K \times 10^4$	$a \times 10^8$
Sodium phenolate	279.4	3.82	2.70
Sodium β-naphtholate	268.1	6.50	2.94
Sodium α-naphtholate	265.3	8.08	3.08
Sodium ethylsulfide	281.4	22.5	4.04
Sodium thiophenolate	275.1	36.0	4.95
Sodium triphenylstannide	(307)	(36)	(4.95)

---

(5) Fuoss and Kraus, THIS JOURNAL, 55, 1019 (1933).

The table illustrates in striking fashion the influence of the substituent groups on the dissociation of electrolytes. Thus, the dissociation constant of sodium phenolate is 3.82×10^{-4}, while that of the β- and α-naphtholates is 6.50 and 8.08×10^{-4}, respectively. The greater size of the naphthyl group, in comparison with that of the phenyl group, has a very marked influence on the dissociation constant. It is particularly interesting to note that the dissociation constant of sodium α-naphtholate is nearly one-third greater than that of sodium β-naphtholate. This shows clearly that it is not only the size of the substituent group, but also the relation of the substituent group to the central charged atom, that determines the dissociation constant.

Sulfur, being a larger atom than oxygen, the dissociation constant of its monosubstituted ions is much greater than that of similar oxygen derivatives. Thus, sodium ethyl sulfide has a dissociation constant of 22.5, which is about three times that of the naphtholates and six times that of the phenolate. The replacement of the ethyl group by a phenyl group raises the dissociation constant from 22.4 to 36.0×10^{-4}. Sodium thiophenolate is an electrolyte as strong as the strongest of the common inorganic salts. The dissociation constant of sodium bromate, for example, is 35.0×10^{-4}.

The data for sodium trimethylstannide do not permit of an accurate determination of constants. It is believed that the values given are not substantially in error. The conductance curve of the stannide closely parallels that of the thiophenolate. The much lower value of K for the methyl derivative as compared with that of the phenyl derivative (K = 0.013, Kraus and Kahler) illustrates the influence of ion size on dissociation.

The a-values vary in accordance with the values of K. As to order of magnitude, they are in reasonable agreement with atomic dimensions. In the case of unsymmetrical ions, the a-values cannot be interpreted simply as the distance between ions; rather they represent an average distance or, perhaps better, they correspond to average energies, depending upon the relative position of the ions in the ion pair.

The results of the present investigation bring out clearly the fact that the strength of electrolytes, in solution in solvents of lower dielectric constant, varies markedly with the constitution of the ions of these electrolytes and that both the dimensions and the configuration of these ions have a marked influence upon dissociation. In general, those electrolytes will be the most highly ionized which have the largest ions and whose configuration is such that their charges are most completely screened by surrounding atoms or groups.

V. Summary

The conductance of the sodium salts of phenol, α- and β-naphthol, ethyl mercaptan, thiophenol and of trimethyltin have been measured in liquid ammonia at −33°.

Values of Λ_0 and of K have been computed and the influence of constitution upon dissociation is discussed.

The Action of Sodium upon Trimethylgallium and Dimethylgallium Chloride in Liquid Ammonia

BY CHARLES A. KRAUS AND FRANK E. TOONDER[1]

I. Introduction

The present paper is concerned with the action of metallic sodium upon trimethylgallium and dimethylgallium chloride. In the light of our knowledge of reactions of similar derivatives of the elements of the fourth group, it might be expected that dimethylgallium chloride would be reduced to the free group $(CH_3)_2Ga$ and that this, in turn, might be further reduced to the negative ion, $(CH_3)_2Ga^-$. On the other hand, no reaction is to be expected in the case of trimethylgallium or, otherwise, a reaction in which one methyl group is substituted by the reducing metal as in the case of tetramethyltin.[2]

Excepting that free dimethylgallium $(CH_3)_2Ga$ is obtained by reduction of the corresponding chloride, there is little resemblance between reactions of organic derivatives of the elements of the third and those of the fourth group of the periodic system. Perhaps the most characteristic reaction of third group elements is that of addition of neutral molecules or negative ions, with formation of coördination compounds. Thus, in the case of boron, we have such coördinate linkage in the BF_4^- ion. Similarly, boron trifluoride combines with neutral molecules, such as ammonia or the amines, to form compounds of the type $BF_3 \cdot NH_3$.[3] There are similar compounds of the organic boron derivatives. Thus, we have $(C_6H_5)_3B \cdot NH_3$,[4] $(C_6H_5)_3B \cdot NH_2^-$,[5] and $(C_6H_5)_3B \cdot OH^-$.[6] The coördinate linkage in these compounds has a striking influence on their stability. For example, triphenylboron oxidizes in air with extreme ease, while potassium amide, under similar conditions, oxidizes explosively; yet the coördinated compound of the two is relatively stable in air.

Gallium shows much the same properties as boron in respect to the formation of coördinate linkages. Thus, trimethylgallium forms an

etherate and an ammoniate[7] and gallium trichloride forms a tetrachlorogallate ion.[8] Dimethylgallium chloride and methylgallium dichloride both form rather stable ammoniates or ammines.[8]

Trimethylgallium, when treated with sodium in liquid ammonia, undergoes a reaction in which the coördinated ammonia molecule is probably involved. Dimethylgallium chloride is reduced to the free group $(CH_3)_2$-Ga which is probably combined with ammonia. The free group reacts with additional sodium in a rather complex manner.

The methylgallium compounds are exceedingly reactive toward oxygen and many of the products of reduction are not only reactive toward oxygen and other substances but are intrinsically unstable. Accordingly, in order to arrive at some notion of the nature of the reactions involved, it has been necessary to depend largely upon indirect means. Only in exceptional cases has it been possible to separate out the products of reaction in pure form for analysis.

II. Action of Sodium upon Trimethylgallium

Weighed samples of trimethylgallium were treated with metallic sodium in liquid ammonia and the evolved gases were collected and measured. Ammonium bromide was added to the resulting solution and the gases evolved in the several stages of this reaction were collected and measured separately.

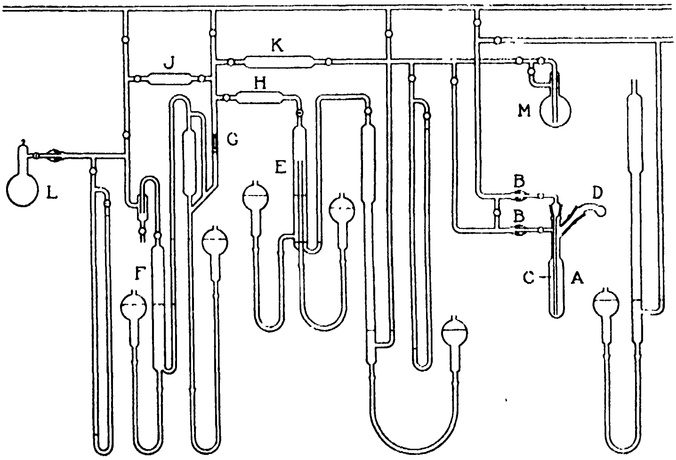

Fig. 1.—Apparatus used in reduction of trimethylgallium.

Apparatus and Procedure.—The apparatus used in this and other reactions described below is illustrated in Fig. 1. A weighed reaction tube A is attached to the system by means of de Khotinsky cement at BB. The tube is provided with a stirring tube C and an addition tube D for adding weighed quantities of substances, such as ammonium bromide, which can be formed into pellets. Gases evolved during the reaction are collected over water in E. These gases are transferred by means of a

---

[7] Kraus and Toonder, *Proc. Nat. Acad.*, **19**, 292 (1933).

[8] Ref. 7, p. 298.

Toepler pump and collected over mercury in F. Water vapor and ammonia are removed by means of drying tubes H, J, K, and the density of the residual gas is determined by weighing in the calibrated density bulb L.

A weighed sample of trimethylgallium monoammine in a fragile glass bulb[7] is introduced into the reaction tube A and, after exhausting and cooling, the bulb is broken. The reaction tube is attached to the system and ammonia is condensed on the gallane, which is readily soluble. Sodium is introduced into the addition tube D previous to exhausting the reaction tube.

The Mechanism of the Reduction Process.—In several experiments known samples of trimethylgallium ammine were treated with one atomic equivalent of metallic sodium in the apparatus described above. Reaction took place immediately with evolution of hydrogen; about 0.4 atom of hydrogen per atom of gallium was evolved in the course of two hours, when reaction ceased. There was no indication of further reaction over a period of fifty hours. Ammonium bromide was then added until the characteristic blue color due to sodium was just discharged. Approximately 0.4 atom of hydrogen per atom of gallium was evolved in this stage of the reaction. On further addition of ammonium bromide to the now colorless solution, approximately 0.2 atom of hydrogen was evolved per molecule of trimethylgallium.

It is evident that several reactions are involved when trimethylgallium is treated with sodium in liquid ammonia. One of these reactions is accompanied by evolution of hydrogen while the second reaction involves some sort of a reduction process, the product of which reacts with ammonium bromide with evolution of hydrogen. Since, on completion of the reaction, approximately 40% of the sodium remains in the free state, it follows that, in one of the reactions, at least two molecules of trimethylgallium per atom of sodium are concerned. The results may be accounted for if we assume the reactions

$$\mathrm{Na} + 2(\mathrm{CH_3})_3\mathrm{Ga{\cdot}NH_3} \longrightarrow (\mathrm{CH_3})_3\mathrm{Ga{\cdot}NH_2{\cdot}Ga(CH_3)_3}^- + \mathrm{Na}^+ + {}^1/_2\mathrm{H_2} + \mathrm{NH_3} \quad (1)$$

$$2\mathrm{Na} + 2(\mathrm{CH_3})_3\mathrm{Ga{\cdot}NH_3} \longrightarrow (\mathrm{CH_3})_3\mathrm{Ga{:}Ga(CH_3)_3}^= + 2\mathrm{Na}^+ + 2\mathrm{NH_3} \quad (2)$$

In the first reaction one atom of sodium is converted to sodium amide with the evolution of hydrogen, and the amide ion forms a coördinated compound with two molecules of trimethylgallium. Reactions of this type are well known in the case of boron, although, in all known cases, only one molecule of borane combines with one amide ion.[9] The second reaction involves the direct reduction of trimethylgallium to a negative trimethylgallium ion. A compound of this type is formed when triphenylboron is treated with metallic sodium in ether solution.[10] The resulting compound, however, is highly colored. In view of the fact that the solutions, in the case of trimethylgallium, are colorless, it is probable that two trimethylgallium ions link together to form a coördinated compound.

On adding ammonium bromide to the reaction mixture, we have, first, the reaction of the ammonium ion with the metallic sodium, in which hydrogen is evolved; then, a reaction of the ammonium ion with the reduced trimethylgallium, in which hydrogen is formed and trimethylgallium is regenerated. Finally, the balance of the ammonium bromide reacts with the sodium amide complex, containing two molecules of trimethylgallium, trimethylgallium being regenerated.

Experimental Data.—A number of reactions were carried out with a view to determining the precise nature of the products of the reaction. The reaction, in general, proceeded much as described above, although the relative amounts of the substances formed in the two reactions varied measurably, depending upon conditions. In one case, where the solution was quite concentrated, one-half of an atomic equivalent of

---

(9) Hawes, Thesis, Brown University, 1927; J. E. Smith, Thesis, Brown University, 1930.

(10) Krause and Polack, *Ber.*, **59**, 777 (1926).

sodium reacted according to reaction (1), and reaction (2) was entirely absent. There was introduced into the reaction tube 0.6475 g. (5.64 m. moles) of trimethylgallium and there was added 0.0844 g. (3.67 m. at.) of sodium. At the end of three hours, 31.6 cc. (2.82 m. at.) of hydrogen was evolved which corresponds precisely to one-half atom of sodium per mole of trimethylgallium. On allowing the reaction tube to stand for twenty-two hours, there was evolved an additional 4.9 cc. (0.44 m. at.) of hydrogen. This evolution of hydrogen was due to slow reaction with the solvent, sodium amide being formed. The initial reaction took place quantitatively according to equation (1). The ammonia was evaporated and the tube allowed to warm to room temperature. On exhausting the reaction tube through a liquid ammonia trap, no material collected in the trap, indicating a complete absence of trimethylgallium ammine, which sublimes readily under these conditions. Ammonia was recondensed in the reaction tube and ammonium bromide was added until the blue color due to sodium just disappeared. On further addition of ammonium bromide to the now colorless solution, no hydrogen was evolved. This indicates the absence of reaction (2).

The attempt was made to vary the proportion of reactions (1) and (2) by carrying out the reduction at lower temperatures. At −76° no reaction whatever occurred. There was a very slow reaction at −48°, accompanied by the evolution of hydrogen. At lower temperatures, both reactions proceeded so slowly that it was not practicable to carry them out. Accordingly, a reaction was carried out at −33°, using a large volume of ammonia and adding the sodium in small pieces (of about 4 milligrams each), one at a time. Of twenty pieces of sodium, seventeen had reacted at the end of six and one-half hours while the eighteenth piece required more than twelve hours for complete reaction. After collecting and determining the gases due to the initial reaction of metallic sodium, ammonium bromide was added to the now colorless solution, the hydrogen was collected and its volume and density were determined. The results were: $(CH_3)_3Ga{\cdot}NH_3$, 0.7330 (5.56 m. moles); H evolved, 19.0 cc. (1.70 m. at.); Na reacted (by wt.), 0.0775 (3.37 m. at.); NH_4Br added, 0.509; H evolved on adding NH_4Br, 18.4 cc. (1.64 m. at.); total H, 37.4 cc. (3.34 m. at.). According to the above data, of 3.37 m. atoms of sodium that reacted, 1.70 m. atoms reacted according to equation (1), yielding 1.70 m. atoms of hydrogen. The remaining 1.67 m. atoms of sodium reacted for the most part according to equation (2). On addition of ammonium bromide, the sodium which was combined with trimethylgallium yielded 1.64 m. atoms of hydrogen according to the equation

$$Na_2[(CH_3)_3Ga]_2 + 2NH_4Br = 2(CH_3)_3Ga{\cdot}NH_3 + 2NaBr + H_2$$

After completion of the last described reaction, 93% of the trimethylgallium ammine was recovered by sublimation from the reaction tube into a weighed, fragile bulb cooled in liquid ammonia.

Reaction in Ethylamine.—In the hope that reaction (1) might be absent if reduction were carried out in ethylamine solution, the reduction of trimethylgallium ammine with lithium in ethylamine solution was investigated. The reactions in ethylamine were similar to, but not identical with, those in liquid ammonia. They took place as follows

$$Li + (CH_3)_3Ga{\cdot}C_2H_5NH_2 \longrightarrow (CH_3)_3Ga{\cdot}C_2H_5NHLi + {}^1/_2H_2 \qquad (3)$$

$$2Li + 2(CH_3)_3Ga{\cdot}C_2H_5NH_2 \longrightarrow [(CH_3)_3Ga]_2^- + 2Li^+ + 2C_2H_5NH_2 \qquad (4)$$

The lithium, cut into small pieces, was added to a solution of trimethylgallium in ethylamine at liquid ammonia temperatures. Prior to adding the lithium, the trimethylgallium ammine was dissolved in ethylamine which was then evaporated in order to carry off the ammonia initially present. Reaction between lithium and trimethylgallium took place somewhat slowly, but, at the end of twelve hours, one atomic equivalent of lithium had reacted. The hydrogen evolved during this stage of the reaction was collected and its molecular weight and volume were determined. On distilling the ethylamine from the colorless solution, hydrogen was evolved. This hydrogen was collected and its molecular weight and density were determined. Since no ammonium bromide had been added, the hydrogen evolved during distillation of the amine must have resulted through a process of oxidation and reduction, presumably according to the reaction

$$Li_2[Ga(CH_3)_3]_2 + 2C_2H_5NH_2 \longrightarrow 2LiC_2H_5NH\cdot Ga(CH_3)_3 + H_2 \qquad (5)$$

The data relating to this reaction are as follows: $(CH_3)_3Ga\cdot NH_3$, 0.2709 (2.06 m. moles); Li, 0.0144 (2.06 m. at.); H evolved during reaction, 9.2 cc. (0.82 m. at.); H evolved during evaporation, 14.2 cc. (1.26 m. at.); total hydrogen evolved, 23.4 cc. (2.08 m. at.).

According to the above results, 39.8% of the gallium reacted according to equation (3) with evolution of hydrogen, while 61.2% reacted according to equation (4), without evolution of hydrogen. The equivalent quantity of hydrogen was, however, given off during evaporation of the solution, reaction (5) taking place. The total hydrogen, 101.0% of the theoretical, is within the limit of experimental error. While the product of reduction according to equation (3) is stable in the dry state as well as in ethylamine solution, the simultaneously formed product of reduction according to equation (4) is measurably stable only in solution at −33° and breaks down on evaporating the solvent.

On finally dissolving the product in liquid ammonia and treating with ammonium bromide, no hydrogen was evolved. This was to be expected in view of equation (5). After evaporating the liquid ammonia, the reaction tube was exhausted through a weighed trap cooled to liquid ammonia temperatures. The recovered material was obviously not the original trimethylgallium ammine, since it was liquid at ordinary temperatures and was markedly less volatile than the original ammine. One should naturally expect trimethylgallium ethylammine to be formed in this case. The weight of recovered material, which was too high for trimethylgallium ammine, would correspond to a recovery of 86% of trimethylgallium ethylammine.

Sodium bis-Trimethylgallium Ammide.—If reactions (1) and (2) express correctly what takes place when trimethylgallium is treated with sodium in liquid ammonia, then we should expect that one molecule of sodium amide would react with two molecules of trimethylgallium in liquid ammonia. Accordingly, a known quantity of sodium in a weighed, fragile bulb was introduced into the reaction tube, where the bulb was broken and the metal converted to sodium amide in the usual way. The ammonia was then evaporated and the bulb of trimethylgallium ammine, previously introduced, was broken and liquid ammonia was condensed in the reaction tube. That reaction took place was indicated by the disappearance of sodium amide, which is very slightly soluble in liquid ammonia. The solvent was now evaporated, the tube was exhausted and the product of the reaction weighed. The results were as follows: Na, 0.0497 (2.16 m. at.); $NaNH_2$, 0.0842 (2.16 m. moles); $(CH_3)_3Ga\cdot NH_3$, 0.5668 (4.30 m. moles); wt. product found, 0.5783 (2.15 m. moles); wt. $[(CH_3)_3Ga]_2\cdot NH_2Na$, calcd., 0.5775 (2.15 m. moles).

On completion of the reaction, the tube was heated to 50° and exhausted through a trap cooled in boiling ammonia. The quantity of material collected amounted to 0.0017 g., showing that the reaction between one molecule of sodium amide and two molecules of trimethylgallium was practically quantitative. On heating the product to 140° *in vacuo*, the material in the reaction tube failed to melt, although some crystals sublimed to the cooler portions of the tube. Trimethylgallium ammine melts at 30°. On cooling the tube and treating the product with ammonium bromide in liquid ammonia and thereafter exhausting the reaction tube through a trap, 48% of the original trimethylgallium ammine was recovered. Evidently some decomposition or rearrangement occurred on heating to 140°, since ordinarily the recovery amounts to 90% or more.

III. Reduction of Dimethylgallium Chloride

A. With One Atomic Equivalent of Sodium.—When dimethylgallium chloride is treated with one atomic equivalent of sodium in liquid ammonia, reduction occurs according to the equation

$$(CH_3)_2GaCl + Na = (CH_3)_2Ga + NaCl \tag{6}$$

The free dimethylgallium combines with one or more molecules of ammonia, probably to form an ammine. When the solvent ammonia is evaporated, a brownish colored solid is precipitated, which decomposes on warming to room temperature with evolution of hydrogen according to the equation

$$(CH_3)_2Ga{\cdot}NH_3 = (CH_3)_2GaNH_2 + {}^1/_2H_2 \tag{7}$$

Dimethylgallium.—Dimethylgallium chloride monoammine was prepared in a reaction tube of the type illustrated in Fig. 2a. It was attached to the system in place of the reaction tube (A) shown in Fig. 1. One atomic equivalent of sodium was introduced into the arm A, which was cut open for the purpose and then sealed. After condensing ammonia in the reaction tube, the sodium was added. Reaction took place immediately without evolution of gas and without formation of a precipitate, except that toward the end of the reaction sodium chloride appeared. The color of the solution changed gradually from yellow to orange; this color, seemingly, was due to dimethylgallium. As the liquid ammonia evaporated, a brown solid appeared and, when nearly all the liquid was gone, gas was evolved and the color of the solid changed from brown to gray. The volume and density of the gas were determined and found to correspond to one atom of hydrogen per molecule of dimethylgallium. At a temperature of 60° or above, a crystalline solid sublimed from the residue. This was later shown to be dimethylgallium amide. Equations (6) and (7) account for the products of reaction.

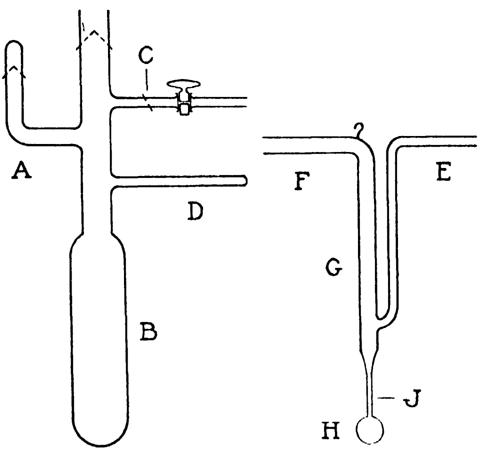

Fig. 2a. Fig. 2b.

Fig. 2.—Apparatus used in preparation of dimethylgallium amide.

In order to determine the stability of dimethylgallium, a second reaction was carried out, identical with the first, except that the ammonia was evaporated at −33°. The ammonia from the reaction tube was absorbed in sodium iodide, contained in a flask M cooled to ice temperature. In this way any evolved gases were not contaminated by air or water, nor were gases lost by absorption in water. On completion of the reaction and evaporation of the solvent, a brownish colored solid remained and no permanent gases were collected. However, on standing overnight, an appreciable quantity of hydrogen was evolved. About half the hydrogen required according to equation (7) was obtained at the end of twenty-four hours. On now warming the residue to room temperature, hydrogen was given off rapidly and the color of the solid in the reaction tube changed from brown to gray. The quantitative data were: m. moles $(CH_3)_2$-

$GaCl\cdot 2NH_3$, 5.47, 5.63; m. atoms Na added, 5.61, 5.66; m. atoms H evolved, 5.40, 5.62; ratio H/Ga, 0.987, 0.998. The dimethylgallium amide resulting from the above reactions was separated and identified.

Dimethylgallium Amide.—Since dimethylgallium amide sublimes readily in a vacuum at 100°, this compound was separated from the residue by sublimation. The material was prepared in tube B of Fig. 2a. On completion of the reaction, the tube was exhausted, filled with nitrogen, and the stopcock was sealed off at C. A Y-tube of the form shown in Fig. 2b, provided with a fragile bulb at the bottom, was weighed and arm E was attached to the pump system by means of de Khotinsky cement. Tube D of the reaction tube was cut and quickly attached to tube F (Fig. 2b) by means of a rubber slip-joint. The tube was at once evacuated and a liquid ammonia bath was placed around the Y-tube and an air-bath, heated to 100°, around the reaction tube. Dimethylgallium amide collected in arm G of the Y-tube. When a sufficient quantity had collected, the tube was heated with a small flame to melt the amide which ran into a bulb H, which was then sealed off at J. The bulb and the Y-tube were then weighed. A number of bulbs were filled in this way for analysis.

Two samples were analyzed for nitrogen and gallium. The sample bulbs were broken in an evacuated tube containing potassium hydroxide. Dimethylgallium amide dissolves slowly in water, and it was necessary to heat to 60° to effect complete solution. The ammonia formed on hydrolysis was absorbed in standard acid and titrated back with standard alkali. The gallium in the residual solution was oxidized with hydrogen peroxide and precipitated with tannin in the presence of acetic acid. A third sample was oxidized completely with sulfuric and nitric acids.

Anal. Subs., 0.2070, 0.3510: cc. of 0.09367 N H_2SO_4, 19.14, 32.24. Found: N, 12.13, 12.13. Ga_2O_3, 0.1672, 0.2647. Found: Ga, 60.09, 60.34. Subs., 0.1435: Ga_2O_3, 0.1163. Found: Ga, 60.26; mean: N, 12.13, Ga, 60.23. Calcd. for $(CH_3)_2GaNH_2$: N, 12.10, Ga, 60.21.

B. With Two Equivalents of Sodium.—A single experiment was carried out in which dimethylgallium chloride was treated with two equivalents of sodium. The first equivalent of metal reacted immediately with the formation of dimethylgallium, which formed an orange colored solution. The second equivalent yielded the familiar blue solution. In the course of twenty hours, 0.37 of an equivalent of hydrogen was evolved. On adding an equivalent of ammonium bromide, 0.54 equivalent of hydrogen was evolved, and a deep brownish-red solution resulted. When the solvent was evaporated, a brown solid was deposited, which yielded one equivalent of hydrogen on warming to room temperature. The color of the solid changed from brown to gray. The data are: m. moles $(CH_3)_2GaCl\cdot NH_3$, 3.74; m. atoms H before adding NH_4Br, 1.38; after adding NH_4Br, 1.95; after evaporation of solvent and warming, 3.74; total H, 7.08.

The total hydrogen collected was a little less than two atoms per mole of compound, which may perhaps be accounted for by loss in transferring. The first stage of the reaction proceeds according to equation (6). The excess sodium then reacts slowly with ammonia, perhaps catalyzed by the gallium compound, to form sodium amide and hydrogen. The resulting sodium amide probably combines with gallium to form a coördinated compound. On adding ammonium bromide, the excess sodium reacts to yield hydrogen, while the sodium amide is neutralized, regenerating dimethylgallium. At room temperature, this compound decomposes with evolution of hydrogen according to equation (7).

IV. Summary

The reaction of trimethylgallium ammine with sodium in liquid ammonia is in accord with the equations

$$2(CH_3)_3Ga\cdot NH_3 + Na = [(CH_3)_3Ga]_2NH_2Na + {}^1/_2H_2 + NH_3$$
$$2(CH_3)_3Ga\cdot NH_3 + 2Na = [(CH_3)_3Ga]_2Na_2 + 2NH_3$$

Depending on conditions, reaction takes place according to the first equation to the extent of from 60 to 100% of the total gallium and according to the second, from 30 to 0%. A similar reaction takes place when trimethylgallium is treated with lithium in ethylamine, except that the first reaction is replaced by the following

$$(CH_3)_3Ga\cdot C_2H_5NH_2 + Li = (CH_3)_3Ga\cdot C_2H_5NHLi + {}^1/_2H_2$$

The compound $Na_2[(CH_3)_3Ga]_2$ reacts with ammonium bromide with evolution of one atom of hydrogen per atom of sodium and the regeneration of trimethylgallium. The corresponding salt of lithium decomposes with evolution of hydrogen as the ethylamine is evaporated, lithium trimethylgallium ethyl ammide being formed.

Dimethylgallium chloride is reduced to dimethylgallium when treated with one atomic equivalent of sodium in liquid ammonia. The free dimethylgallium combines with ammonia and may be obtained as a solid at −33°, where an internal oxidation–reduction takes place slowly according to the equation $(CH_3)_2Ga\cdot NH_3 = (CH_3)_2GaNH_2 + H_2$. At room temperature the reaction is rapid. The trimethylgallium amide resulting from this reaction has been identified.

When trimethylgallium chloride is treated with two atomic equivalents of sodium, dimethylgallium is first formed, which reacts slowly with sodium presumably according to the equation $(CH_3)_2Ga\cdot NH_3 + Na = (CH_3)_2Ga\cdot NaNH_2 + {}^1/_2H_2$. In this compound the amide ion is linked to gallium by a coördinate linkage. On neutralizing with ammonium bromide, dimethylgallium ammine is regenerated and this compound undergoes internal oxidation–reduction with evolution of hydrogen on evaporation of the solvent.

Observations upon the Ignition of Magnesium Ammonium Phosphate. VIII

BY SAMUEL J. KIEHL AND HENRY B. HARDT

There are two interesting phenomena associated with the ignition of magnesium ammonium phosphate which have been noted in the procedure for the quantitative determination of either phosphorus or magnesium. The one phenomenon is the flash which passes through the substance in the crucible during the process of ignition. The other is the dark instead of the white residue so often obtained after the ignition has been performed.

The statements in the literature as to the cause of the "flash" in the ignition of $MgNH_4PO_4$ differ widely. Possibly the one most commonly mentioned is exemplified by Karaoglanow and Dimitrow,[1] who claim that the flash is due to the presence of organic matter. They state that the flash never occurs if all organic matter is absent; they also state that incandescence will not occur if the salt is precipitated at boiling temperature, and will if precipitated at lower temperatures. They claim that the properties of $Mg_2P_2O_7$ depend upon occurrence of incandescence. Their "flashed" variety is hard, lava-like, gray to black in color, while the unflashed is amorphous, loose and quite white. Balareff[2] also obtained the two varieties but claims that moist $MgNH_4PO_4 \cdot 6H_2O$ always gives the white variety, while drying over phosphorus pentoxide for several weeks before igniting always gives black residues. He does not believe, therefore, that the gray color results from impurities, and obtains gray residues even when the precipitate has been filtered through asbestos. But in the same report he says that the gray salt examined with the microscope was seen to consist of white material containing black spots. Balareff[2] believes that the properties of the pyrophosphate obtained depend upon the degree of hydration before ignition. Popp[3] in 1870 stated that the flash was likely due to an intra-molecular change within the pyrophosphate molecule. He even accepted the theory that a change from the crystalline to the amorphous form might account for the luminescence. After reviewing and rejecting all foregoing explanations, Wöhler[4] in 1926 advanced the hypothesis that luminescence is due to a type of surface fusion or sintering. Gmelin[5] long ago believed the phenomenon to be a change from the amorphous to the crystalline form.

Since magnesium pyrophosphate is so important in quantitative analysis and in view of the many conflicting statements and opinions which have appeared in the literature, a study of some of the properties of $MgNH_4PO_4 \cdot 6H_2O$ based upon simple experiments would be highly desirable.

Preparation of Materials.—The preparation of all salts and materials used in this investigation has been described by us previously.[6]

Apparatus.—For determining the temperature of luminescence of the salts, the apparatus shown in Fig. 1 was used. F was a long-necked, round-bottomed 100-cc. Pyrex flask which served as an air-bath. B was a bulb about 15 millimeters inside diameter, on a Pyrex tube of about 7 millimeters inside diameter. The bulb held from 0.1 to 0.2 g. when about half filled. The junction of the platinum–platinum-rhodium thermocouple, T, was in the center of the sample. The thermocouple was connected to potentiometer K, previously described by us.[6]

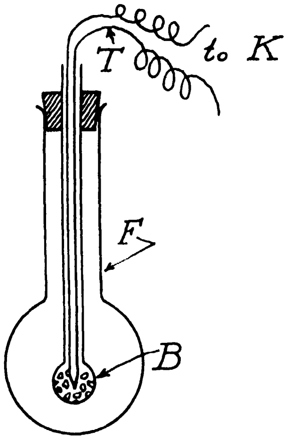

Fig. 1.

For heating the salts *in vacuo*, a thick-walled Pyrex tube 40 centimeters in length and 5 centimeters in diameter, with a ground-glass cap fitted with a stopcock, was employed. The lower third was placed in an electric furnace and the upper part was protected from the heat of the furnace by two tightly fitting asbestos sheets, so that when evacuated the lower part could be heated to above 450° while the upper end remained at room temperature. A platinum crucible containing the salt was lowered into the tube by means of a glass rod bent at the bottom into the form of a ring.

The ignitions were made in uncovered porcelain Gooch crucibles by means of either the Meker burner or an electric muffle furnace capable of maintaining a temperature of 1100°.

Experimental

TABLE I

LUMINESCENCE UPON IGNITION

	Salt	Relative intensity of flash	Temp. of flash, °C.	Nature of product
1	$MgNH_4PO_4 \cdot 6H_2O$ pptd. cold	Very strong	550–600	Snow-white, insoluble in water, volume less than half of original
2	$MgNH_4PO_4 \cdot 6H_2O$ pptd. at boiling temp.	Strong	600–615	Same as 1
3	$MgNH_4PO_4 \cdot H_2O$	Weak	600–625	Snow-white, sintered, insoluble, slightly less in vol. than original
4	$Mg_2P_2O_7$ by previously igniting $MgNH_4PO_4 \cdot 6H_2O$ at 480° in muffle	Very strong	550–600	Same as 1
5	$Mg_2P_2O_7$ by evacuating $MgNH_4PO_4 \cdot 6H_2O$ at 300°, 8 hrs.	Very strong	550–600	Same as 1
6	$MgHPO_4 \cdot 3H_2O$	Weak	550–650	Same as 3
7	$MgHPO_4 \cdot 7H_2O$	Weak	550–650	Same as 3

The $Mg_2P_2O_7$ in No. 5 above was prepared by evacuating a tube built for the purpose (described under "apparatus"), in which was placed a platinum crucible con-

---

(6) Kiehl and Hardt, THIS JOURNAL, 55, 605 (1933).

taining about 5 or 6 g. of the salt. The large samples could be successively weighed, evacuated, weighed, ignited and weighed. Thus one sample of 5.9736 g. after three hours of evacuation at 300°, weighed 2.7179 g. It was ignited to constant weight over a Meker burner. The weight was then 2.7073 g. A bright flash occurred during the process. The loss in weight during the ignition over the Meker was 4 parts per 1000, and the flash was only slightly, if at all, less intense than when $MgNH_4PO_4 \cdot 6H_2O$ is ordinarily ignited.

Consequently, experiments were performed with small samples to ascertain if the material could be changed stoichiometrically to pyrophosphate before the flash occurred. The following procedure was used and the results are recorded in Table II.

A stock solution was made by placing the carefully prepared crystals of $MgNH_4PO_4 \cdot 6H_2O$ in distilled water and dissolving them by adding dilute hydrochloric acid. The concentration was determined so that 45 cc. of the solution yielded approximately 0.15 g. of magnesium pyrophosphate. For the quantitative experiments, 45 cc. of this solution was measured by a buret into a 250-cc. beaker; 50 cc. of water and six drops of magnesia mixture were then added, and precipitation effected by the addition of very dilute ammonium hydroxide at 90–100° until alkaline. After eight hours or more the precipitate was transferred to the prepared Gooch crucible and dried in an oven at 110°. This preliminary procedure was followed in all analytical experiments. Seven different samples, after the above treatment, were weighed following each successive heating in a manner indicated by captions of Table II and then flashed and finally weighed.

TABLE II

THE EFFECT OF THE FLASH ON THE WEIGHT OF $Mg_2P_2O_7$

After heating one hour at 480°, g.	After 8 hours more at 480°, g.	After the flash, g.	After heating 1.5 hours at 925°, g.
0.1481	0.1480	0.1478	0.1478
.1476	.1473	.1471	.1473
.1478	.1480	.1478	.1479
.1480	.1481	.1478	.1479
.1482	.1482	.1480	.1480
.1474	.1474	.1474	.1473
.1479	.1479	.1478	.1478

The data in Table II indicate that conversion to the pyrophosphate was complete before the flash occurred.

Another interesting fact was learned in the flash. Our system rose in temperature at least fifty degrees during the change with samples of one-tenth of a gram. Heat was evolved. A substance of greater stability was without doubt formed. The substance also before the flash was quite soluble in acids while the final residue after the flash, as is commonly known, was difficultly soluble.

Moreover, when any of the hydrates of $MgNH_4PO_4$ or $MgHPO_4$ were converted to the pyrophosphate by heating below 500° and the residues examined with the microscope, it was found that the shapes of the original crystals had been retained. They were, however, always opaque. During the flash this shape disappeared entirely. But it was suspected, however, that the opaque crystal-shaped particles were amorphous because they were opaque and that since a large amount of energy was liberated in the transformation, the final amorphous-looking material might be crystalline.

In attempting to answer the questions thus raised, x-ray diffraction pattern photographs of samples of the salts in question were made. These photographs show in Fig. 2 very definite crystal patterns for 1, $MgNH_4PO_4 \cdot 6H_2O$; 2, $MgNH_4PO_4 \cdot H_2O$; and 4, the residue ($Mg_2P_2O_7$) after the flash from either $MgNH_4PO_4 \cdot 6H_2O$ or $MgNH_4PO_4 \cdot H_2O$. But 3, the unflashed pyrophosphate from either $MgNH_4PO_4 \cdot 6H_2O$ or $MgNH_4PO_4 \cdot H_2O$, shows no pattern and is therefore not crystalline. Samples of $Mg_2P_2O_7$ fused in an oxy-gas flame or heated in a muffle at 1000° for ten hours gave patterns identical with 4. The form thus obtained is no doubt the stable form.

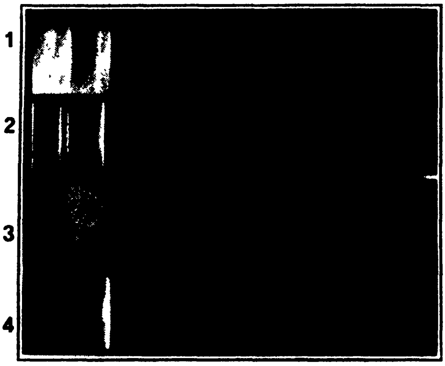

Fig. 2.

The Dark Residue.—$MgNH_4PO_4 \cdot 6H_2O$ possesses the very striking and interesting property of attaching firmly certain types of organic compounds while it is losing water of hydration and ammonia. When $MgNH_4PO_4 \cdot 6H_2O$ was heated in an open platinum crucible without contact with organic materials, it invariably gave a white residue, but in an atmosphere of certain gaseous organic compounds a black residue always resulted. Stearic acid wetting the end of a stirring rod which was held in the crucible above the salt—not touching it—while it was gently heated produced a black residue. Glycerin and paraffin treated similarly gave the black residue. A bit of filter paper placed upon the bottom of the platinum crucible with the salt on the other side out of contact produced gaseous products when it was gently heated and caused the formation of a black residue. A gentle stream of unignited commercial gas used as fuel in our laboratory—an ordinary commercial water gas enriched with illuminants—was directed upon the salt during the gentle heating. A black residue was left. In preparing the furnace for a long period of service at 250°, a clean strip of asbestos paper was placed in the bottom. The salt upon a clean watch glass which was covered with a larger one held by glass supports was placed in the furnace set for 250°. After one hour the salt was a dirty brown from the vapors given off, probably by the binder used in the asbestos paper. This material even after heating at 250° for days and final ignition over the Meker burner could not be freed from this coloration. A strip of the same asbestos paper 6.3 mm. wide and 5.1 cm. long placed across the top of the uncovered crucible invariably caused a brown-black residue to be formed when it was gently heated. The following liquids left the residue white when employed as above: benzene, carbon tetrachloride and chloroform. None of the following gases produced a coloration of the residue: hydrogen, acetylene, carbon dioxide, carbon monoxide, or air. On the other hand, the same treatment was applied to the magnesium ammonium phosphate monohydrate and the residue was white or under the severest test but a very light gray. When the $MgNH_4PO_4 \cdot 6H_2O$ was boiled with absolute alcohol, five molecules of alcohol substituted for five molecules of water. Ether also will displace some of the water.

It seems therefore that the hexahydrate during the process of losing water of hydration possesses an extraordinary capacity for firmly attaching certain types of carbon compounds, which decompose upon heating to higher temperatures and leave graphitic carbon.

Discussion

The x-ray photographs furnish the evidence that the two original salts are crystalline substances, that the unflashed but converted pyrophosphate from both sources is amorphous, and that the flashed pyrophosphates from both sources are identical in crystalline form.

The flash is therefore caused by the sudden heating of the material to incandescence when the energy is released upon crystallization of an amorphous substance. J. Böhm[7] has reported a similar behavior for other substances. The melting point of the substance, 1383°, together with its optical properties have been reported by Olaf Anderson.[8]

An amorphous substance is a supercooled liquid and is metastable. It should, upon crystallization, liberate energy. It should be more soluble. That the crystallization should occur rapidly between 500 and 650° for these substances is not strange. The melting point is 1383°, and below this the velocity of transition would gradually increase and reach a maximum which might be somewhere between 500 and 650°, then recede as is the case with many other substances. In this case a very rapid evolution of heat raises the temperature of the substance to incandescence. In fact, by holding the materials for a considerable time at a little over 500°, the crystalline form has been prepared from the amorphous less quickly and without the flash.

The dark colored residue from our experiments is caused by the adsorption of gaseous carbon compounds such as would result from the destructive distillation of cellulose. With carefully purified materials and in an atmosphere free from such compounds, a snow-white residue results. With gentle ignition of the hexahydrate in an atmosphere charged with gaseous products from charring filter paper, stearic acid, glycerin and some other substances, the black residue forms.

(7) Böhm, *Z. anorg. allgem. Chem.*, **149**, 217 (1925).

(8) Olaf Anderson, *J. Wash. Acad. Sci.*, **4**, 318 (1914).

The monohydrate does not possess this property to any degree comparable to the hexahydrate. But very light gray colored residues were produced under circumstances which produced the black residues with the hexahydrate.

It seems reasonable, therefore, that a substitution of these gaseous carbon compounds might be made for the water in the structure of complex hexahydrate. Higher temperatures would cause the firmly bound carbon compound to decompose and leave graphitic carbon which, upon further ignition, is extremely difficult to oxidize.

The authors wish to acknowledge their indebtedness to Professor Paul F. Kerr of the Department of Geology, Columbia University, for the x-ray work which appears in this paper.

Summary

1. The luminescence or flash during the ignition of magnesium ammonium phosphate hexahydrate and of magnesium ammonium phosphate monohydrate is due to the rise of temperature caused by the large quantity of heat liberated when the amorphous form of $Mg_2P_2O_7$ crystallizes.

2. The magnesium ammonium phosphate hexahydrate during the process of losing water of hydration in the early stages of ignition possesses the property of attaching firmly within its complex structure certain gaseous organic compounds, if present, which later break down and leave graphitic carbon.

The Sorption of Organic Vapors by Resinous and Cellulosic Materials

BY CLARENCE H. WINNING AND JOHN WARREN WILLIAMS

The objects of a recent sorption balance study of the behavior of glyceryl phthalate resins in the presence of acetone and methyl alcohol vapors were stated to be five-fold: (1) to determine the form of the sorption isotherms at several temperatures and to interpret the curves in terms of the porous structure of the resin; (2) to determine the heat of the sorption processes by the comparison of two isotherms; (3) to make an estimate of the average pore size from the sorption behavior in the neighborhood of saturation; (4) to study the changes in structure produced by variations in the curing process to which the resin has been subjected; (5) to study the reversibility of the sorption process. The results of this study[1] were so interesting that it was decided to extend the work to other artificial resins, to several natural resins and to certain derivatives of cellulose, using the vapors of ethyl ether and chloroform as sorbate molecules.

---

[1] Winning and Williams, *J. Phys. Chem.*, **36**, 2915 (1932).

The apparatus used was a McBain–Bakr balance, adapted to the sorption of vapors by powdered resin samples. It is completely described in the earlier article. Except for insignificant details the experimental procedure used was the same as that already described. Its particular advantage lies in the fact that it permits a continuous and complete sorption and desorption experiment to be made without disturbing the sorbent in any way, both with respect to the equilibria attained at the several partial pressures and to the rate at which these equilibrium values are approached. At the same time any effects of a true hysteresis will probably be recognized as readily by this method as by any other of procedure. The time allowed for the attainment of equilibrium was extended in certain cases to two full days; in the majority of cases, however, less time was required.

Experimental

Materials Used.—The glyptal resin spoken of in this article was prepared from glycerin and phthalic anhydride according to directions previously given. It was not "cured," and would therefore correspond to what has been called Resin I in the earlier article.

Phenolphthalein benzoate resin was prepared following the directions recently given by Zelinsky and Maksorow.[2]

A method of Lilienfeld[3] was used in the preparation of the benzyl cellulose. The material was heated in an evacuated tube for two days at 160° to remove absorbed liquid.

The cellulose acetate material was prepared by an acetylation process which results in a complete solution of the product.

As samples of natural products resins described as Pontianic Borneo and Congo fossil were used.

The organic liquids used, chloroform and ether, were subjected to rigorous purifications before being sealed into the sorption chambers.

Discussion

The Sorption and Desorption Processes.—High molecular weight substances of the type considered in this article are frequently assumed to have practically no permanent interspaces within the structural framework. They should then take up vapors by processes other than condensation unless these adsorption processes result in a partial resolution into the constituent molecules. The sorption curves for acetone and methyl alcohol on glyptal could be divided into three parts. In the first of these regions the highly polar sorbate molecules were able gradually to overcome strong cohesive forces, thereby penetrating the structure. Once the sorbate molecules have penetrated the structure the equilibrium value for the amount adsorbed is attained more readily and the isotherm becomes parallel to the pressure axis, indicating the completion of a process which we have assumed to be the filming of the structural units. As the partial pressure of the sorbate is further increased, a limited swelling takes place and the capillary spaces formed become filled with condensed liquid. Thus the process of adsorption is followed by one of condensation within the pores which have been opened up.

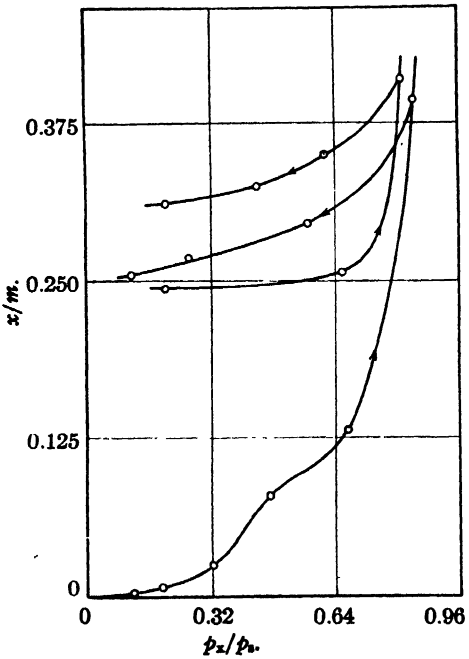

Fig. 1.—Glyptal-chloroform, 35 and 50° isotherms.

In the extension of the work to other sorbents and to other sorbate materials it was found that no two of the systems behaved exactly alike, yet in certain cases marked similarities in sorption and desorption curves were evident. A sample of "uncured" glyptal resin was found to take up chloroform vapor less readily than either acetone or methyl alcohol at the lower vapor pressures, but the three sorption regions described above are again recognizable in the 50° isotherm (Table I, Fig. 1). The adsorption process is an exceedingly slow one. This is probably to be accounted for on the basis of a closely knit structure which makes the inner surface areas difficultly accessible to the vapors of a larger molecule like chloroform, for it is believed that our experimental conditions preclude the necessity of a displacement of strongly adsorbed gases from the surfaces. The desorption process is irreversible to a marked extent, even far into the so-called condensation region. It is difficult to account for the tenacity with which the chloroform vapors are held, especially in the region where large amounts of vapor have been taken up and the uncured glyptal has assumed the appearance of a semi-fluid mass. A restrained diffusion would seem to furnish the most likely explanation, in which case experiments over much greater periods of time would undoubtedly improve the situation.

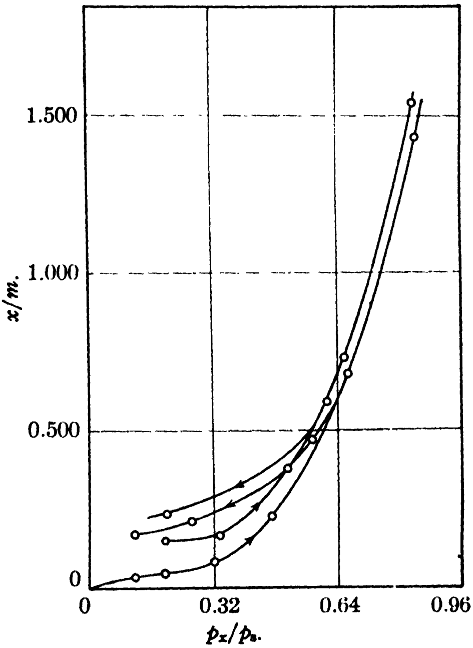

Fig. 2.—Phenolphthalein benzoate-chloroform, 35 and 50° isotherms.

The phenolphthalein benzoate resin, one of a series of phenolphthalein resins prepared by Zelinsky and Maksorow, was chosen as typical of a substance believed to have properties intermediate between the amorphous resins and those materials which are characterized by some regularity in structure. It takes up chloroform vapor in a normal way (Table I, Fig. 2), the sorption isotherm having the typical "S" shape which is so characteristic of a swelling gel. After completion of the 50° isotherm the same sample was used for experiments at 35°. It will be observed that at this temperature the sample did not begin to increase in weight until a partial pressure of 0.3 was reached.

The chloroform sorption and desorption data for the benzyl cellulose resin (Table I, Fig. 3) are interesting because of their resemblance to those which are presented for cellulose acetate using chloroform as sorbate (Table I, Fig. 4), and to those which have already been considered in the earlier article where acetone and methyl alcohol vapors were taken up by this ester. In all these cases closed sorption and desorption cycles are established. However, the hysteresis is much less marked with benzyl cellulose and it is possible to construct an equilibrium curve by interpolation, from which certain thermodynamical calculations seem justified. In this way information with regard to the sorption process in the region of the higher partial pressures for substances of cellulosic nature may be obtained. It should also be pointed out that the benzyl cellulose is much more readily disintegrated by chloroform vapors than is cellulose acetate. In this respect the ether is similar to an uncured glyptal. It is generally true that the sorption and desorption processes approach apparent equilibrium at a more rapid rate in the case of the cellulosic materials studied than is the case with the resins.

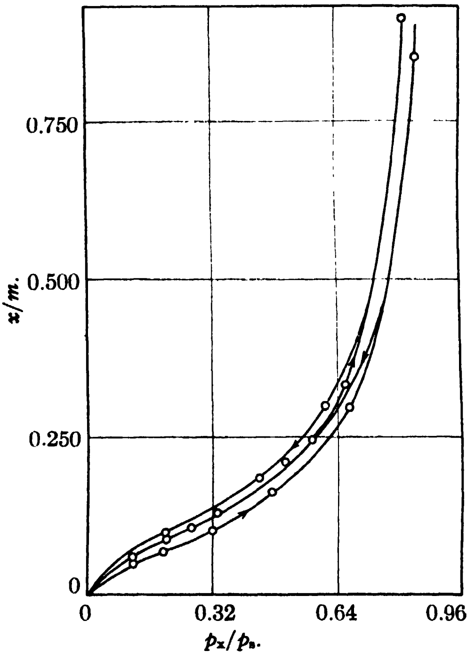

Fig. 3.—Benzyl cellulose–chloroform, 35 and 50° isotherms.

The sorption of ether vapor by the natural resins (Table II, Fig. 5) closely resembles that of acetone by cured glyptal resins. This resemblance suggests a similarity in structure. These natural resins are fossilized or aged to different degrees. The more mature resin (Pontianic Borneo) offers the greater resistance to the penetration of the vapors in the region of low partial pressures, presumably because of a more compact structure. The sorption and desorption processes are completely reversible in the higher partial pressure areas.

Irreversibility of the Sorption.—In no system investigated did we find the sorption and desorption processes to be completely reversible. In certain cases they approached reversibility when the partial pressures corresponded to the "capillary condensation" region. But if one subjects a sample of uncured glyptal resin to the action of chloroform vapor, the sorption and desorption processes are not at all reversible, even in the region of extremely high partial pressures. This will be evident from an inspection of Fig. 1. The 35° isotherm was determined using the same sample that had been used previously at 50°. Reduction in partial pressure for a period of several days did not serve to lower the vapor content to any appreciable extent.

On the basis of the hysteresis behavior, the substances studied may be divided into two classes, those which give a closed hysteresis cycle and those which apparently do not return to their original condition no matter how rigorous the evacuation treatment. Of the substances investigated, glyptal, phenolphthalein benzoate, and the natural resins did not return to their original weight. In agreement with Urquhart,[4] with Sheppard and Newsome[5] and with others who have studied the sorption of water vapor by cellulose derivatives, these materials were found to complete a cycle upon desorption whether acetone, methyl alcohol, or chloroform vapors were used in the experiments. The hysteresis cannot be entirely accounted for on the basis of the theory of the curvature of the liquid meniscus in the capillary spaces,[6] nor does its explanation on the basis of an interference of air or water with the wetting and filling of the pores seem satisfactory. It must be bound up in some way with the interaction between the active parts of the surface of the structural units and the molecules approaching these surfaces.

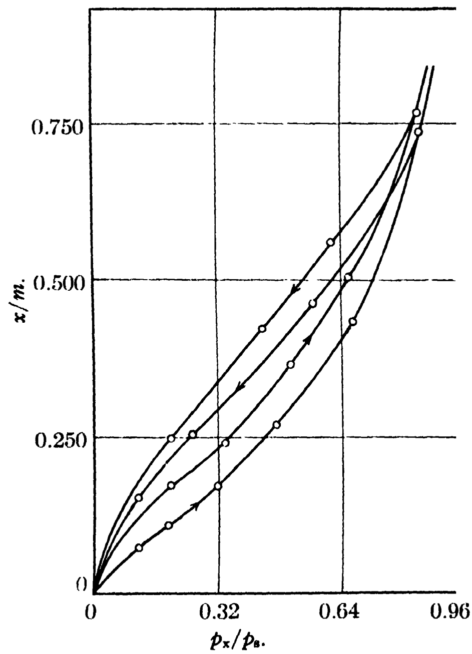

Fig. 4.—Cellulose acetate–chloroform, 35 and 50° isotherms.

The difference between the closed cycle type of hysteresis (cellulose derivatives) and that in which the desorption process fails to reduce the amount of vapor adsorbed to extremely small quantities at the very low partial pressures seems to be a real one, probably to be explained in terms of a difference in the forces which bind the liquid to the solid. Thus, while it was not considered safe to resort to an interpolation process to locate equilibrium curves for thermodynamic calculations in the case of the cellulose acetate, such a treatment has proved quite satisfactory in the

case of the glyptal,[1] phenolphthalein benzoate and natural resins. The data for the benzyl cellulose sorption could be treated in this manner only because the area of the hysteresis cycle was small. Such a procedure is not without real experimental justification in the case of the resins because desorption experiments carried out over very greatly extended periods of time decrease the observed hysteresis to a certain extent. This is clearly indicated by the arrow in Fig. 3 of the earlier article. Usually the hysteresis area does not extend far into the region of capillary condensation; furthermore, it is greatest at the infinitely small vapor pressures.

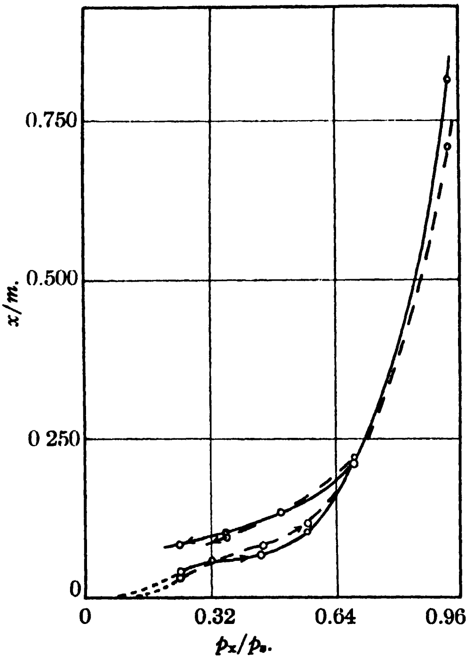

Fig. 5.—Ether vapor, 35° isotherms: Congo fossil———; Pontianic Borneo— — —.

A tentative explanation for the difference in the two kinds of hysteresis may be suggested if it can be assumed that the build of a gel material of the type considered in this article is predetermined by molecular orientations in the solution form. In general it seems safe to consider that elongated and regularly shaped units in the sol form may lead to the formation of an orderly and sensibly reproducible structural arrangement in the gel form, while odd-shaped molecules may be expected to give rise to accidental packings as the gel is again formed. The swelling of a gel may be explained by saying that either the forces holding the micelles together to form the massive material, or the forces causing the aggregation of molecules (or both, as the case may be), are overcome as the sorbate is able to penetrate more and more deeply. The sorption process is described as one in which first the structural units (molecules) are filmed, and then a condensation takes place in the voids or capillaries formed by the continued penetration of the sorbate. There is, therefore, a definite tendency toward a solution process. As the sorbate is removed from a system the reassociation of molecules may be such as to permit its eventual complete removal if the arrangement is a regular, and, as it was in the cases investigated by us, a less closely knit one; or it may be such as to effectively block and trap relatively large amounts of the sorbate due to random arrangements of molecules which may have different sizes as well as irregular shapes. Also, it is a recognized fact that in the study of the energetics of the sorption processes the distances between adsorbing surfaces and sorbate molecules are of fundamental significance in determining the relative importance of the adhesive and cohesive forces which result. A regular arrangement would seem to favor cohesion between adsorbing surfaces while in a random arrangement the adhesive forces could not be so completely overcome because the distance between adsorptive surfaces would always be variable, thus preventing practical return to the vapor-free or original state. Experiments designed to test this suggestion are now being made.

Thermodynamics of the Sorption Process.—Another of the methods by which there may be made available information with regard to the sorption processes at the solid–vapor interface is a study of the heats of the sorption. Provided the assumption can be made that the available solid surface remains constant in area during the adsorption, the affinity of such a surface which already contains the amount x of adsorbed vapor for the molecules of the vapor is

$$-\Delta F = RT \ln (p_s/p_x)$$

The total heat of wetting, $-\Delta H$, may therefore be determined using the Gibbs–Helmholtz equation

$$\Delta H = \Delta F - T(\partial \Delta F/\partial T)_x$$

Performing the operation indicated and integrating

$$-\Delta H = \frac{2.3\ RT_1T_2}{T_2 - T_1}\left(\log\frac{p_{x2}}{p_{x1}} - \log\frac{p_{s2}}{p_{s1}}\right)_x = -\Delta H_1 + \Delta H_2$$

The first term on the right side of this equation is the differential heat of adsorption and the second term, which is independent of the amount adsorbed, is the heat of vaporization of the liquid being condensed in the capillaries.

At low values of partial pressure the magnitudes of $-\Delta H$, and therefore of the differential heats of adsorption, may be very high. Our data are sufficient to show that as the amount of vapor adsorbed becomes greater $-\Delta H$ approaches zero because the value for the differential heat of adsorption approaches that of the latent heat of vaporization of the liquid being taken up by the solid material. This is shown by the data which have been collected to form Table III. The latent heat of vaporization for chloroform at its boiling point is 58.8 calories per gram.[7] The value calculated to 42.5° will be slightly more than 3 calories larger, or approximately 62 calories. The last column of both parts of Table III indicates a differential heat of adsorption which is only slightly larger than this value, suggesting that after the adsorption on the surface of the structural units of the materials has been completed the gel structure is opened up by a limited swelling and a condensation of the vapor takes place in the capillaries formed in this manner.[8] These data may therefore be considered to

indicate the importance of the process of condensation to liquid in the region of higher partial pressures.

Summary

1. A balance of the McBain–Bakr type has been used to study the sorption of chloroform vapor by samples of glyptal, phenolphthalein benzoate, benzyl cellulose and cellulose acetate maintained at 35 and 50°. The sorption of ether vapor by samples of two natural resins maintained at 35° has also been investigated.

2. The sorbent materials may be characterized as typical swelling gels. As vapors continue to be taken up by them, the first process of surface adsorption is followed by a physical process of condensation of sorbate in capillary spaces or voids. These capillaries have been opened up after the structural units, probably molecules, have been completely filmed.

3. The hysteresis behavior of the resinous materials is different from that of the two cellulose derivates. An attempt is made to account for this difference on the basis of structural considerations. Regular

[a] These tables contain data which are entirely analogous to those of Table V of the previous article [Winning and Williams, *J. Phys. Chem.*, **36**, 2915 (1932)]. The data of the last column of this Table V are values calculated per gram of sorbent; therefore the word "mol" was inadvertently inserted.

arrangement in build is believed to favor practically complete removal of sorbed vapors at extremely low partial pressures while random arrangement may lead to conditions which result in retention.

4. The heats of the several sorption processes have been calculated from the free energy changes, and their temperature coefficients.

The Potential of the Silver-Silver Iodate Electrode at 25°

BY J. N. PEARCE AND VERDA I. WIRTH

Any slightly soluble salt of a metal may form, potentially, a good electrode, provided the electrode is perfectly reversible and the metallic salt is stable in solution. The present paper gives briefly the results obtained from a study of the silver-silver iodate electrode.

Materials and Apparatus.—The silver crystals used in the preparation of the electrodes were formed by the electrolysis of a hot, concentrated solution of pure silver nitrate, using a platinum wire cathode and a pure silver anode, surrounded by a porous cup. A current of five to ten amperes gave uniform, well-defined crystals which were free from amorphous silver.

Silver iodate was prepared by adding a dilute solution of pure silver nitrate slowly and with rapid stirring to a large volume of a dilute solution of potassium iodate. The precipitate was washed free from excess salts and dissolved in a pure concentrated solution of ammonium hydroxide. The ammonia was allowed to evaporate spontaneously, leaving the iodate in the form of fine white crystals.[1] These were washed thoroughly and stored under conductivity water until used.

All other chemicals were carefully purified by approved methods. All solutions were made on the weight molal basis in conductivity water.

The experimental data recorded in the following tables are the mean potential values obtained from three to five cells, each containing three to five individual electrodes. While the calomel electrodes attained equilibrium quickly, the iodate electrodes required four or five days. The deviations of the potentials of the different electrodes in any single iodate half-cell did not exceed 0.05 mv., and the mean deviation of duplicate half-cells containing potassium iodate did not in any case exceed 0.2 mv.

The determination of the potentials of the iodate electrodes involved the measurement of electromotive forces of cells, with ion transference, of the type: Hg, Hg_2Cl_2, KCl (0.1 m), KIO_3 (0.1 m), $AgIO_3$, Ag. The half-cells were connected by a modified form of the Lamb and Larson[2] flowing junction device. The liquid junction potentials were calculated by means of the relation used by Lewis and Sargent,[3] namely

$$E_l = RT/nF \ln \lambda_1/\lambda_2$$

where λ_1 and λ_2 are the equivalent conductances of the chloride and iodate solutions at the same concentrations, respectively. This potential must be added to the potential of the cell with ion transference, E_t, to give the potential of the cell, E, without ion transference. Since data on the conductance of potassium iodate solutions[4] at 18° only are available, we have made the assumption that the ratio of the equivalent conductances of the two salt solutions is the same at 25° as at 18°. The validity of this assumption was affirmed by comparing the ratios of the conductances of potassium chloride solutions with those of potassium chlorate and bromate at the same two temperatures. The potential data thus obtained are collected in Table I. The solutions in all cells were under an atmosphere of pure nitrogen.

TABLE I

THE ELECTROMOTIVE FORCES OF CALOMEL-IODATE CELLS AT 25 ± 0.02°

m	0.20	0.10	0.05	0.01
E_t, volt	.0850	.0833	.0825	.0810
E_l, volt	.0096	.0087	.0082	.0075
E_{298}, volt	.0946	.0920	.0907	.0885

To calculate the potentials of the iodate electrodes in the given potassium iodate solutions it is only necessary to add the potentials of the calomel electrodes in the same concentrations of potassium chloride. The latter were calculated by means of the equation: $E = E^\circ - 0.05915 \log a_{Cl^-}$, using for the potential of the electrode, Hg, Hg_2Cl_2, $Cl^-(a = 1)$, $E^\circ = 0.2676$ volt,[5] and the activity coefficients as obtained by Harned[6] for potassium chloride. The potentials of the calomel electrodes thus calculated are given in Table II. By adding these potentials to the total potentials, E_{298}, of the calomel-iodate cells, Table I, we obtain directly the potentials of the electrode: Ag,$AgIO_3$,$KIO_3(m)$, in the various concentrations of potassium iodate. These electrode potentials are given in the fifth column of Table II.

TABLE II

THE POTENTIALS OF THE CALOMEL AND SILVER IODATE ELECTRODES AT 25°

m	γ[6] KCl	γ[3] KIO_3	E_{298} Calomel	E_{298} Iodate	E°_{298} Iodate
0.20	0.712	...	0.3178	0.4124	...
.10	.764	0.692	.3336	.4256	0.3571
.05	.815	.765	.3498	.4405	.3567
.01	.899	.882	.3886	.4771	.3552

Two methods are available for calculating E° for the silver-silver iodate electrode. The potential E° is given by the equation

$$E = E^\circ - 0.05915 \log a_{IO_3^-} \quad (1)$$

---

[4] "International Critical Tables," 1929, Vol. VI, pp. 234 and 252.

[5] *Ibid.*, 1929, Vol. VI, p. 332.

[6] Harned, THIS JOURNAL, 51, 416 (1929).

Subtracting 0.05915 log $m_{IO_3^-}$ from both sides of (1), we obtain a modified form of a relation employed by Lewis and Randall[7]

$$0.05915 \log (a/m)_{IO_3^-} = E^\circ - (E + 0.05915 \log m_{IO_3^-})$$

The log a/m is equal to zero at infinite dilution and hence $E^\circ = (E + 0.05915 \log m_{IO_3^-})$. If we plot the quantity in parentheses against the square root of the molality, the intercept on the ordinate at $m = 0$ is equal to E°.

Since extrapolation is precarious in any case, and because of possible errors in determining the potential of the most dilute solution, which was the most difficult to obtain, we have calculated the potential, E°_{298}, by (1), using accepted values[8] for the activity coefficients of potassium iodate. The values of E°, which should be the same at all concentrations, are given in the last column of Table II. It is evident that the potential of the 0.01 m electrode is too low. Omitting this, we take as the most probable value of the potential of the Ag, $AgIO_3$, IO_3^-, (a = 1) electrode, $E^\circ_{298} = 0.3569$ volt.

Summary

The electromotive forces of a series of cells of the type: Hg,Hg_2Cl_2,KCl-(m),KIO_3,$AgIO_3$,Ag, have been measured at 25°. By combining these values with the potentials of the corresponding calomel electrodes, the potential of the Ag,$AgIO_3$,IO^- ($a = 1$) electrode is found to be, $E^\circ_{298} = 0.3569$ volt.

The Optical Properties of the Double Salt $(NH_4)_2SO_4 \cdot CaSO_4 \cdot 2H_2O$

BY ALBERT R. MERZ, JOHN O. HARDESTY AND STERLING B. HENDRICKS

During the course of an investigation of the hygroscopicities of mixtures of fertilizer salts not having common ions,[1] one of the solid phases obtained in the systems, $NH_4^+Ca^{++}NO_3^-SO_4^=$ and $NH_4^+Ca^{++}H_2PO_4^-SO_4^=$, was found to be a double salt of calcium and ammonium sulfates. Three double salts, in which the ratios of ammonium sulfate to calcium sulfate are 1:1, 1:2 and 1:5, respectively, have been reported in the literature. The double salt with the ratio 1:2 does not exist below 75°[2] and, as the vapor pressure measurements were carried out at 30°, it therefore remained to identify the salt as one of the other two compounds. Since the double salt with the ratio, 1:5, cannot exist, in the system $NH_4^+Ca^{++}SO_4^=$, in contact with solid ammonium sulfate,[2] gypsum was added to a saturated solution of ammonium sulfate which was then evaporated until considerable ammonium sulfate had crystallized and finally allowed to stand for several days. Microscopic examination of the solid phases disclosed both am-

(1) A. R. Merz, W. H. Fry, J. O. Hardesty and J. R. Adams, *Ind. Eng. Chem.*, **25**, 136 (1933).

(2) J. D'Ans and O. Schreiner, *Z. anorg. Chem.*, **62**, 141 (1909).

monium sulfate and the same double salt as was found present during the vapor pressure determinations, thus indicating that the double salt in question had the 1:1 ratio.

D'Ans and Schreiner[2] state that the double salt of ammonium and calcium sulfate having the 1:1 ratio is an ammonium syngenite, analogous in composition to syngenite, and forms in a saturated ammonium sulfate solution according to the reaction $(NH_4)_2SO_4 + CaSO_4{\cdot}2H_2O = (NH_4)_2SO_4{\cdot}CaSO_4{\cdot}H_2O + H_2O$. Bell and Taber,[3] however, claim that the compound contains two molecules of water of crystallization and should be given the formula $(NH_4)_2SO_4{\cdot}CaSO_4{\cdot}2H_2O$. Since the optical properties and density of this salt appear not to have been reported, it was considered desirable to determine them, especially as the information thus gained would aid in settling the question as to its composition.

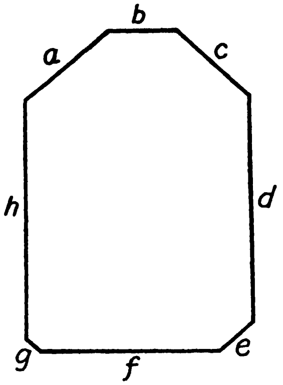

Fig. 1b.

Fig. 1a.

To obtain the double salt as the sole phase in contact with the liquid phase, 251 g. of ammonium sulfate, 36.65 g. of gypsum and 1500 cc. of water were evaporated at 30° over a period of eight days to a volume of 500 cc. to give a point in the field of the 1:1 salt.[4] Microscopic examination showed the solid phase to consist only of crystals identical with those of the double salt previously obtained. Since washing the salt with water quickly decomposes it, leaving gypsum as a residue, and washing with alcohol–water and alcohol–ether, as carried out by D'Ans,[5] has been shown by Bell and Taber to result in decomposition also, the method of residues was used for the chemical determination of the composition. The material used for the optical work was obtained separately by suction filtration and air drying.

Analysis of the mother liquors gave water 63.99%, ammonium sulfate 35.69% and calcium sulfate 0.32%; of the moist crystals, water 32.82%, ammonium sulfate 40.39% and calcium sulfate 26.79%, whence by calculation or graphically, using triangular coördinates, the dry double salt contains 11.47% water of crystallization. This corresponds to the theoretical value, 11.84%.

(4) "International Critical Tables," McGraw-Hill Book Co., Inc., New York, 1928, Vol. IV, p. 388.

(5) J. D'ans, *Ber.*, **39**, 3326 (1906).

Optical Properties.—The common crystal habit is that shown in Fig. 1a. A centered acute bisectrix interference figure was obtained from some flat needles of this type. The direction of vibration of the slowest ray, γ, is parallel to the elongation. A very few crystals of the type shown in Fig. 1b were observed in wet samples. The angles ah, cd, and de are equal as measured under the microscope. The crystal section was apparently perpendicular to the optic normal.

The indices of refraction ascertained by the immersion method are N_D: $\alpha = 1.522$; $\beta = 1.527$; $\gamma = 1.529$. The crystals are optically negative.

The density, measured by the centrifugal suspension method, is 2.07. Greater accuracy was impossible owing to the minuteness of the dried crystals.

It is interesting to compare the optical properties of this compound with those of ammonium sulfate and gypsum.[6]

	$(NH_4)_2SO_4$ mascagnite	$CaSO_4{\cdot}2H_2O$ gypsum		$(NH_4)_2SO_4{\cdot}CaSO_4{\cdot}2H_2O$
α	1.521	1.5195	1.5208	1.522
β	1.523	1.5216	1.5230	1.527
γ	1.533	1.5283	1.5305	1.529
d_{20}	1.7681[7]	2.32[8]		2.07
Crystal system	Orthorhombic	Monoclinic		Orthorhombic?
Mol. vol.	74.74 cc.	74.2 cc.		147 cc.
Mol. refractivity (calcd. by Lorenz–Lorentz formula)	22.89	22.67	22.85	45.12

The value of the molecular refractivity of $(NH_4)_2SO_4{\cdot}CaSO_4{\cdot}2H_2O$ is, within the limit of error, equal to the sum of the values for $CaSO_4{\cdot}2H_2O$ and $(NH_4)_2SO_4$. This is likewise true for the molecular volumes. These facts further confirm the composition of the hydrated double salt as being $(NH_4)_2SO_4{\cdot}CaSO_4{\cdot}2H_2O$.

The Character of the Absorption of Some Amines in the Near Infra-red[1]

BY URNER LIDDEL AND OLIVER R. WULF

Observations in the infra-red on the spectra associated with the CH, NH, OH and SH groups in aliphatic and aromatic organic molecules[2] have shown that such investigations constitute a fruitful approach to a study of differentiating characteristics of these molecules. At the suggestion of Dr. F. G. Cottrell, the authors have undertaken an investigation of a considerable number of aromatic and aliphatic amines for the purpose of correlating characteristic differences in their spectra, in so far as possible, with the known chemical properties of these molecules.[3] In view of the importance attached by organic chemists to the electrical characteristics of portions of molecules in connection with their chemical properties, we were early convinced that the usefulness of such a study would be greatly increased by a quantitative determination of some physical property characteristic of the radical or group being studied and it was decided to measure the absorption coefficient in the region of characteristic N–H absorption.[4] A beginning has now been made on this, and we are communicating in this paper the first results of a study of a number of amines in carbon tetrachloride solution working with the absorption lying in the vicinity of 1.50μ which is due to the N–H portion of the molecule.[5]

Experimental

The infra-red glass spectrograph used throughout this present work has been described by Brackett and Liddel.[6] The excellent operating characteristics of this instrument have contributed greatly to the present work. Illustrative records for solutions of aniline and phenol in carbon tetrachloride under the conditions of slit width used in the present work are shown in Fig. 1, these being records of galvanometer deflections with wave length, and except in the positions of characteristic absorption of the compounds and the water vapor in the light path, they are records in arbitrary units, of the radiation from the tungsten lamp source modified by the transmission of the optical parts of the instrument. Certain characteristic absorptions are indicated. Determination of the absorption coefficients was carried out by recording at appropriate intervals on the experimental plate segments of both the base line of no galvanometer deflection (shutter introduced corresponding to complete opacity), and of the intensity of the lamp source by way of a second optical system carrying the light to the slit around the absorption cell rather than through it. Before and after each experimental plate a complete record was taken under the same conditions except that the cell contained pure carbon tetrachloride instead of the solution of the amine being studied. From the average of these two records it was possible to determine the curve of the galvanometer trace on the solution plate as it would have been had not the solute been present in the solution and to the same scale as this solution plate, even in the event of appreciable zero drift in the galvanometer reading and of changes in the lamp intensity with time, by using these traces of the base line and of the lamp intensity by way of the constant auxiliary light path, which are contained on all records. Thus one has a measure of the intensity of the radiation after passing through the solution and after passing through the same cell containing carbon tetrachloride but without the solute, hence the transmission of the solute. Since the concentration of the solution is known, the transmission for a definite number of molecules in the light path is known, and hence the absorption coefficient over the region of the spectrum covered may be calculated.

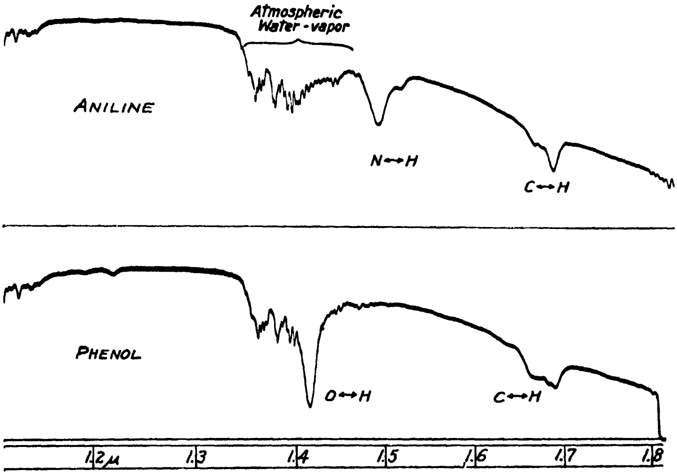

Fig. 1.—Illustrative records of aniline and phenol with characteristic absorptions indicated.

A small correction to the observed deflections was necessary owing to the presence of a certain amount of scattered light in the spectrograph. The determination of this correction was accomplished in the following manner. A measurement was made of the transmission of a certain concentration of aniline which reduced the intensity at the peak of the N–H absorption to roughly 70%. This value, which is a little in error owing to stray light, was used to compute a path length at the same concentration which would reduce the intensity at this same wave length to a fraction of 1% and the apparent intensity was then noted using this absorption. It showed a value of nearly 5%. This difference was taken as the fraction of the total deflection at this wave length that was due to scattered light, after applying a small additional correction. In the observation using the highly absorbing path of aniline, the stray light itself was somewhat reduced owing to the reduction of the total radiation entering the spectrograph. This latter was estimated as roughly 7% from the records themselves. In the case of the weakly absorbing paths ordinarily worked with, then, the stray light would be greater than the above by roughly 7% of itself. Therefore 5% of the deflection at this wave length in the absence of the solute or in the presence of weak N–H absorption seems a satisfactory estimate of stray light. To illustrate that this correction is small, the results for aniline solution containing 10^{20} molecules per square centimeter cross section of the light path may be cited. At the peak of absorption, the observed ratio of I/I_0 was found to be

0.67. If now both of the intensities making up the ratio are high by about 5%, the corrected ratio becomes 0.64. Thus, at the present stage of this research, while the correction is of sufficient importance to be taken into account, a small error in the estimation of the correction is not serious.

The estimate of stray light was also carried out in a constant path length at two different concentrations, reducing in this way the intensity in the same ratio as was mentioned above in the case where constant concentration and two different path lengths were used. The procedure at two different concentrations involves Beer's law, and a test of this law was made with aniline over a concentration range from 0.033 to 0.41 molal. Beer's law was followed within the limits of error of our measurements. At these dilutions this is not surprising, though in very concentrated solutions this law would undoubtedly fail.[4]

We have worked chiefly in a cell length of 5 cm. and a concentration of solute such that 10^{20} molecules are contained in one sq. cm. of light path, thus a concentration of 0.033 molal. Variations from this are noted in the table of results. All the amines have been studied in carbon tetrachloride solution. Many were originally Eastman Kodak Co. products, and, where we had reason to expect impurities, from age, discoloration, etc., redistillation or recrystallization was performed. β,β,β-Triphenylethylamine and γ,γ,γ-triphenylpropylamine were very kindly supplied by Professor L. Hellerman of the Johns Hopkins University, having been prepared by Dr. R. L. Garner. β-Phenylethylamine and γ-phenylpropylamine were supplied through the courtesy of Dr. W. H. Carothers of the du Pont Co. From a study of the boiling and melting points of the products finally used we believe that in no case, unless mentioned explicitly below, were impurities present to an extent of more than a few per cent. and usually much less. Since experience would not lead one to expect the presence of any substance having a much greater absorption power than the amine being studied and at the same position in wave length, we feel that the purity of the compounds has been ample to justify the conclusions which have been arrived at in this preliminary study. The principal conclusions are based upon the consistency of the data rather than the results of any one substance. The presence of any impurity not an amine, in any given percentage, could only affect the results by making our calculations of absorption coefficients too low by that amount.

Regarding the improbability of the presence of any highly absorbing impurity in this same region it should be pointed out that this region is apt to be rather free from possible trouble. Strong absorption depending upon electronic transitions rarely if ever comes so deep in the infra-red, so far as is known, while the absorption due to the oscillation of heavy masses, such as C–C, lie far enough in the infra-red that even their first overtones (higher overtones would be of such low intensity as to render them unimportant) are well beyond 1.5μ. Only the absorption associated in part at least with the oscillation in a H linkage can very well enter here. For these reasons, the question of small amounts of impurities in the materials studied is probably not a serious one in any case. Furthermore, fortunately, moderate absorption occurs in the first overtones of many H linkages in moderate path lengths of dilute solutions, thus, as in the present work, some hundredths molal in paths of a few centimeters. Solvents whose molecules possess only heavy atoms, such as carbon tetrachloride or tetrachloroethylene, are of course free of absorption in this region unless impurities, such as chloroform in carbon tetrachloride, are present. This region of wave length seems thus rather well adapted to the purpose of the present paper.

Results

The absorption curves to follow are plots of the absorption coefficient ϵ against frequency of absorption in cm.$^{-1}$; $\epsilon = \log_{10} I/I_0/cd$, the units being those commonly employed, c in moles per liter and d in centimeters. We do not feel justified in claiming a greater absolute accuracy than ±0.05 in the values of ϵ and ±8 cm.$^{-1}$ in frequency. Some differences in the curves within these limits are probably real, since the magnitude of some effects is undoubtedly small, even beyond detection in the present experiments.

The points on the curves represent the calculated values for the absorption coefficient determined from the records themselves and the lines are interpolations of these points. Measurements for calculation of absorption coefficients were made from the records at arbitrary wave lengths, hence points were not always read at the exact peaks of absorption; however, close visual comparisons of the original records with the drawn curves of absorption, given in the results to follow, showed their exact similarity.

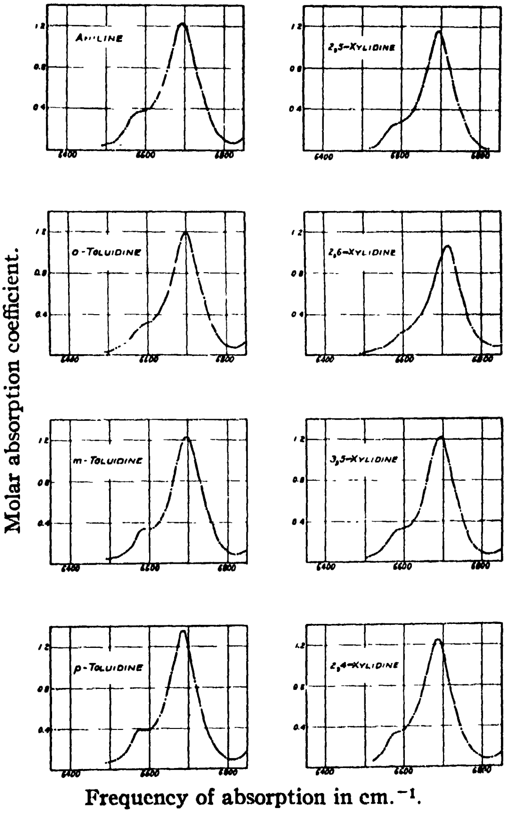

Fig. 2.

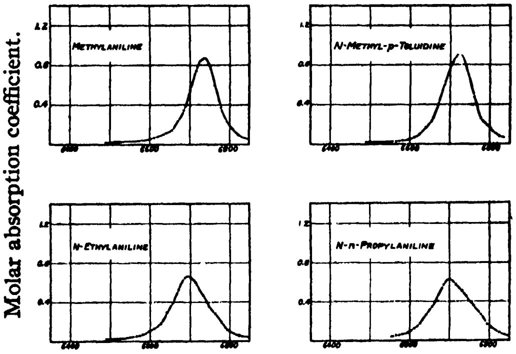
A series of aromatic amines was chosen to observe the effects, if any, of the substitution of a methyl group for one or two of the hydrogen atoms in various positions of the aromatic nucleus on the absorption of the NH portion. All the primary amines (Fig. 2) are very similar, both in the form of the curve and intensity of absorption. However, small differences occur, reproduced on two independent sets of data of which the average is recorded. Aniline has a fairly symmetrical absorption with a maximum at 6693 cm.$^{-1}$, and another much weaker band around 6600 cm.$^{-1}$ unresolved from the main peak. Methyl substitution ortho to the amine group reduces the absorption in the region of 6600 cm.$^{-1}$ and apparently shifts the median of the main absorption to very slightly higher frequency. Substitution in the meta position has no obvious effect, and in the para position shifts the peak to lower frequencies and increases the absorption coefficient of the peak. In the xylidines, substitution of the second methyl group seems to have only the added effect of the methyl group in the second position; *i. e.*, 3,5-xylidine is exactly like *m*-toluidine; 2,4-xylidine a rough composite of ortho and para toluidines. It must be mentioned that there is real absorption in the vicinity of 6950 cm.$^{-1}$ which apparently varies in intensity with the long wave length dissymmetry of the bands, *i. e.*, in *p*-toluidine and aniline, it is appreciable, and in 2,6-xylidine it is negligible; however, its apparent variation with the dissymmetry of the peak would suggest a definite relation which should be investigated. No measurements can be given on this absorption at the present time, since it lies in the midst of strong absorption, due to water vapor, which, although removable with this spectrograph, we are using as a check on the dispersion of the instrument.

A methyl group attached to the N atom of aniline and *p*-toluidine decreases the intensity of absorption to about two-thirds that of the corresponding primary amine and very appreciably increases the frequency of absorption of the remaining N–H bond, whereas an ethyl group in aniline decreases the absorption to one-half and has no effect on the main frequency. In propylaniline the intensity is the same as ethylaniline, though absorption occurs at a slightly higher frequency. Thus the absorption per N–H bond is about the same in ethyl- and propylaniline as in aniline, but greater in methylaniline by some 35%. In all these compounds the absorptions at 6600 cm.$^{-1}$ and around 6950 cm.$^{-1}$ have so diminished as to be no longer observable (Fig. 3).

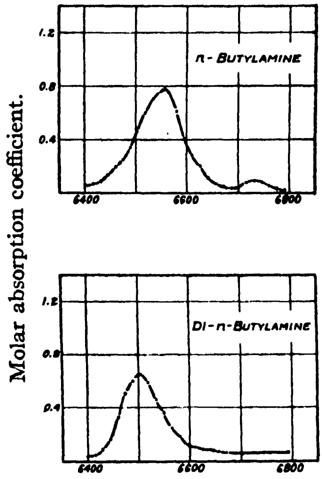


Frequency of absorption in cm.$^{-1}$.

Fig. 3.

The normal aliphatic primary amines are characterized by an appreciable decrease in the absorption coefficient compared with the aromatic amines, as well as the known[6] shift in the frequency of absorption. A very interesting result is the exact similarity within experimental error of the curves for *n*-propyl, butyl, amyl and heptyl amines, so that only the curve for *n*-butylamine is given in Fig. 4. The same is true for the secondary amines di-*n*-propyl, di-*n*-butyl and di-*n*-amyl. These differ from the primary amines in having a lower absorption coefficient, which, however, is greater per N–H bond by about 50% in the secondary than in the primary amines. The peak of absorption is at a longer wave length, 6504 cm.$^{-1}$ compared to 6556 cm.$^{-1}$ for the primary.

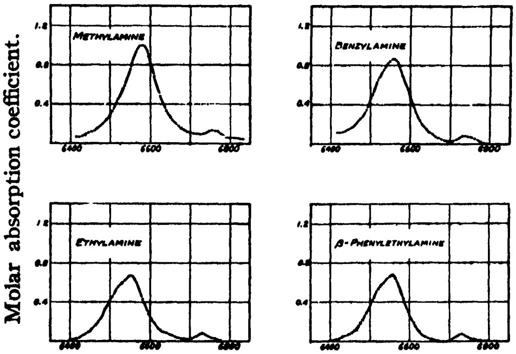
Methylamine (Fig. 5) differs from the foregoing aliphatic amines by absorbing at a higher frequency and with greater intensity, while ethylamine differs oppositely. Benzylamine, β-phenylethylamine and γ-phenylpropylamine are to all appearances normal aliphatic amines, as to shape of the curve and frequency of absorption, except that benzylamine absorbs with slightly greater intensity and β-phenylethylamine possibly slightly less. The intensity measurements of these latter two, however, are not reliable, and no measurements at all can be given for the phenylpropylamine, due to a peculiar reaction between these compounds and the solvent, carbon tetrachloride, increasing in speed with the length of the carbon chain, so that in γ-phenylpropylamine a record suitable only for wave length determinations could be obtained. It was observed that reaction occurred between the solvent and many other of the amines after several days, causing, however, no experimental difficulties over the short time required for experimental work. These reactions will be the subject of a note soon to be published by Dr. L. B. Howard.



Frequency of absorption in cm.$^{-1}$

Fig. 4.

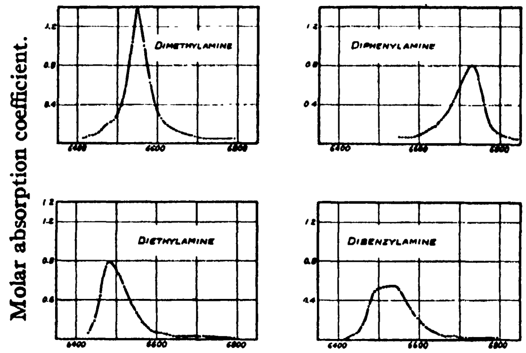
The secondary amines shown in Fig. 6 differ markedly among themselves and from their corresponding primary compounds. The only secondary aromatic amine we have been able to obtain is diphenylamine, which absorbs at a higher frequency than aniline, has only one apparent absorption maximum, but here again with an intensity value greater than one-half that of aniline, and by about 35%. Dimethylamine has a quite symmetrically peaked absorption but an intensity greater than one-half methylamine by about 180%. The absorption of diethylamine has only one apparent maximum, which is greater in intensity than ethylamine. The absorption curve of dibenzylamine is perhaps the oddest of all, and leads to suspicion of impurities; however, careful redistillation of the amine *in vacuo* failed to have any effect on the absorption, and also the carbylamine reaction for the presence of primary amines was entirely negative.



Frequency of absorption in cm.$^{-1}$.

Fig. 5.

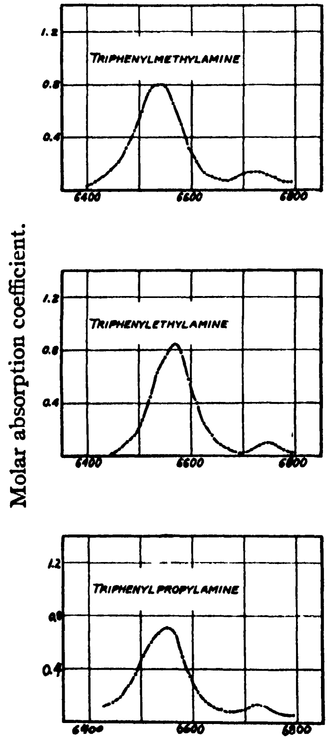
Triphenylpropylamine (Fig. 7) is very similar in shape and position to benzylamine; the median of the absorption of triphenylmethylamine lies at a slightly longer wave length, of triphenylethylamine at slightly shorter wave length. Although these compounds were probably quite pure no certain measurement of the purity could be obtained, hence no emphasis can be placed on the alternation in intensity of absorption at the maximum in this series.



Frequency of absorption in cm.$^{-1}$.
Fig. 6.

As examples of other types of amines, the absorption of pyrrole and fluorylamine is shown (Fig. 8). Fluorylamine has a distinctly aliphatic type of absorption, very similar to benzylamine, absorbing with possibly slightly greater intensity, and at somewhat longer wave lengths. The absorption of pyrrole apparently consists of a single intense band, greater in intensity at the peak than any other amine studied, and lying at the highest frequency observed, which might not be unexpected, on account of the linking of the N atom to two ethylenic carbon atoms.

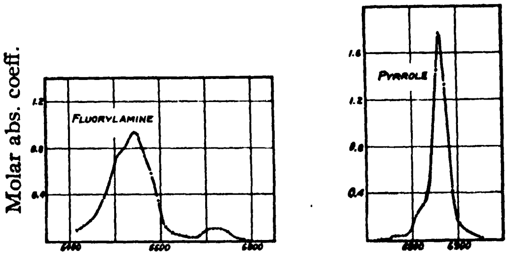
Since a composite of the curves of diphenylamine and *n*-propylamine in certain concentrations might result in a curve similar to that of *p*-toluidine, records of a mixed solution of these in concentrations purposely chosen to resemble as nearly as possible *p*-toluidine were clearly differentiable from the latter by the separation of the maxima, there being no close resemblance.



Frequency of absorption in cm.$^{-1}$.
Fig. 7.

Discussion

While the present results are preliminary in a study to be continued and extended to a much greater number of types of amines, they seem to indicate a few important facts. First, the absorption coefficient for the N–H bond in its absorption at 1.5μ throughout a very considerable range in character of the compounds, comprising aliphatic and aromatic primary and secondary amines, remains of the same order of magnitude. Second, there are measurable differences in this absorption coefficient from class to class, *i. e.*, primary aliphatic, secondary aliphatic, primary aromatic, and secondary aromatic, as well as differences in the position of the maximum of the absorption. Third, when a normal paraffin radical greater than two carbon atoms long is attached to the amine group, the absorption coefficient and position of the maximum of absorption vary very little, less than our present ability to detect. A similar remark holds for the corresponding secondary aliphatic amines, the absorption per N–H bond being somewhat greater in this group than in the former. A measurable variation is found within the primary aromatic amines studied, a dissymmetry in the absorption appearing in varying amounts in these compounds and perhaps accounting for the variation in the total absorption and in the position of the maximum within this group. Only one secondary purely aromatic amine has been studied, diphenylamine. It has a greater absorption coefficient per N–H bond and a different position of the maximum than has aniline, its closest analog in the primary group, thus exhibiting a behavior somewhat similar to that observed in the aliphatic amines. However, it should be pointed out that in the case of the aliphatic amines the secondary amine maximum was shifted to lower frequency, while in the aromatic amines diphenylamine had its maximum at a higher frequency than aniline.



Frequency of absorption in cm.$^{-1}$.

Fig. 8.

The first point mentioned above suggests the use of this quantitative data as a method of determining the total number of N–H bonds present in a given amount of unknown substance. Thus, for example, it is possible that it may be applied in this way to a study of such molecules as the alkaloids and chlorophyll. The second point suggests that a differentiation between classes may be possible from the differentiation in the position of the maximum of absorption, the quantitative measure of the absorption coefficient of the N–H bond for the respective classes making possible a determination of the number of N–H bonds of any one kind present by a method which seemingly may be brought to considerable accuracy. The third point, interesting but less useful, may permit a certain amount of differentiation within the primary aromatic amines. It is proposed to utilize the first two points in the extension of this work and to continue the work to the other commonly occurring forms of the N–H group as well, for example pyrroles, imines, etc. Also, it should be possible to carry these measurements to other solvents, in some cases more suitable than carbon tetrachloride, such as tetrachlorethylene, and in a similar way to the above, to the O–H and S–H bonds. In principle also it could be carried to the C–H bond, though in organic molecules the practical application of the latter might be limited to compounds containing only a few C–H groups. Spectra are now being recorded in this Laboratory of some aliphatic and aromatic hydrocarbons enabling a study of this last point.

VALUES OF THE ABSORPTIONS AT THEIR MAXIMA

[a] In calculation of the transmission coefficients of this solution, which was slightly turbid, this value was used as the correction factor, and was determined on the basis of 100% transmission at 6300 cm.$^{-1}$.

The authors gratefully acknowledge the interest of Dr. F. G. Cottrell, and the assistance of Drs. G. E. Hilbert and L. B. Howard, as well as valuable discussions with other members of the Staff of the Fixed Nitrogen Research Laboratory.

Summary

Absorption coefficients have been measured in the absorption lying at about 1.5μ due to the N–H group in a number of primary and secondary aliphatic and aromatic amines, and the positions of the maxima of absorption have been determined.

A method is suggested for the utilization of such data, as yet in a somewhat restricted field, for the detection of the presence of N–H groups, and for the approximate determination of the number of N–H groups present per cubic centimeter of a solution as well as the way in which this group is linked in the molecule.

Complex Compounds in Eder's Solution

BY G. H. CARTLEDGE AND S. L. GOLDHEIM[1]

Several attempts have been made to explain the mechanism of Eder's reaction, $2HgCl_2 + C_2O_4^= \longrightarrow Hg_2Cl_2 + 2CO_2 + 2Cl^-$. Most of the students of this reaction have assumed, as will be pointed out later in the discussion of their work, that the photochemical properties of this solution of oxalate and mercuric chloride are dependent on a mercuri-oxalate complex.

The present work was undertaken in order to determine the nature of the complexes which exist in Eder's solution and the extent to which they form. This information was sought by: (1) experiments on the partition of mercuric chloride between benzene and aqueous oxalate solutions, and (2) determinations of the freezing point depressions in Eder mixtures. Preliminary freezing point experiments made in this Laboratory by Mr. F. B. Slagle showed that the formation of the complex or complexes is attended by a small diminution in the number of molecules.

Since chloride ion is known to have a marked effect on the reaction and is also known to form complexes with mercuric chloride, a careful study of the literature on mercuri-chloro complexes as well as that on mercuri-oxalate complexes was made.

Throughout this work, the ionization of mercuric chloride is neglected, the figures given by Drucker,[2] $(Hg^{++})(Cl^-)^2/(HgCl_2) = 0.95 \cdot 10^{-14}$ at 25° and $(Hg^{++})(Cl^-)/(HgCl^+) = 5.3 \cdot 10^{-8}$ at 25°, showing that this assumption is permissible.

---

[1] This paper is abstracted from the dissertation presented by S. L. Goldheim to the Faculty of Philosophy of the Johns Hopkins University in partial fulfilment of the requirements for the degree of Doctor of Philosophy.

Literature

Mercuri-oxalate Complexes.—Roloff[3] attempted to show by the rather dubious ebullioscopic method the presence of complexes such as $(NH_4)_2Hg(C_2O_4)Cl_2$, $(NH_4)_2Hg_2(C_2O_4)_2Cl_2$ and others. Berger[4] assumed the presence of a complex without giving its formula. Bekhterev[5] has also mentioned the presence of complex mercury salts in Eder's solution. Other workers have studied the system $K_2C_2O_4$–HgC_2O_4–H_2O and found definite complexes, which are, of course, solid salts in equilibrium with saturated solutions.

Mercuri-chloro Complexes.—A great mass of conflicting data on these complexes exists. A critical study of forty-four articles on this subject leads to the conclusion that the work of Linhart[6] is the most definite and quantitatively accurate. This work shows that in solutions of mercuric chloride and alkali chloride (represented by MCl) below 40° the following molecular species may exist: $HgCl_2$, Hg_2Cl_4, MCl, M^+, Cl^-, $MHgCl_3$, $HgCl_3^-$, M_2HgCl_4, $HgCl_4^=$, MHg_2Cl_5, $Hg_2Cl_5^-$, $M_2Hg_2Cl_6$, $Hg_2Cl_6^=$. We neglect any ionization of $HgCl_2$ or Hg_2Cl_4. The proportions of these species in any solution depend chiefly on the concentrations. With the mercuric chloride in excess of the alkali chloride, the complexes are those having the greater proportion of mercury. The equilibrium constants necessary for calculations of these species are known from Linhart's work, which is used as the basis for the present research.

Theoretical

A scheme of complex formation in Eder's solution which would satisfy three points has been sought: first, the distribution experiments; second, the measurements of freezing point depressions; and, third, the known reaction rates, assuming that the reaction is, as has been suggested, a decomposition of the mercuri-oxalate complex.

The following schemes were tried

$$HgCl_2 + 2C_2O_4^= \rightleftarrows Hg(C_2O_4)_2^= + 2Cl^- \tag{1}$$

$$Hg_2Cl_4 + 4C_2O_4^= \rightleftarrows Hg_2(C_2O_4)_4^{----} + 4Cl^- \tag{2}$$

$$HgCl_2 + C_2O_4^= \rightleftarrows HgClC_2O_4^- + Cl^- \tag{3}$$

$$HgCl_2 + C_2O_4^= \rightleftarrows HgCl_2C_2O_4^= \tag{4}$$

$$Hg_2Cl_4 + C_2O_4^= \rightleftarrows Hg_2Cl_4C_2O_4^= \tag{5a}$$

$$2HgCl_2 + C_2O_4^= \rightleftarrows Hg_2Cl_4C_2O_4^= \tag{5b}$$

$$Hg_2Cl_4 + C_2O_4^= \rightleftarrows Hg_2Cl_2C_2O_4 + 2Cl^- \tag{6a}$$

$$2HgCl_2 + C_2O_4^= \rightleftarrows Hg_2Cl_2C_2O_4 + 2Cl^- \tag{6b}$$

(6) Linhart, THIS JOURNAL, **37**, 258 (1915); **38**, 1272 (1916).

$$2HgCl_2 + 2C_2O_4^{=} \rightleftarrows Hg_2Cl(C_2O_4)_2^{-} + 3Cl^{-} \qquad (7)$$
$$Hg_2Cl_4 + 2C_2O_4^{=} \rightleftarrows Hg_2Cl_2(C_2O_4)_2^{=} + 2Cl^{-} \qquad (8a)$$
$$2HgCl_2 + 2C_2O_4^{=} \rightleftarrows Hg_2Cl_2(C_2O_4)_2^{=} + 2Cl^{-} \qquad (8b)$$

The distribution measurements lead to equilibrium constants for schemes 1 to 7 showing decided drifts in these values when arranged in the order of varying ratio of bichloride to oxalate. The constant is the same for (8a) and (8b) and shows no drift. Measurements of the freezing point depressions, however, show that (8b) is the correct representation, and an additional reason for adopting this scheme is that this permits an explanation of certain of the reported reaction rate measurements.

In the distribution experiments successive portions of Eder's solution were shaken with benzene until the mercuric chloride in the benzene was in equilibrium with that in the *original* aqueous solution. The concentration in the benzene was determined. Then, knowing the original concentrations of mercuric chloride and potassium oxalate, the following calculations were made. All concentrations are expressed in moles per liter.

As has been stated, the only scheme of complex formation which fits the experimental results is

$$2HgCl_2 + 2C_2O_4^{=} \rightleftarrows Hg_2Cl_2(C_2O_4)_2^{=} + 2Cl^{-} \qquad (1)$$

We have at the same time the equilibria

$$2HgCl_2 \rightleftarrows Hg_2Cl_4 \qquad (2)$$
$$HgCl_2 + Cl^{-} \rightleftarrows HgCl_3^{-} \qquad (3)$$
$$Hg_2Cl_4 + Cl^{-} \rightleftarrows Hg_2Cl_5^{-} \qquad (4)$$
$$HgCl_3^{-} + Cl^{-} \rightleftarrows HgCl_4^{=} \qquad (5)$$
$$Hg_2Cl_5^{-} + Cl^{-} \rightleftarrows Hg_2Cl_6^{=} \qquad (6)$$
$$Hg_2Cl_6^{=} + Cl^{-} \rightleftarrows HgCl_3^{-} + HgCl_4^{=} \qquad (7)$$

Equation 7 is included for completeness but does not enter the calculations. Equation 2 fixes a relationship between $HgCl_2$ and Hg_2Cl_4. The remaining five equations contain five unknowns and yield, on inspection, five algebraic equations, containing these. The solution has been carried out, and calculations made on this basis check the results here presented. Because, however, of the large amount of arithmetic involved it has been found more satisfactory to neglect equations 5 and 6 when dealing with solutions of low chloride ion concentration, as is the case in Eder mixtures. Equations 1 to 4 then lead to the following three algebraic equations

$$\Sigma HgCl_2 = a + 2b + 2x + y + 2z$$
$$(y)/(a)(2x - y - z) = A$$
$$(z)/(b)(2x - y - z) = B$$

The symbols used in this discussion are: $(HgCl_2)_b$, the concentration in the benzene—experimentally determined; $a = (HgCl_2)_w$, the concentration in the water layer[6]—$a = 11.90(HgCl_2)_b$; $b = (Hg_2Cl_4)$, the concentration of the double molecules[6]—$b = 0.297 \cdot a^2$; $x = (Hg_2Cl_2(C_2O_4)_2^{=})$, the concentration of the oxalate complex; $y = (HgCl_3^-)$; $z = (Hg_2Cl_5^-)$; $\Sigma HgCl_2$, the original formality of mercuric chloride; $\Sigma K_2C_2O_4$, the original formality of potassium oxalate.

At equilibrium the concentration of the chloride ions will then be $(2x - y - z)$, and that of the oxalate ions will be $(\Sigma K_2C_2O_4 - 2x)$.

A and B are constants having the values 9.8 and 37, respectively.[6]

Solving the three algebraic equations (most simply by determinants), we obtain the results

$$\begin{aligned} x &= (\Sigma HgCl_2 - a - 2b)(aA + bB + 1)/(2)(2aA + 3bB + 1) \\ y &= (\Sigma HgCl_2 - a - 2b)(aA)/(2aA + 3bB + 1) \\ z &= (\Sigma HgCl_2 - a - 2b)(bB)/(2aA + 3bB + 1) \end{aligned}$$

Using the values of x, y and z thus obtained, the equilibrium constant of formation of the oxalate complex may be calculated

$$\begin{aligned} K' &= (Hg_2Cl_2(C_2O_4)_2^{=})(Cl^-)^2/(HgCl_2)^2(C_2O_4^{=})^2 \\ &= (x)(2x - y - z)^2/(a)^2(\Sigma K_2C_2O_4 - 2x)^2 \end{aligned}$$

This constant, K', differs from the true equilibrium constant, K, by a factor due to the activity coefficients of the ions. If the activity coefficient is represented by γ, we will call $\gamma_{Cl^-} = \gamma_I$. To a reasonable approximation, $\gamma_{Hg_2Cl_2(C_2O_4)^{=}} = \gamma_{C_2O_4^{=}} = \gamma_{SO_4^{=}} = \gamma_{II}$. We may calculate the ionic strengths[7] of each solution used, and find corresponding values for γ_{Cl^-} and $\gamma_{SO_4^{=}}$. The constant, K, will then equal $(K')(\gamma_I)^2/(\gamma_{II})$.

In the freezing point experiments, the sum of the freezing point depressions of the separate mercuric chloride and potassium oxalate solutions is compared with the depression of the mixture containing the same concentrations of salts. For every mole of $Hg_2Cl_2(C_2O_4)_2^{=}$, of $HgCl_3^-$, or of $Hg_2Cl_5^-$ that is formed, the sum of all the moles in solution is reduced by one, while the effect on the equilibrium $2HgCl_2 \rightleftarrows Hg_2Cl_4$ is inappreciable (less than 0.001 mole at all the concentrations studied). Hence the product, $(1.86)(x + y + z) = \delta_{calcd.}$, should give the amount by which the depression calculated on the basis of no complex formation (that is, the sum of the depressions of the separate solutions), exceeds the actual depression. This calculated value of δ may then be compared with the observed value.

Experimental

Materials. Mercuric Chloride.—Baker C. P. salt, labeled as containing 0.001% Fe, was three times recrystallized from water and dried in an oven.

Potassium Oxalate.—Djang[8] has showed that ammonia is present in the precipitate of mercurous chloride when ammonium oxalate is used in Eder's reaction; hence potassium oxalate was used throughout this work. Baker C. P. salt, labeled as containing 0.0006% Fe, was three times recrystallized from water and dried over calcium chloride in a desiccator.

Potassium Iodate.—Kahlbaum best salt was powdered and dried in an oven.

---

(7) Lewis and Randall, "Thermodynamics," 1923.

(8) Djang, Dissertation, Johns Hopkins University, 1930.

Benzene.—Baker "Thiophene-free" C. P. benzene was redistilled once in a simple distilling apparatus and the liquid boiling at 80–81° (uncorrected) was used.

Solutions.—Mercuric chloride solution was made up to the approximate concentration desired and standardized against potassium iodate according to the method of Jamieson.[9]

Potassium oxalate solution was made up approximately and standardized against potassium permanganate in the usual manner.

Potassium iodate solution was made up accurately according to Jamieson's directions.

Apparatus and Methods.—The distribution experiments were carried out in a water thermostat, painted black, kept out of direct sunlight, and regulated to 25.00 ± 0.02°. It was found convenient to shake the solutions in foil-covered hydrogenation bottles of about 250-cc. capacity. The thick walls of these diminish the possibilities of sudden temperature changes. The bottles were fitted with spring-clamped porcelain plugs, as caps, firmly seated in the necks of the bottles by means of chamois-skin washers. Such an arrangement allowed fast work with little loss of benzene by evaporation. Both aqueous and benzene layers were removed by *blowing* out in a pipet.

Two series of freezing point experiments were made, one set carried out in a one-pint Dewar flask, according to the method suggested by Richards;[10] and the other set done by the Beckmann method as usually described.[11]

Potassium oxalate concentrations were determined in the usual manner with potassium permanganate, duplicate titrations being run in practically all cases.

The analyses for mercuric chloride were in most cases made by the potassium iodate method of Jamieson, which was found by check experiments to be very satisfactory. In the freezing point experiments with pure mercuric chloride the analyses were made by measuring the density of a 10-cc. portion and reading off the molality from a curve prepared from figures collected by Comey.[12] Two of these analyses were checked by the sulfide method. In a few other cases the sulfide method was used.

The mode of procedure in the distribution experiments was as follows: 100 cc. of benzene and 50 cc. of the Eder mixture, of known concentration in mercuric chloride and potassium oxalate, were put in the bottles in the thermostat and shaken for two hours. After standing for another half to three-quarters hour, the bottom (aqueous) layer was blown out in a pipet, and a fresh 20-cc. portion of the Eder mixture added. This process was repeated until the benzene had been shaken with four portions of solution, preliminary experiments having shown that four successive shakings were needed to ensure equilibrium conditions. Shaking was found more satisfactory than stirring, equilibrium being reached in equal times. After the last shaking, the solutions again stood half to three-quarters of an hour in order to settle, and a 25-cc. sample of the benzene layer was carefully blown out from as near the top as possible. This sample was evaporated over a lamp bulb in a stream of air, fifteen to twenty minutes being required and check experiments showing that there was no detectable loss of mercuric chloride. A test with potassium permanganate showed that no detectable amount of potassium oxalate went into the benzene. The mercuric chloride left on evaporation of the benzene was determined by the Jamieson method.

Results

The results of the distribution experiments are given in Table I. The symbols used as column headings are explained on page 3585. Set A

includes solutions in which the potassium oxalate concentration was constant; Set B, those in which the mercuric chloride concentration was constant; and Set C, those in which the concentrations were varied simultaneously, Experiments 11, 12, 1, 13, having the total salt concentration constant. Set D includes experiments with ammonium oxalate.

The ionic strengths of the solutions used in these experiments vary from 0.04 in No. 9 to 0.42 in No 11. Inasmuch as the ion activity coefficients are not well known for the higher values of the ionic strength, the correction of K' to K will not be made in the present paper. A rough calculation, however, shows that the value of K is approximately 0.1.

In Table II are presented the freezing point depressions of pure mercuric chloride and pure potassium oxalate solutions. The results for the potassium oxalate solutions by the Beckmann method are given uncorrected for the supercooling; in the final calculations this error cancels out. In each set of the table, the first column is the concentration in moles per liter, and the second column is the observed freezing point depression.

Discussion

The results show that in the distribution experiments duplicate runs agree within about 1% in the measured concentration of mercuric chloride. On account of the subtractions involved in the calculations experimental errors are multiplied fifteen or twenty-fold in the final value of K'. Errors are introduced into K' also by the fact that the constants A and B are known to only two-place accuracy, and that the activity coefficients are not known. The calculations are least accurate when the oxalate-ion concentration is very low, as in Experiments 9 and 10 of Table I. Another factor that is beyond our control is the hydrolysis of the mercuric chloride. Considering only the experiments in which neither component is present in greater than three to one excess over the other, the values of K' show no drift as the concentration ratio is varied, whereas decided drifts are obtained when other schemes of formulation are tried. Thus, if we arrange the significant experiments of Table I in order of decreasing ratio of bichloride to oxalate, taking average values of K' for runs having approximately equal ratios of the formalities, we obtain the values of K': 0.050, 0.047, 0.056, 0.039, 0.045, 0.036, when $\Sigma HgCl_2/\Sigma K_2C_2O_4$ varies from 2.2 to 0.37. According to scheme 4 (page 3585) the corresponding values of the constant are: 9.5, 6.3, 5.8, 4.6, 4.5, 4.4. When the concentration ratio differs widely from unity it is most likely that the composition of the complex changes, as is known to be the case with the chloro complexes.

The agreement between the calculated and observed values of δ (Table IV) is also satisfactory, these being obtained from differences of measurements which are hardly accurate to more than 0.003°. Furthermore, these values are compared in solutions of only approximately the same composition and, of course, at two different temperatures, 0 and 25°. Thermal effects, however, on solutions of this type of complex should be relatively small in the neighborhood of room temperature. The observed values of δ are all less than would be expected if the complex had the formula $HgCl_2C_2O_4^{=}$.

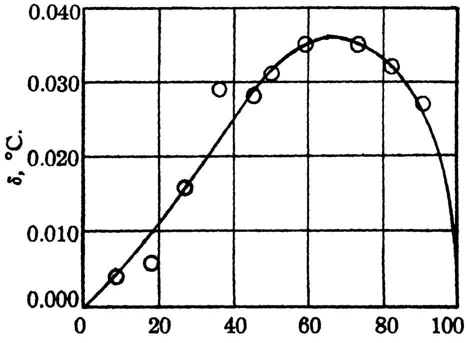

Fig. 2.

The variation in the value of δ with the ratio of bichloride to oxalate in solutions whose gross formality is constant is particularly striking. This variation is shown graphically in Fig. 2, from which it is evident that the greatest decrease in the freezing-point lowering occurs with an excess of bichloride. This is undoubtedly due to the effect of the mercuric chloride in forming chloro complexes, which is to be expected from a formulation such as the one here proposed, but not if the complex is formed by the reaction $HgCl_2 + C_2O_4^{=} \rightleftarrows HgCl_2C_2O_4^{=}$ in which no chloride ions are liberated.

The scheme of complex formation presented on page 3585 is thus in good agreement with experiment, such an agreement not being found for any of the other formulations which were tried. It will be convenient to remember that in the original Eder solution, as usually made up (Expt. 15, Table I), the concentration of the complex $Hg_2Cl_2(C_2O_4)_2^{=}$ is approximately 0.01 molar.

Discussion of the Rate of the Eder Reaction.—The mercuri-oxalate complex which has been shown to exist in Eder's solution may be made the basis of an explanation of the reaction rate measurements.

Roseveare,[13] Roseveare and Olson,[14] and Wyckoff and Baker[15] have found that the rate of Eder's reaction is proportional to the first power of the mercuric chloride concentration under certain conditions. This is to be expected from a consideration of the equilibrium equation. If we assume that no excess of chloride ion is initially present, the formation of a complex mercuri-chloro-oxalate ion liberates two chloride ions, so that, as a first approximation, the chloride-ion concentration is twice the concentration of the complex ion. We have, therefore

$$\begin{aligned}(Hg_2Cl_2(C_2O_4)_2^{=}) &= K(HgCl_2)^2(C_2O_4^{=})^2/(Cl^-)^2 \\ &= K(HgCl_2)^2(C_2O_4^{=})^2/4(Hg_2Cl_2(C_2O_4)_2^{=})^2\end{aligned}$$

from which, for a given oxalate concentration, $(Hg_2Cl_2(C_2O_4)_2^{=}) \propto (HgCl_2)^{2/3}$. Since our measurements show that, within limits, the free $HgCl_2$ is proportional to the total mercury present (Expts. 1 to 5, Table I), in the early stages of the decomposition reaction the rate should be roughly proportional to somewhat less than the first power of the concentration of mercuric chloride. This was found to be the case for both the thermal and x-ray photolytic reactions. When chlorides are initially present the order of the reaction as to mercuric chloride should increase, according to our formulation. This appears to be the case, since the results of Roseveare and Olson (Ref. 14, Tables II and III) agree better with a second order equation than with a first order one when considerable potassium chloride is present. The presence of high concentrations of chlorides so complicates the problem, however, that we cannot be certain what the results mean. It appears most likely that the composition of the mercuri-chloro-oxalate complex changes when chlorides are present in considerable concentration. Not only so, but the kinetic relationships are also complicated by salt effects quite apart from the specific action of the chloride ions, as has been shown for Eder's reaction by Berger.[4]

---

(13) Roseveare, THIS JOURNAL, **52**, 2617 (1930).

(14) Roseveare and Olson, *ibid.*, **51**, 1716 (1929).

(15) Wyckoff and Baker, *Am. J. Roentgenol. Radium Therapy*, [6] **22**, 551 (1929).

Particularly interesting results are obtained, however, when we consider the order of the reaction with respect to oxalate ion. Roseveare and Olson found that the rate varies as the second power of the oxalate-ion concentration in the absence of oxygen, but in two experiments run with the solutions saturated with oxygen, the reaction became first order with respect to the oxalate concentration. Likewise; Roseveare found a first-order rate with respect to oxalate in the x-ray photolysis in the *absence* of oxygen. Dhar[16] also found the reaction to be monomolecular as to both mercuric chloride and potassium oxalate with no chloride added and with an indefinite concentration of oxygen (solutions previously saturated with carbon dioxide). These conflicting results are clarified by considering the different conditions under which the rates were measured.

From our equilibrium equation $(Hg_2Cl_2(C_2O_4)_2^-) = K(HgCl_2)^2(C_2O_4^-)^2/(Cl^-)^2$, the reaction rate with respect to the oxalate concentration should have different values according as the chloride ion accumulates during the reaction or else remains more or less fixed. As previously pointed out (page 3592, *et seq.*), if no chloride ion is initially present the concentration of the complex ion varies as $(HgCl_2)^{2/3}(C_2O_4^-)^{2/3}$, or, the initial reaction rate should be less than first order with respect to oxalate. This situation prevails when the mercury is not present in considerable excess and no potassium chloride is added; under these conditions, the initial chloride-ion concentration is equal to twice the concentration of the complex. Now these are exactly the conditions under which the oxygen experiments of Roseveare and Olson and the x-ray photolysis of Roseveare were carried out. On the other hand, if chloride ion is added to the reaction mixture, the additional chloride ion liberated in the formation of the complex is inappreciable and the concentration of the complex varies as the square of the oxalate-ion concentration. Also, if no potassium chloride is added but mercuric chloride is used in considerable excess, the chloride ion initially liberated is extensively removed by the formation of chloro complexes, so that in this case also the rate should vary as the square of the oxalate ion concentration.

From the results of our distribution experiments it is uncertain whether the same mercuri-chloro-oxalate complex persists as the oxalate–mercury ratio deviates widely from unity, but it is significant that the kinetic measurements reveal just the variation in reaction order that our formula leads us to expect. If the formula were $HgCl_2C_2O_4^-$, as proposed by Roseveare, the maximum concentration of complex for a given total salt concentration should occur when the mercuric chloride and potassium oxalate were present in equimolal proportions; whereas, according to our measurements, the maximum formation of complexes occurs on the mercuric chloride side of metathetical equivalence.

---

[16] Dhar, *J. Chem. Soc.*, **111**, 690 (1917).

Summary

1. The results of experiments on the partition of mercuric chloride between aqueous potassium oxalate and benzene are presented.
2. The freezing point depressions of mercuric chloride and of potassium oxalate solutions and of mixtures of these have been determined.
3. It is shown that calculations from the distribution and freezing point experiments lead to the following scheme of complex formation in Eder's solution:

$$2HgCl_2 + 2C_2O_4^{=} \rightleftharpoons Hg_2Cl_2(C_2O_4)_2^{=} + 2Cl^-$$
$$HgCl_2 + Cl^- \rightleftharpoons HgCl_3^-$$
$$Hg_2Cl_4 + Cl^- \rightleftharpoons Hg_2Cl_5^-$$

4. This scheme is shown to be in harmony with reaction rate measurements on Eder solutions over a corresponding range of concentrations.

A Study of Polarization Currents Due Solely to Changes in Electrode Area[1]

BY KENNETH E. GLIDDEN[2] AND W. A. PATRICK

Introduction

The purpose of this investigation was to study the adsorption of mercurous ions at a mercury surface by measuring the current flowing between two mercury electrodes immersed in a mercurous sulfate solution while one of the electrodes was undergoing a slow definite increase in area. Similar studies have been made in the past, but always under conditions that made the interpretations of results quite difficult.

Heyrovský and co-workers have used the dropping mercury electrode to investigate a variety of chemical problems. Semerano gives a discussion of the work of these investigators using the polarograph, an instrument for the automatic recording on photographic paper of the current-voltage curves obtained with the dropping mercury cathode.[3] Frumkin and Schofield[4] have used the dropping mercury electrode to verify the Lippmann equation. Frumkin measured the current caused by a stream of mercury drops falling through the various solutions used, while Schofield actually measured the amount of mercurous salt which was removed from a solution by an expanding mercury surface.

All the dropping electrode experiments, in regard to the adsorption at the expanding surface, are ambiguous due to the rapid formation of mercury drops in the solution with the subsequent changes of metal ion concentration at the electrode surface. Furthermore, the change of solute concentration thus produced causes a change of interfacial tension, which in turn causes a variation in the size of the drops. If we add to the above objections the possibility of a slow rate of surface orientation at the electrode surface, it is evident that most dropping electrode experiments are complicated phenomena that defy analysis.

The fundamental assumption in this paper is that the adsorption of mercurous ions is equivalent to the current measured. It is an experimental fact that a rain of mercury drops falling through a solution containing for example lead ions does not adsorb lead ions from solution, and hence it appears that we are dealing with specific adsorptive forces rather than purely electrostatic forces. At the present time there is no direct evidence that our fundamental assumption is correct. The fact that the adsorption of mercurous ions calculated from our polarization current measurements on the basis of the above assumption agrees fairly well with the adsorption obtained from an entirely different method, leads us to believe that our fundamental assumption is reasonable.

Apparatus

The currents were produced with the apparatus shown in Fig. 1. The slowly expanding surface consisted of a mercury drop on the tip of a ground and polished capillary tube *a*, 1.41 millimeters in diameter. The fixed surface electrode *b* was made by sealing a 1-cm. tube through the wall of the cell *c*. The cell was cylindrical in shape, approximately 8 by 50 cm. The area of the mercury drop in contact with the solution was increased by adding mercury to the main reservoir *d* from the auxiliary reservoir *e*. The cross sectional area of the main reservoir was approximately 800 times that of the capillary bore, and hence if dV_c is the volume increase of the mercury drop produced by a volume increase dV_r at the reservoir, dV_c is approximately equal to $dV_r/800$.

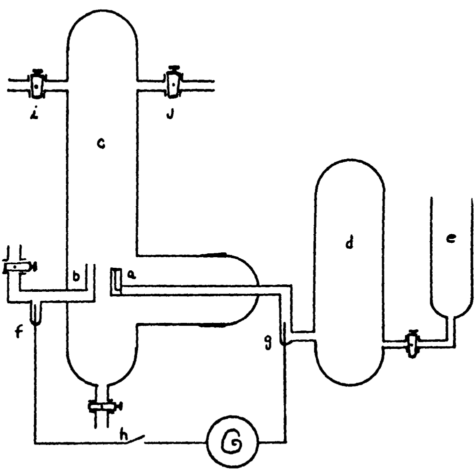

Fig. 1.—Diagram of apparatus (scale: 1 in. = 20 cm.).

Tungsten wires were sealed in the electrodes at *f* and at *g* and connected to the poles of a Leeds and Northrup galvanometer as shown in the diagram. A switch *h* was employed to open and close the circuit. The entire apparatus was supported on hard rubber or bakelite to eliminate current leakage.

The drop was observed with a cathetometer telescope containing a calibrated screw micrometer eyepiece. A lens was placed between the telescope and object to increase the magnification.

Experimental

Introduction of Solution into Cell.—The entire cell was evacuated through the stopcock at *i* with a mercury diffusion pump backed by an oil pump. Carefully purified mercury was then added through the auxillary reservoir *e* until the level of the mercury in the capillary electrode was just at the tip. The level in *b* was likewise adjusted by adding mercury through a stopcock provided for that purpose.

A stock solution of mercurous sulfate was prepared by saturating distilled water with C. P. mercurous sulfate. A small amount of mercury was kept in contact with the solution to prevent the formation of mercuric salts. After standing in contact with solid mercurous sulfate for ten days or more, the solution was filtered and analyzed for mercury by electrolysis. The stock solution is of course acid due to hydrolysis, but the exact acidity was unknown.

A bulb of about 250 cc. capacity (not shown in the diagram) joined to stopcock *j* was then filled with a solution of mercurous sulfate, which was prepared by diluting the stock mercurous sulfate solution with boiled distilled water which had been cooled rapidly to prevent absorption of oxygen from the air. Stopcock *j* was then opened slightly to allow a trickle of solution to enter the polarization cell. During this process practically all of the dissolved gases are drawn out of the solution and removed from the system by the pumps. If the flow of solution from the bulb to the cell does not exceed 150 cc. per hour, the de-aerated solution will contain not more than 10^{-5} cc. of oxygen per 100 cc. of solution. The stopcock at *i* was opened for thirty seconds every five minutes to draw off air removed from the solution. Solution was added to the cell through the bulb until a total of 1000 cc. had been added. Since a great deal of water is lost through the pumps during the de-aeration process, boiled distilled water which had been cooled rapidly was added to the cell through the de-aerator until the total volume of solution was 1000 cc.

To change the concentration in the cell, a pear-shaped bulb was sealed on at *j*. This bulb was evacuated, sealed off from the pumps and cooled with a mixture of solid carbon dioxide and ether. Stopcock *j* was then opened and water from the cell allowed to distil over, approximately six to eight hours being required to distil over 100 cc. The initial concentration of mercurous sulfate solution in the cell was known and hence the successive concentrations could be estimated by weighing the amounts of water removed by distillation.

Current Measurements.—The procedure followed in the current measurement was as follows. The flow of mercury from the auxiliary to the main reservoir was adjusted to such a rate that the meniscus of the mercury drop on the capillary tip passed between two cross hairs in the telescope eyepiece in 120 ± 5 seconds. The switch *h* was thrown as the meniscus passed the first cross hair, and the galvanometer deflection read every ten seconds for the entire time interval. The above procedure was repeated several times for each particular concentration of mercurous sulfate solution in the cell.

Area Measurements.—The optical system for viewing the drop was not sufficiently sensitive to detect the area change over an interval of ten or fifteen seconds, and hence the average rate of change over the one hundred twenty second interval was measured.

The area of a segment of a sphere is $2\pi rh$ where r is the radius of the sphere and h the height of the segment. The radius of the drop on the capillary tip is not the same as the radius of the capillary and it varies with the height of the drop above the tip. Assuming that the drop is spherical, the average rate of change of mercury surface in contact with solution may be calculated as follows. Let h_0 be the height of the meniscus above the tip of the capillary at time 0; h_t the height after t seconds; r_0 and r_t the radii of curvature of the drop at the two positions; S_0 and S_t the areas of the segments; and a the radius of the capillary. Then $r_0^2 = a^2 + (r_0 - h_0)^2$ and $r_0 = (a^2 + h_0^2)/2h_0$. A similar expression for r_t in terms of h_t and a may also be written. Since $S_0 = 2\pi r_0 h_0$ and $S_t = 2\pi r_t h_t$ it follows that

$$\frac{\Delta S}{\Delta t} = \frac{S_t - S_0}{t - 0} = \frac{2\pi(r_t h_t - r_0 h_0)}{t - 0} = \frac{\pi(h_t^t - h_0^2)}{\Delta t}$$

This final expression gives the average rate of change of mercury surface in contact with solution during the time interval considered, and if the total area change is small, the average rate does not differ greatly from the instantaneous rate.

Experimental Results

The data obtained for seven concentrations of mercurous sulfate solution in which the electrodes were immersed are summarized in Table I. The first column lists the concentration of mercurous sulfate solution in millimoles per liter; the second gives the average rate of change of mercury surface in contact with solution, expressed in square centimeters per second; the third column gives the actual current in amperes flowing between the electrodes, these values computed from the observed galvanometer deflections and the galvanometer sensitivity; the fourth column lists the adsorption per unit time, these values calculated from the current measurements and the factor 2.07×10^{-8} g. of mercurous ion per coulomb, and expressed in grams of mercurous ion per second; the final column gives the adsorption per unit surface, expressed in grams of mercurous ion per square centimeter of mercury surface. These values were calculated by dividing the adsorption per unit time by the change of mercury surface per unit time. All the values in Table I represent the mean of twenty or more individual measurements. The total area change in all cases was 0.00391 square centimeter.

A plot of the values of adsorption of mercurous ion per square centimeter against concentration of mercurous sulfate solution is shown in Fig. 2.

Discussion of Results

These experiments were undertaken with a view to ascertaining whether or not these small currents could throw any light on the extent of ion orientation at the electrode surface. Experiments performed by Seidel in which he employed the micro-balance to measure the extent of mercurous ion adsorption at mercury surfaces, indicated that a unimolecular layer was formed at a concentration of 0.13 millimole of mercurous sulfate per liter.[5] Above this concentration no further increase in adsorption was detectable notwithstanding the fact that the interfacial tension between mercury and solution continued to diminish. The adsorption calculated from the polarization currents reported in this paper substantiates the results obtained by Seidel, especially in regard to the constancy of adsorption above a certain critical value of mercurous sulfate solution concentration. The actual value for the adsorption of mercurous ion per unit surface is of the same order of magnitude from both methods, that from the polarization current measurements being one-third that obtained from the micro-balance measurements.

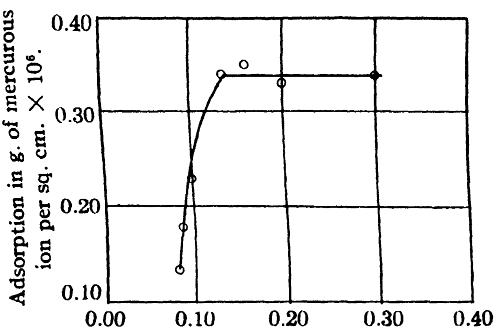

Fig. 2.—Adsorption curve for mercurous ions at a mercury surface.

The Gibbs adsorption equation for an ideal solute may be stated as follows:

$$u = -1/RT\, \partial\sigma/\partial \ln c \quad (1)$$

u being the number of moles of solute adsorbed per unit surface, σ the interfacial tension, c the bulk concentration, R and T having the usual significance.

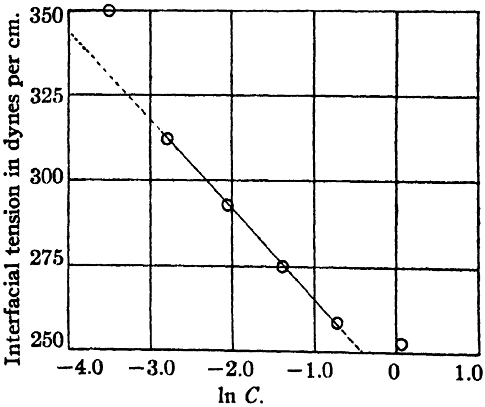

Fig. 3.—Surface tension–ln C curve for $Hg\text{-}Hg_2SO_4$.

From equation (1), it is evident that the condition for a constant value of positive adsorption is that the interfacial tension decrease linearly with the logarithm of the concentration. Patrick's data on the interfacial tension between mercury and mercurous sulfate solution show that the relationship is linear

---

(5) Seidel, Dissertation, the Johns Hopkins University, June, 1931.

from a concentration of 0.13 to 0.50 millimole of mercurous sulfate per liter, and that deviations occur in dilute or concentrated solutions. These data are shown in Fig. 3.[6]

A thermodynamic interpretation of equation (1) may be obtained by the following considerations. Assume an interface of area ω, interfacial tension σ, in contact with a solution of osmotic pressure p and volume v. A small change of area $d\omega$ results in the following change of internal energy

$$dU = TdS + \sigma d\omega - pdv \tag{2}$$

σ is by definition the work required per unit increase of surface, and hence the term $\sigma d\omega$ represents the increase in the free energy of the system. TdS and pdv are, respectively, the heat absorbed and the volume work performed when the area of the interface is increased by $d\omega$.

The free energy (F) is defined as

$$F = H - TS = U + pv - TS \tag{3}$$

This expression is differentiated and combined with equation (2), and at constant temperature the following expression is obtained

$$dF = \sigma d\omega + vdp \tag{4}$$

By applying the criterion for equilibrium, *i. e.*, $dF = 0$, we obtain

$$\sigma d\omega = -vdp \tag{5}$$

This equation shows that with an increase $d\omega$ of the interface, the change in free surface energy is exactly equal to the osmotic work performed in the process.

By differentiating equation (5) and neglecting all differentials of higher order than the first, we obtain

$$d\sigma d\omega = -dv\, dp \tag{6}$$

This equation may be written as

$$\left(\frac{\partial\sigma}{\partial v}\right)_\omega = -\left(\frac{\partial p}{\partial \omega}\right)_V \quad \text{(7a)} \qquad \text{or} \qquad \frac{\partial\sigma}{\partial c}\frac{\partial c}{\partial v} = -\frac{\partial p}{\partial c}\frac{\partial c}{\partial \omega} \quad \text{(7b)}$$

All of the coefficients in (7b) with the exception of $\partial\sigma/\partial c$ may be evaluated from the osmotic pressure law for an ideal solute, and the Gibbs definition of concentration.

$$p = cRT \quad \text{(8)} \qquad c = (n - u\omega)/v \quad \text{(9)}$$

In equation (9), c gives the bulk concentration, n the total number of moles of solute, v the total volume, ω the total surface and u the adsorption coefficient of the constituent in the surface layer. If an increase of surface decreases the concentration of one constituent in the body of the solution, that constituent is said to be adsorbed at the surface. Hence u represents the excess of the adsorbed constituent in the surface layer above that required to give the surface layer the same composition as the body of the solution.

---

(6) Patrick, *Z. physik. Chem.*, **86**, 545 (1914).

An evaluation of the coefficients in equation (7b) results in the Gibbs adsorption equation for an ideal case. We have seen that the sole condition for a constant value of adsorption is that the intensity factor of the surface energy, the interfacial tension, decrease linearly with the logarithm of the solute concentration. In spite of the fact that Patrick's data on the interfacial tension between mercury and mercurous sulfate solution show that this condition is fulfilled (within a certain range of concentration), the authors believe it worth while to present a modification of the Gibbs theory.[6]

If one accepts the fact that above a certain critical concentration no further increase in adsorption occurs, it is necessary to account for the continued lowering of the free surface energy. Our contention is that this lowering is due entirely to the orientation of electrically charged particles at the surface. In other words, the free surface energy lowering only occurs through the mechanism of orientation, and this oriented surface layer is the seat of a definite amount of electrical energy which is governed primarily by the geometry of the surface particles.

We now define concentration in terms of an oriented unimolecular layer of adsorbed particles as follows

$$c = (n - q/NF)/v \tag{10}$$

q being the total charge at the surface, NF the number of coulombs associated with a mole of surface particles, n the total number of moles and v the total volume. The ratio q/NF hence gives the number of moles of solute particles absorbed at the surface.

With an interface of area ω, interfacial tension σ, surface charge q, surface potential ϵ, in contact with a solution of osmotic pressure p and volume v, a change of area $d\omega$ results in the following change of internal energy

$$dU = TdS + \epsilon dq - pdv \tag{11}$$

This equation is identical with the fundamental equation in the derivation of the Gibbs equation with the exception that an electrical energy term (ϵdq) replaces the term ($\sigma d\omega$) for the lowering of the free surface energy. ϵ is the intensity factor in the electrical energy term which is comparable to the intensity factor σ in the surface energy term of equation (2).

The free energy expression (3) is then differentiated and combined with (11)

$$dF = \epsilon dq + vdp \quad \text{(at constant temperature)} \tag{12}$$

By applying the criterion for equilibrium, $dF = 0$, differentiating and neglecting all differentials of higher order than the first, we obtain

$$d\epsilon\, dq = -dv\, dp \tag{13}$$

This equation may be written as

$$\left(\frac{\partial \epsilon}{\partial p}\right)_q = -\left(\frac{\partial v}{\partial q}\right)_p \quad (14a) \qquad \text{or} \qquad \frac{\partial \epsilon}{\partial c}\frac{\partial c}{\partial p} = -\frac{\partial v}{\partial c}\frac{\partial c}{\partial q} \quad (14b)$$

The coefficients appearing on the right-hand side of (14b) may be evaluated from the definition of concentration previously stated, equation (10); $\partial c/\partial p$ may be found from the osmotic pressure law for an ideal solute. If one regards the adsorbed layer as a double electric layer, the question immediately arises as to how the potential of such a combination varies with the solute concentration. We postulate that the potential of the surface layer will vary with the solute concentration according to the usual thermodynamic relationship

$$\epsilon = (RT/NF) \ln c \tag{15}$$

An evaluation of the coefficients in (14b) leads to the identity

$$\frac{RT}{NF}\frac{1}{c}\frac{1}{RT} = \frac{v}{c}\frac{1}{NFv} \text{ or } 1 = 1 \tag{16}$$

This final step shows that the argument presented above is thermodynamically correct.

It now remains to show that the decrease of free surface energy between mercury and mercurous sulfate solution with increasing solute concentration is of an order of magnitude to be accounted for by the formation of an oriented unimolecular layer of solute particles. The problem may best be attacked by considering the adsorbed layer as a parallel plate condenser.

The capacity of a single parallel plate condenser may be calculated from its geometry, *i. e.*, the area of the plates and the distance of separation; capacity is also related to the charge and potential of the plates. These relationships are shown in the expression

$$C = K\omega/4\pi d = q/e \tag{17}$$

In order to simplify the calculation, we will assume that the radius of the cation and anion are the same, and hence in the above expression, $d = 2r$. If ω is the area occupied by one charged particle of radius r, the capacity then becomes

$$C = K\pi r^2/8\pi r = Kr/8 \tag{18}$$

Since the mercurous ion bears two unit charges, the potential of the double layer becomes

$$\epsilon = 16/Kr \tag{19}$$

The charge per square centimeter may be obtained by multiplying the number of surface particles per square centimeter by the charge of each surface particle, hence

$$q/cm^2 = 1/\pi r^2 \quad 2 \times 9650/N \quad \text{e. m. u.} \tag{20}$$

Since electrical energy is the product of charge and potential, the energy associated with one square centimeter of surface is given by the expression

$$\epsilon \cdot q = 16/Kr \quad 2 \times 9650/N\pi r^2 = 16.2 \times 10^4/Kr^3 \tag{21}$$

This final expression for the energy is given in ergs per square centimeter if r is expressed in Ångström units, and shows that the energy associated with the surface layer depends primarily on the geometry of the surface particles.

In order to make the calculation for the electrical energy per unit surface, the dielectric constant K and r must be known. The value of r may be calculated from the experimental value of the adsorption of mercurous ion, 0.34×10^{-6} g. of mercurous ion per square centimeter of mercury surface, and is found to be 2.5 Å. The dielectric constant of the oriented layer is unknown but will very probably be close to that of water.

Using the values $K = 81$ and $r = 2.5$ Å., the energy per square centimeter of an oriented unimolecular layer of mercurous sulfate particles is found to be approximately 120 ergs.

Since we have postulated that the lowering of the free surface energy is due entirely to the formation of an oriented unimolecular layer of solute particles, it is evident that the lowering of the interfacial tension between mercury and mercurous sulfate solution must be of the same order of magnitude as the energy required to form this surface layer. Patrick's data for the interfacial tension between mercury and mercurous sulfate solution show that the lowering from 0.13 to 1.03 millimole of mercurous sulfate per liter (the approximate region in which we postulate a unimolecular layer of solute particles) is 42 ergs per square centimeter. Since our calculation for the electrical energy associated with one square centimeter of surface involves many questionable assumptions, the agreement between the two values is all that can be expected.

Summary

1. The current flowing between a fixed and expanding mercury surface, both surfaces in contact with a mercurous sulfate solution, has been measured. On the assumption that the current measured is equivalent to adsorption of mercurous ions, the adsorption of mercurous ions is constant above a certain critical solute concentration.

2. The lowering of the interfacial tension between mercury and mercurous sulfate solution can be accounted for by the formation of an oriented unimolecular layer of mercurous sulfate particles at the mercury surface.

Calcium Nitrate. IV. Heats of Dilution of Solutions of Calcium Nitrate in Water

BY WARREN W. EWING AND ALFRED N. ROGERS

If n_2 moles of solute are dissolved in n_1 moles of water giving a solution of concentration m, the increase in heat content, ΔH, is a measure of the heat absorbed by the reaction. This is called the total or integral heat of solution. If n_2 moles of solute are dissolved in such a large volume of solution of concentration m that there is no change in concentration, the increase in heat content, $n_2 \Delta \mathrm{H}_2$ is called the partial, or differential, heat of solution of the solute. Similarly, if n_1 moles of water are dissolved in such a large volume of solution that there is no change in concentration, $n_1 \Delta \mathrm{H}_1$ is termed the partial, or differential, heat of solution of water in the solution. These quantities are related by the equation

$$\Delta H = n_2 \Delta \mathrm{H}_2 + n_1 \Delta \mathrm{H}_1 \qquad (1)$$

where $\Delta \mathrm{H}_2$ and $\Delta \mathrm{H}_1$ are the partial molal heats of solution of solute and solvent, respectively. If ΔH is known at several concentrations, $\Delta \mathrm{H}_2$ can be evaluated by determining the slope of the curve obtained by plotting ΔH against m. $\Delta \mathrm{H}_1$ can then be evaluated by means of equation (1). $\Delta \mathrm{H}_1$ can also be calculated from vapor pressure data if the vapor pressures of the solutions are known at two temperatures. In this article, the determinations of the partial heat of solution of water in calcium nitrate solutions from calorimetric data and from vapor pressure data are presented.

Previous studies on heats of dilution in concentrated solutions have been made by a few workers, notably by Randall and Bisson[1] on sodium chloride solutions; and by Harrison and Perman[2] on calcium chloride and potassium chloride solutions; but the solubility of the substances studied had only a limited range, the highest concentration of sodium chloride, for example, being only 6.12 molal. The concentration of a saturated solution of calcium nitrate anhydride in water at 25° is 77.3%, or 20.75 moles in 1000 g. of water. At this concentration, the solution is supersaturated with respect to the dihydrate, the trihydrate and the tetrahydrate. The solution is stable enough that it can be kept for long periods of time, however; and it withstands considerable experimental manipulation without crystallizing. Solutions of calcium nitrate, therefore, serve as systems on which heat of dilution studies can be carried out over a very large range of concentrations.

Randall and Bisson[1] and MacInnes and Braham[3] have measured $\Delta \mathrm{H}_1$ directly by dissolving small quantities of water in large volumes of solution.

---

This procedure was not feasible with calcium nitrate solutions because the concentrated solutions were both viscous and in a metastable condition. When small quantities of water were added to the viscous solution, it was difficult to obtain uniform distribution. There was also danger that the manipulation in the calorimeter would disturb the metastable equilibrium whereupon the whole solution would crystallize. The procedure followed was to dissolve small quantities of solution in 1000 g. of water. These heats of dilution could be calculated to infinite dilution since Lange and Streeck[4] have measured heats of dilution of calcium nitrate solutions from one-tenth molal to infinite dilution. From these heats of dilution and the heat of solution of calcium nitrate anhydride, the quantities involved in equation (1) can be calculated.

Experimental

The apparatus used has been described in a previous article.[5] The only alteration was the replacement of the mercury-in-glass thermometer by a platinum resistance thermometer. This thermometer was of the knife blade type, made by Leeds and Northrup, and calibrated at the Bureau of Standards. The resistance of this thermometer was measured by means of a Mueller type temperature bridge, made by the Eppley Laboratory, Inc. The resistances of this bridge were immersed in oil, of which the temperature was maintained constant by a thermostatic control. Resistances could be measured to 0.0001 ohm, and estimated to 0.00003 ohm. This gave temperature differences accurate to 0.0005°.

In each run four small sealed bulbs containing a calcium nitrate solution of known concentration were placed in the calorimeter containing 1000 g. of water. The solution

was introduced into the water by breaking the bulbs and the temperature change accurately measured. From this temperature change and the heat capacity of the calorimeter, the changes in heat content were calculated. The data are given in Table I. Also data for strontium nitrate solution are included in this table. These results for strontium nitrate will be discussed when vapor pressure measurements, which are now being made, are completed. Column 7 contains the change in heat content when one mole of calcium nitrate contained in a solution of the concentration designated in Column 2 is diluted in enough water to give infinite dilution. These heats were plotted against concentration in Curve I, Fig. 1.

Accuracy of Results.—Applying the equations of the theory of errors to our results, we find that the root mean square deviation is 43.5 joules. The probable error of any observation is 0.6745 × 34.5 = 29.3 joules. It is immediately obvious, however, that this is not a true measure of the accuracy, for the "spread" or maximum deviation of the results for any particular solution varies from 5 to 179 joules. The deviations can be accounted for as follows.

The heat capacity of the calorimeter and its contents was determined for each individual heat determination by passing a known current I through a resistance R inside the calorimeter for a time t. The heat evolved, RI^2t, caused a rise in temperature ΔT, the heat capacity being obtained from the relation

$$C = Q/(\Delta T) = RI^2t/(\Delta T)$$

Now the error in Q is

$$\Delta Q = RI^2\Delta t + 2RIt\Delta I + I^2t\Delta R$$

Since I and R can be measured with great precision, the second and third terms are negligible. This leaves us

$$\Delta Q = RI^2\Delta t = 17.07 \times (0.444)^2 \times 0.4 = 1.346 \text{ joules}$$

Here, we are assuming a probable error of 0.4 second in the heating interval due to closing and opening of the heater switch. Now

$$\Delta C = \frac{\Delta Q}{(\Delta T)} - \frac{Q}{(\Delta T)^2}\,\Delta(\Delta T)$$

or for the *probable* error in C

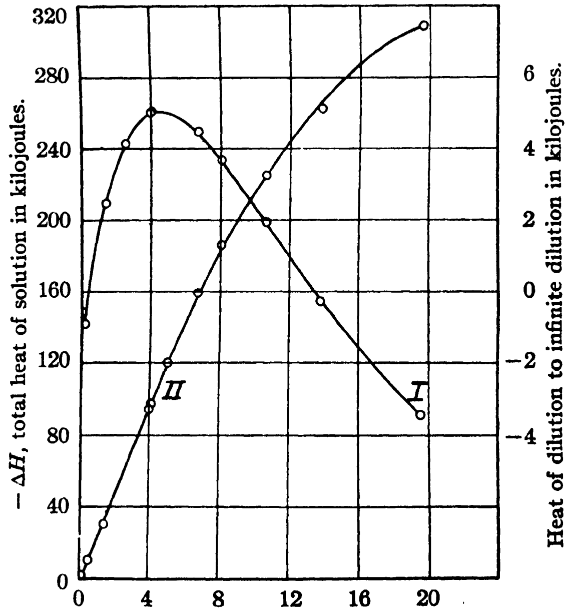
$$\text{probable } \Delta C = \sqrt{\left(\frac{\Delta Q}{\Delta T}\right)^2 + \left[\frac{Q}{(\Delta T)^2}\,\Delta(\Delta T)\right]^2} = \sqrt{\left(\frac{1.346}{0.59}\right)^2 + \left[\frac{2600}{(0.59)^2}\,(0.00045)\right]^2} = \pm 4.1 \text{ joules per } 1^\circ$$

As stated before, the temperature could not be estimated more closely than 0.0003°. A temperature change, therefore, may be in error by as much as 0.0006°. A probable error of 0.00045° was considered a fair estimate of the precision of the temperature measurement This is the value used in obtaining ΔC above.

The error in heat capacity together with the temperature error when combined by a process similar to the above, produces an error in heat of dilution. In order to convert the latter into joules per mole of dry salt, we must multiply by a factor depending on the original concentration of the solution, the weight of the solution diluted, and the molecular weight of the salt in question. The resulting probable error ranges from 86.2 joules per mole $Sr(NO_3)_2$ for the 19.5% $Sr(NO_3)_2$ solution down to 15.8 joules per mole $Ca(NO_3)_2$ for the 69.5% $Ca(NO_3)_2$ solution. In general, our calculations show that the lower the original concentration, the higher the probable error. This conclusion is corroborated by our observations.

Discussion

These heat data can be compared with vapor pressure data by thermodynamic methods. In order to do so, it is necessary to calculate them on a different basis. The values required are the partial molal heats of solution of water, ΔH_1, in the solutions of various concentrations. These can be calculated from the above data and the total heat of solution of calcium nitrate anhydride. The latter value has been given in a previous article,[5] as $\Delta H = -19{,}250$ joules. The following calculation illustrates the method.



Concentration of $Ca(NO_3)_2$ in m. per 1000 g. H_2O.

Fig. 1.—Curve I, heat of dilution to infinite dilution. Curve II, total heat of solution.

Let xH_2O designate the amount of water required to form a 1.393 molal solution of $Ca(NO_3)_2$ containing one mole of $Ca(NO_3)_2$.

$$Ca(NO_3)_2(s) + yH_2O \longrightarrow Ca(NO_3)_2(aq.);\ \Delta H = -19{,}250\text{ j.}$$

$$Ca(NO_3)_2(1.393\ m) + (y - x)\ H_2O \longrightarrow Ca(NO_3)_2(aq.);\ \Delta H = +2479\text{ j.}$$

$$\text{Subtracting } Ca(NO_3)_2(s) + xH_2O \longrightarrow Ca(NO_3)_2(1.393\ m);\ \Delta H = -21{,}729\text{ j.}$$

This gives the change in heat content when a mole of solid calcium nitrate anhydride is dissolved in enough water to give the designated concentration. These heats of solution are tabulated in Column 8, Table I. These heats multiplied by the values of the concentrations, *m*, in column 2, give the heats of solution of *m* moles of calcium nitrate anhydride in 1000 g. of water, as tabulated in Column 9. The total heats of solution in Column 9 were plotted against the concentrations in Column 2, giving Curve II in Fig. 1. The slope of this curve, $d(\Delta H)/dm$, gives the partial molal heat of solution of calcium nitrate, ΔH_2, at the designated concentrations. This slope was obtained by setting up equations for the curve and differentiating with respect to *m*. The circles represent the values given in Column 9. The solid line represents the graph of the equations.

Values for the partial molal heats of solution of calcium nitrate, $d(\Delta H)/dm = \Delta H_2$, are tabulated in Column 3, Table II. Column 1 contains the molal concentration and Column 2 the mole ratio in the various solutions. These partial molal heats of solution are plotted against concentration in Curve I, Fig. 2. The *y* intercept, −20,599 joules, was calculated at zero concentration from the equation for the total heat of solution.

Partial molal heats of solution of water, ΔH_1, were calculated from the total heats of solution and the partial heats of solution of calcium nitrate by means of equation (1). Curve II, Fig. 2, is the partial molal heat of solution of water determined in this manner; the values are tabulated in Table II, Column 4.

Partial heats of solution of water from vapor pressure data can be calculated by means of thermodynamic equations. The process of dissolving one mole of water in a large body of solution without change in concentration can be considered to take place in three isothermal steps. One mole of water vapor is evaporated at its own vapor pressure. This vapor is then expanded from the vapor pressure of water to the vapor pressure of the solution. It is then condensed into an infinite quantity of solution. The heat involved in this process, ΔH_1, is the sum of the individual heat changes in the three steps. If water vapor is assumed to be a perfect gas at these low pressures, the heat involved in step 2 becomes negligible. Applying the Clapeyron-Clausius equation, with the usual assumptions, to the first and third steps gives the equation

$$\Delta H_1 = (RT_2T_1/(T_2 - T_1)) \ln (p_2p_1'/p_1p_2') \qquad (2)$$

where p_1 and p_2 are the vapor pressures of water at temperatures T_1 and T_2 and p_1' and p'_2 are the corresponding properties for the solution. Equation (2) is essentially the Kirchhoff[6] equation. Porter[7] derived and discussed Kirchhoff's equation from a standpoint of change in internal energy and pointed out that the steps indicated above are applicable to changes in heat content.

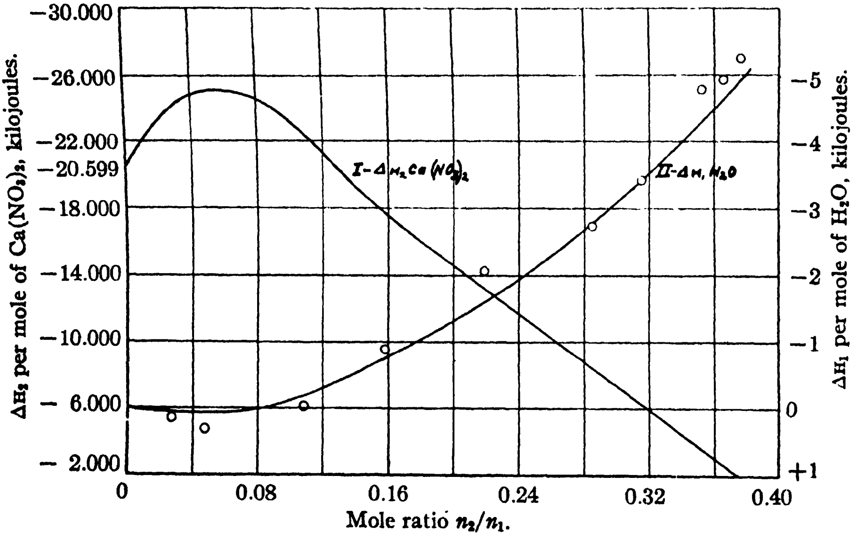

Fig. 2.—Partial molal heats of solution of $Ca(NO_3)_2$ and of H_2O.

Values of ΔH_1 calculated from equation (2) using the vapor pressures of calcium nitrate solutions measured by Ewing[8] are tabulated in Table II, Column 5. Values of ln p were plotted against $1/T$ and pressures were picked from the resulting straight lines at 20 and 30°. These calculated values of ΔH_1 are indicated as circles on Curve II, Fig. 2. The deviations of the values of ΔH_1 calculated from heat measurements and from vapor pressure measurements are tabulated in Column 6, Table II. The average deviation of 230 joules represents a deviation of 0.1 mm. in the vapor pressure of the 1.4 m solution and 0.003 mm. for the 19 m solution. The author estimated a maximum error of 0.1 mm. in the vapor pressure measurements.

The authors wish to acknowledge their indebtedness to Mr. R. J. DeGray for assistance with the electrical hook-up and to Mr. Simon Deptula for translating Russian literature on heats of dilution.

Summary

1. Heats of dilution of calcium nitrate solutions to infinite dilution have been measured. The concentrations of the solutions studied range from 1.39 *m* to 19.55 *m*.

2. The total heat of solution of calcium nitrate and the partial heats of solution of calcium nitrate and of water have been evaluated by means of the heat of dilution measurements.

3. Values of the partial heat of solution of water calculated from calorimetric measurements have been compared with those calculated by means of Kirchhoff's equation from vapor pressure measurements.

Properties of Electrolytic Solutions. VIII. Conductance of Some Ternary Salts in Liquid Ammonia

BY CHARLES A. KRAUS AND PAUL B. BIEN[1]

I. Introduction

In the three preceding papers of this series,[2] results have been presented for the conductance of various types of binary salts in liquid ammonia with a view to determining the influence of ion constitution on the properties of electrolytes, particularly the dissociation constant. It seemed of interest to extend the investigation to ternary salts. Little is known regarding the behavior of ternary salts in non-aqueous solvents, particularly of ternary salts of divalent negative ions. Usually, ternary salts are very difficultly soluble in liquid ammonia although there are a few salts, most of them of somewhat complex structure, which are readily soluble.

When benzophenone is treated with two atomic equivalents of sodium, the well-known disodium ketyl salt is formed. With one equivalent of sodium,[3] a monosodium salt is formed which may be looked upon either as a binary salt derived from the anion $(C_6H_5)_2CO^-$ or as a disodium salt of the divalent benzpinacol ion. It was hoped that conductance measurements might throw some light on this question. The dialkyl and diaryl tin derivatives, when treated with two atomic equivalents of sodium, yield compounds of the type Na_2SnR_2,[4] which are readily soluble in liquid ammonia and in which, presumably, there exists the divalent ion, $R_2Sn^{=}$. These salts are of particular interest because both charges are associated with the same atom, in place of two different atoms as is the case in the derivative of benzophenone. Unfortunately, disodium diphenylstannide undergoes reaction (presumably with the solvent) at concentrations below about 200 liters. It was found possible, however, to form a salt, $Na_2[Sn(C_6H_5)_2]_2$, which may be looked upon as the disodium salt of tetraphenyldistannane. Here again it is possible that the Sn–Sn bond breaks down in solution to yield the univalent ion R_2Sn^-. It was thought that conductance measurements might throw some light on the state of the electrolyte in solution. A similar type of salt is obtained on treating hydrazobenzene with sodium or potassium amide. Here, we have a salt corresponding to the formula $M_2[N(C_6H_5)]_2$ which may dissociate to give the simple ion $C_6H_5N^-$. It might be expected that, upon treating this salt with additional sodium, disodiumphenylamide, $Na_2NC_6H_5$, might be formed. However, no reaction occurs when disodium benzhydrazide is treated with additional atoms of sodium. For purposes of comparison with monosodium diphenylketyl, the conductance of sodium benzhydrolate was measured.

[3] Wooster, *ibid.*, 50, 1388 (1928).

II. Apparatus and Procedure

The apparatus employed in the present investigation was substantially the same as that of Kraus and Hawes and need not be described here. Some minor changes were introduced, the most important of which was that the solution was stirred by boiling. A platinum tube, closed at the bottom, was sealed into the tube connecting the two chambers of the cell at the bottom (see Kraus and Hawes). A small heater was constructed consisting of a copper rod, the end of which projected into the platinum tube and the upper part of which was wound with resistance wire which was electrically insulated from the copper rod. Heat was transmitted from the copper rod through the platinum tube into the solution, which was thus boiled and stirred very conveniently. Three-way stopcocks were attached to the withdrawal tubes used for emptying the cell or for withdrawing solution. These stopcocks eliminated one additional stopcock in each case and permitted connecting the top of the capillaries with the interior of the cell when the process of withdrawal was completed.

The method of making up the solution and of carrying out the dilutions was the same as that of Kraus and Hawes. The cell was calibrated against a standardized reference cell and the electrical measuring apparatus was the same as that used in previous work. Before making up the solutions, the cell was washed until the conductance reached a value of approximately 1×10^{-7}. No corrections have been applied to the data for the conductance of the solvent. Monosodium and disodium diphenylketyl were made up by treating benzophenone with one and two atoms of metallic sodium. The monosodium ketyl was also prepared by treating benzpinacol with sodium amide. The conductance values were the same for the two methods of preparation.

Sodium benzhydrolate was prepared by treating benzhydrol with sodium amide. It might be expected that disodium diphenylketyl might be prepared by treating benzhydrol with two equivalents of sodium amide. This, however, was not the case. In liquid ammonia solution, neither sodium nor potassium amide acts upon the monoso-

---

(4) Kraus and Greer, THIS JOURNAL, 47, 2568 (1925); Kraus and Brown, *ibid.*, 52, 4031 (1930).

dium or potassium salt of benzhydrol. The solutions were in all cases colorless and the conductance corresponded to that of a mixture of the amide and the mono-salt of benzhydrol. When the solvent was evaporated and the mixture of benzhydrolate and amide heated to room, or higher, temperatures, reaction occurred as was indicated by the appearance of the red color characteristic of the dimetal ketyl. There is here an interesting case where a salt is stable in liquid ammonia solution without hydrolysis but which cannot be made by the action of a base on the corresponding acid.

Disodium benzhydrazide was prepared by the action of sodium amide on hydrazobenzene. Monosodium hydrazobenzene could not be prepared. If hydrazobenzene is treated with one equivalent of sodium amide, the disodium salt is formed and the additional hydrazobenzene is not acted upon. It was found impossible to split the N–N bond to form disodium phenylamide by treating disodium benzhydrazide with an equivalent amount of sodium. Neither was it possible to prepare the salt by the action of sodium amide upon monosodium phenylamide. An attempt to carry out measurements with the disodium salts of dihydroxybenzenes was unsuccessful because of the fact that none of these salts was appreciably soluble in liquid ammonia.

III. Results

Equivalent conductance values of the various salts are given in the following table. Although in a number of instances the conductance was measured below 10^{-4} *N*, the data are not presented since it was felt that they were not sufficiently reliable. The conductance of the solvent introduces uncertainties at lower concentrations, particularly in the case of salts that are poor conductors.

Only one series of measurements is given for each salt, although check determinations were made in the case of all salts with the exception of dipotassium diphenylhydrazide.

IV. Discussion

The conductance curves are shown graphically in the accompanying figure, where the logarithms of concentrations are plotted as abscissas and the conductance values as ordinates. Inspection of the figure will show that practically all the salts are rather weak electrolytes. For purposes of comparison, there are drawn curves for sodium triphenylstannide ($K = 130 \times 10^{-4}$) and sodium phenolate ($K = 3.82 \times 10^{-4}$). It will be noted that, although sodium phenolate is quite a weak electrolyte in liquid ammonia, it is a better conductor than most of the salts measured in the present investigation. The conductance curve for sodium phenolate rises much more steeply than does that of the salts which we have measured.

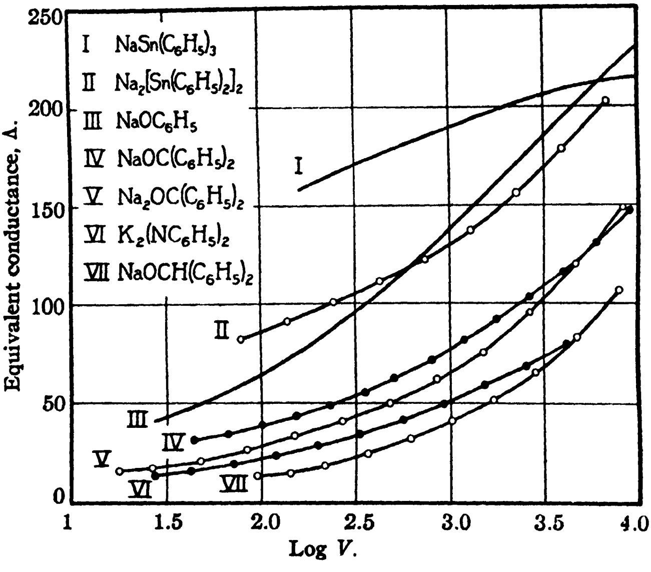

Fig. 1.—Conductance of salts in liquid ammonia.

According to the Debye–Hückel theory, we should expect the conductance of ternary salts to be much lower than that of corresponding binary salts. If a mass action effect occurs, as in the case of binary electrolytes, the constitution of the ions should have a marked influence on conductance.

The conductance curve for disodium ketyl lies slightly below that of the monosodium salt at higher concentrations but very nearly coincides with it at low concentrations. This indicates that the ionization of the two salts is approximately the same. Analysis of the curve for monosodium ketyl according to the method of Fuoss and Kraus[5] indicates that we are not dealing here with a simple binary equilibrium. It is impossible, however, to state definitely that the equilibrium is a purely ternary one. It is possible that a combination of binary and ternary equilibria exists and it is also conceivable that the charge on the monoketyl ion oscillates between oxygen and carbon. It is a remarkable fact that monosodium ketyl is a much better conductor than sodium benzhydrolate. The only difference between the two salts is that a hydrogen atom is associated with the aliphatic carbon atom in the one case and not in the other. It seems evident that constitutional factors play a large part in the dissociation phenomenon in the case of these salts.

Disodium benzhydrazide is a much weaker electrolyte than disodium ketyl. The low conductance value of this electrolyte indicates that we are here dealing with a ternary equilibrium. If the N–N bond were broken, the conductance of the resulting binary electrolyte should correspond approximately to that of sodium or potassium phenylamide. The conductance of potassium phenylamide has been measured by Kraus and Hawes and is enormously greater than that of the benzhydrazide here measured.

Disodium tetraphenyldistannide is a relatively good electrolyte. At low concentrations the conductance approximates that of sodium triphenylstannide but at higher concentrations the conductance is much below that of the binary salt, as may be seen from the figure. Evidently, we have to deal, here, with a ternary salt, but there is a possibility that an equilibrium exists between the univalent ions $(C_6H_5)_2Sn^-$ and the divalent ion $[(C_6H_5)_2Sn]_2^{=}$. It is known that the Sn–Sn bond is weak and it is quite conceivable that it is broken down under the action of electrostatic repulsion.

Although the data admit of only a qualitative interpretation, they seem to show that the ternary salts of divalent negative ions are much less highly ionized than are corresponding binary salts, and that, as in the case of salts of simpler ions, the dissociation as indicated by the conductance is the greater the larger the negative ion. It is hoped that at a later date more exact data may be presented. For this purpose, the experimental technique is being perfected.

Summary

Conductance values are presented for a number of salts of ternary type in liquid ammonia. In several of these salts the charges on the anion are associated with different atoms and there exists the possibility of dissociation of the anion complex into simple ions.

The results are discussed. Dipotassium diphenylhydrazide seems to behave like a ternary salt. In the case of disodium tetraphenyldistannide, there is evidence of dissociation of the anion complex. The conductance

curve for monosodium diphenylketyl does not correspond to that of a simple binary electrolyte.

Properties of Electrolytic Solutions. IX. Conductance of Some Salts in Benzene

BY RAYMOND M. FUOSS AND CHARLES A. KRAUS

I. Introduction

In the first paper of this series,[1] the conductances of tetraisoamylammonium thiocyanate and of tri-isoamylammonium picrate in benzene were reported. With the apparatus then available, it was impossible to investigate the conductance at concentrations below the minimum; in fact, it was only possible to argue by inference from the behavior in mixed solvents that the conductance in a strictly non-polar solvent such as benzene would show a minimum. The appearance of inflection points in the conductance curves in the neighborhood of 0.001 N for some salts and not for others also made further experimental work desirable. It seemed especially important to determine, experimentally at least, how the complexity of the curve depended upon the ions of the electrolyte.

By constructing cells with constants as low as 0.003 and by improving the electrical measuring system, it has been possible to measure conductances at concentrations below 10^{-6} N with an accuracy of several per cent. We report herewith the conductance of tetraisoamylammonium thiocyanate, picrate, iodide, bromide, chloride and fluoride in benzene at 25°. Actual minima in conductance, followed by slopes approximating that required by the law of mass action, were found in the case of the picrate, thiocyanate, iodide and bromide; and the minimum was located for the chloride and fluoride. Dissociation constants calculated from the conductance data are of the order of 10^{-18}; among the halides, the iodide is the strongest salt ($K = 5 \times 10^{-18}$) and the fluoride is the weakest ($K = 6 \times 10^{-19}$), which is the order one might expect in non-polar (not solvating) solvents.

II. Materials, Apparatus and Method

Salts.—The preparation of tetraisoamylammonium thiocyanate and iodide has already been described. The iodide used as the starting material for this series of experiments melted at 141°, which is 5° higher than our previous value. The picrate, bromide, chloride and fluoride were prepared by neutralizing the hydroxide with the corresponding acid in alcoholic solution. The picrate was recrystallized from alcohol; the other salts were used directly as obtained from (room temperature) evaporation of the solution in which they were prepared. The fluoride is *extremely* hygroscopic; for the conductance experiments, samples were placed in a small weighing bottle which was heated to constant weight *in vacuo* at 70°. Dry air was admitted to the vacuum oven before capping the weighing bottle, which, after weighing, was emptied into a conductance cell previously evacuated and filled with dry air.

---

[1] Kraus and Fuoss, THIS JOURNAL, 55, 21 (1933).

Benzene.—In addition to the treatment previously described, the benzene for these experiments was refluxed for six hours over (molten) potassium.

Conductance Cells.—For concentrations greater than 10^{-4} *N*, cells of several designs were used, much like those previously described. For the most dilute solutions, a different model was constructed (Fig. 1). The electrodes are three platinum cylinders, 5 cm. long and 8, 10 and 12 mm. in diameter, held concentrically by means of lead glass beads fused around light platinum wires welded to the cylinders. The seams are soldered with gold. The inner and outer cylinders are connected by platinum wires, so that both surfaces of the central cylinder are used. The lead wires from the cylinders are connected to thin platinum tubes which are sealed through the Pyrex glass envelope[2] at one end as shown in the figure, the exterior copper leads being soldered to the ends of the platinum tubes. The cell constant was found to be 0.003049 by indirect comparison with a cell standardized by means of 0.1 demal potassium chloride solution. The volume of the electrode compartment is about 17 cc.

Manipulation was as follows: benzene was pumped by dry air pressure from a 250-cc. storage cell (into which it was distilled immediately before the conductance experiment) onto a sample of salt weighed into the cell. After weighing the cell, and determining the conductance, the cell was wiped free from thermostat oil and weighed. Then, by means of dry air pressure applied through the stopcock in the cap, about half of the solution was blown out through the sealed-in capillary siphon. The cell was weighed, and a portion of pure benzene was pumped in. The dilution ratio could be varied from 0.3 to 0.6, depending on the relative amounts of solution emptied and benzene added.

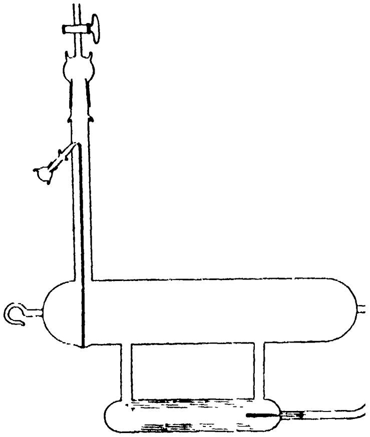

Fig. 1.—Conductance cell.

Electrical Equipment.—The previous method of using a sensitive galvanometer as ammeter has been discarded in favor of a Wheatstone bridge circuit. The cell formed one arm of the bridge, a megohm wire-wound coil[3] the second, a 0–10,000 ohm dial resistance box the third, and either a 10^4, 10^5 or 10^6 ohm coil the fourth. The bridge current was furnished by three 45-volt radio B-batteries and balance was determined by means of a galvanometer whose sensitivity was 10^{-10} amp./cm. at 2 meters scale distance. Corrections for solvent conductance, and for conductance of the glass between the electrodes and other leaks amounted to about 3×10^{-15} mho.

III. Experimental Results

The experimental results are given in Tables I–VI, and are shown graphically in Fig. 2. It will be noted that the conductances in the dilute region for the thiocyanate are somewhat higher than those previously reported. The measurements were extended to concentrations as low as 10^{-7} *N*, but, with the present methods, were somewhat erratic at concentrations below 10^{-6} *N*. The low concentration conductances, in general, appeared to be too high, perhaps due to traces of moisture. We intend to investigate the low concentration region in solvents of low dielectric constant in a closed system where even slight contamination can be

avoided. In the present communication, therefore, no data are given for the extremely dilute range. No attempt was made to carry the conductances to very high concentrations. It might be mentioned, however, that all of the halides appear to be quite soluble except the iodide, whose saturation concentration at 25° is less than 10^{-3} *N*. The picrate liquefies on the addition of a small amount of benzene, but the liquid phase produced requires a considerable volume of benzene for complete solution. Saturation is less than 0.1 *N*.

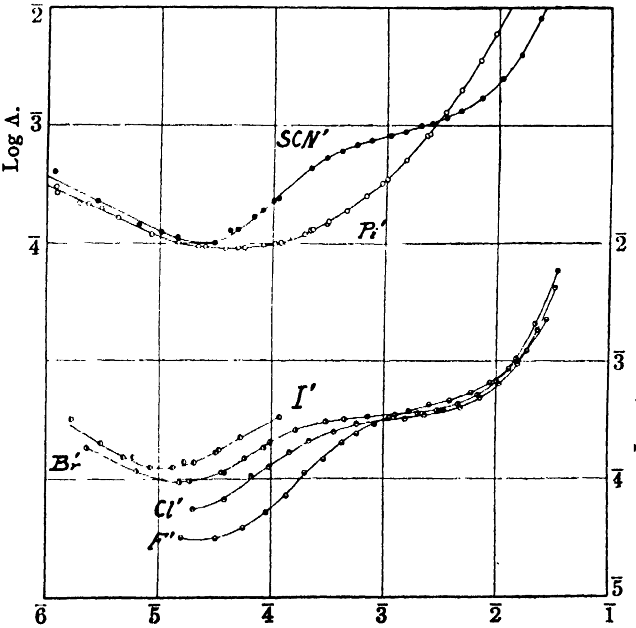

Fig. 2.—Conductance curves for tetraisoamylammonium salts in benzene at 25°.

IV. Discussion

As may be seen from Fig. 2, all the salts exhibit a conductance minimum at concentrations between 10^{-4} and 10^{-5} *N*, and in those cases (picrate, thiocyanate, iodide, bromide) where the specific conductance was sufficiently large to permit measurement at low concentrations, the rise in conductance below the minimum is in agreement with the slope of -0.5 required by the law of mass action. We conclude, therefore, that electrolytes exhibit a normal behavior in non-polar solvents.

At concentrations above 0.01 N, the equivalent conductance in all cases shows the very rapid increase with concentration which is characteristic of electrolytic solutions in solvents of low dielectric constant. Between the minimum and the higher concentration range is the region where inflection points may occur in the conductance curve. Their appearance seems to depend very much on the nature of the electrolyte: they are very noticeable for the bromide and are entirely lacking for the picrate. In the case of the halides, it is only in the neighborhood of the first inflection after the minimum that the curves show any marked differences from each other. Evidently, this region is controlled primarily by the specific properties of the ions involved. Two of these have been identified, namely: the distance parameters a and a_3 which, together with the dielectric constant and the temperature, are sufficient to describe the binary equilibrium $A^+ + B' \rightleftharpoons AB$ and the triple ion equilibrium $AB_2' + A_2B^+ \rightleftharpoons 3AB$.

By means of equation (8) of our previous paper,[4] it is possible to calculate $K\Lambda_0^2$ from the data locating the minimum in conductance. Although values of the limiting conductance Λ_0 are not known for electrolytes in benzene, a good estimate of the order of magnitude of the mass action constant K can be made by setting $\Lambda_0 = 100$ for all the salts. This value is based on the viscosity of benzene,[5] $\eta_{25} = 0.0060$, and a round value of Walden's constant for the product $\Lambda_0\eta$ for salts of the type studied here. This estimate for Λ_0 can hardly be in error by more than ±50%, which corresponds to only ±0.4 in log K. The results of this calculation are given in the third column of Table VII, which also includes, for the sake of comparison, values for the ternary isoamyl picrate.[6]

TABLE VII

CONSTANTS FOR SALTS IN BENZENE AT 25°

[4] Fuoss and Kraus, This Journal, 55, 2390 (1933).

[5] Landolt-Börnstein, Tables, p. 145.

[6] Kraus and Fuoss, This Journal, 55, 21 (1933).

The quaternary picrate is the strongest salt of the group and the ternary picrate is much the weakest. Particularly interesting is the series presented by the four halides: $K\,(\mathrm{I}') > K(\mathrm{Br}') > K(\mathrm{Cl}') > K(\mathrm{F}')$. In a non-polar solvent we might expect complete absence of solvation (in the sense of orientation of solvent dipoles in the fields of the ions). In this event the halides should show a regular decrease in apparent ion size from iodide to fluoride, and the latter should be the weakest salt among the halides. This is precisely what we find experimentally. The decrease of K with decreasing atomic number is, in fact, probably greater than that calculated above, because the value of the *product* $K\Lambda_0^2$ *decreases* from iodide to fluoride, while the limiting conductance presumably increases.

The values of the parameter a calculated from the above constants and equations (5) and (6) of our third paper[7] range from 5.75×10^{-8} cm. for the quaternary picrate to 4.8×10^{-8} cm. for the ternary picrate.

The shift of the minimum with changing salt constitution is described by the constant k, given in the last column of Table VII. This constant[8] describes the equilibrium between free ions and ion pairs (dipoles), on the one hand, and ion triples, on the other. A large value of k (*i. e.*, small negative logarithm) corresponds to a low probability for the formation of an ion triple. The constant increases with increasing dissymmetry, either in relative size or in location of charge, of the ions which make up the salt; k is smallest for the quaternary iodide and greatest for the ternary picrate. The halide ions may all be represented as charged spheres, and here k increases as the size of the negative ion decreases, the size of the (rather large) positive ion remaining the same. It is interesting to note that, while the iodide and thiocyanate have nearly the same K for the binary equilibrium, the k for the triple equilibrium is larger for the thiocyanate, as is shown by the appearance of the minimum at a higher concentration. In the negative ion of the quaternary picrate, the charge is located on one end of the negative ion, and this reduces the chances of formation of ion triples; correspondingly, among the quaternary salts measured, k is greatest for the picrate. In the ternary picrate both ions could best be represented by ellipsoids with charges at one end of the longest axis, rather than by spheres, and this marked dissymmetry leads to a very large k. If we represent all ions as spheres, and calculate parameters a_3 by means of equations (14) and (16) of our fourth paper[8] we obtain $a_3 = 7.4 \times 10^{-8}$ for the quaternary iodide and 14.8×10^{-8} for the ternary picrate.

The appearance of inflection points on the high concentration side of the minimum also appears to be directly related to the symmetry of the salt. In the neighborhood of 10^{-3} N, the conductance curve of the bromide is almost horizontal, and the slope of this inflection region increases to chloride and fluoride, so much so in the latter case, that the fluoride curve,

---

(7) Fuoss and Kraus, THIS JOURNAL, **55**, 1019 (1933).

(8) Fuoss and Kraus, *ibid.*, **55**, 2387 (1933).

which lies below the others at high and at low concentrations, cuts across the others twice in this region. The thiocyanate has nearly the same inflection slope as the fluoride and the picrate curve exhibits no inflection points whatsoever. Preliminary calculations indicate that the complete conductance function is of the form

$$\Lambda = A_{-1}c^{-1/2} + A_1c^{1/2} - A_2c + A_3c^{3/2} - A_4c^2 + - \ldots$$

where the even powers of the square root of concentration correspond to the formation of ion clusters containing an even number of ions. The formation of the latter corresponds to a decrease in conductance with increasing concentration, and, depending on the relative magnitudes of the coefficients A_n, the inflection points are more pronounced, the greater the negative coefficients. There is at least qualitative agreement between the apparent molecular weights determined from freezing point measurements[9] and the apparent association calculated from conductance data. It therefore seems likely that it will be possible to account generally for the properties of electrolytic solutions up to moderate concentrations on the basis of equilibria between simple ions and more complex structures formed from them due to the action of Coulomb forces.

Summary

1. Conductances are reported for tetraisoamylammonium picrate, thiocyanate, iodide, bromide, chloride and fluoride in benzene at 25° in the concentration range 0.02–0.000001 *N*.

2. It is shown that the conductance of electrolytes in a non-polar solvent conforms to the law of mass action at low concentrations.

3. Relationships between the structure of electrolytes and their conductance curves in solvents of low dielectric constant are discussed.

The Heat Capacities of Sodium Carbonate and Bicarbonate and Silver Carbonate at Low Temperatures[1]

BY C. TRAVIS ANDERSON[2]

The measurements described in this paper, which are a part of a series carried out in this Laboratory in a general program of determination of the thermal properties of important metallic carbonates, had a further incentive in the desire to compare the entropies so obtained with the corresponding figures from thermal decomposition. A discrepancy of several units still exists in the entropy of carbon dioxide as determined from equilibria, the third law, or spectroscopic data.

The method, apparatus and accuracy have been described in previous publications.[3] A new calorimeter with a gold wire resistance thermometer was constructed and used in the heat capacity determinations of the sodium bicarbonate. The heat capacity measurements with this new calorimeter are probably better than 1% at 55°K., as the gold wire resistance thermometer does not have the rapid diminishing resistance or the decrease of temperature coefficient that the copper wire resistance has at this low temperature. At higher temperatures the errors are probably substantially the same as with the copper wire resistance thermometer.

Materials

The sample of sodium carbonate used was Merck anhydrous C. P., and analysis showed the impurities to total less than 0.1%. A 91.4-g. sample was studied.

The sample of sodium bicarbonate was a product of Squibb. An analysis showed it to be better than 99.8% sodium bicarbonate, the impurities being about 0.1% each of water and sodium carbonate. No correction was made for these small impurities. The calorimeter was filled with 127.0 g.

The sample of silver carbonate was prepared in this Laboratory. Silver nitrate prepared from pure silver foil and C. P. nitric acid was recrystallized several times, dissolved in a large volume of water and a deficiency solution of sodium carbonate was added to precipitate the silver carbonate. Carbon dioxide was passed into the cold liquid for several hours in the dark, the liquid decanted and more water added. This was continued until no traces of sodium nitrate could be detected in the supernatant liquid. It was then filtered by suction, washed, dried over sulfuric acid and finally over phosphorus pentoxide. A conversion to metal indicated a purity of 99.96% silver carbonate.

Hydrogen was used as the conducting gas in the first series of measurements. It was found to have reacted with the silver carbonate. To remedy this difficulty helium was then used as the conducting gas, with 261.7 g. of silver carbonate.

The Specific Heats.—No previous low temperature measurements have been made on any of these carbonates. The results obtained in this

84.25	15.26	145.2	20.52	283.7	26.50
93.53	16.28	173.9	22.03	290.4	26.62

respectively. In changing joules to calories the factor 1/4.184[4] was used. The calculations were made on the basis of Na = 22.997, C = 12.00, O = 16.00, H = 1.008, and Ag = 107.88.

Calculation of Entropies.—The entropies were calculated by the usual method of plotting the heat capacity against the logarithm of the temperature. The heat capacity curves were extrapolated to the absolute zero by means of combination of Debye and Einstein functions. The Debye functions used had the following parameters (Θ): for Na_2CO_3, 137.6; $NaHCO_3$, 209.5; and Ag_2CO_3, 96.2.

The following combinations of Debye and Einstein functions were found to fit the specific heat curves per formula weights of these carbonates.

$$C_{Na_2CO_3} = D\,(138)/T + 2E\,(266)/T + 2D\,(737)/T$$
$$C_{NaHCO_3} = D\,(210)/T + 2E\,(292)/T + 2D\,(1601)/T$$
$$C_{Ag_2CO_3} = D\,(96)/T + 2E\,(172)/T + 2E\,(497)/T$$

The Na_2CO_3 combination fits the experimental heat capacity curve up to 200°K., the $NaHCO_3$ combination to 225° and the Ag_2CO_3 to about 160°. The results of the entropy calculations are given in Table IV.

TABLE IV

The Ionization Constants of a Number of Methylated Quinolines and of Certain Saturated Bases Isolated from Petroleum Distillates

BY W. A. FELSING AND B. S. BIGGS

During an investigation dealing with extraction and identification of nitrogen bases[1] from petroleum distillates, it seemed worth while to determine the ionization constants of all the monomethylquinolines and of some of the higher homologs. All of the bases identified so far from petroleum distillates belong to the series just mentioned. It seemed desirable to ascertain any order, if such existed, in the variation of these constants with the location of the methyl radicals in the quinoline nucleus; it was also desirable to know the relative strengths of the aromatic and non-aromatic petroleum bases, since such information might be of value in devising a scheme of separating the two types of bases found in petroleum distillates.

The method adopted for this investigation was the electrometric determination of the $[H^+]$ produced by the hydrolysis of the perchlorates of the bases under consideration. Use was made of an accurate potentiometer set-up, a saturated calomel half-cell, and a platinum wire in conjunction with quinhydrone. The calomel electrode was standardized by measurement against a 0.05 N potassium acid phthalate buffer solution, the P_H of which was known. In the P_H determinations of the quinolines, the potentials were reproducible to 0.0002–0.0005 volt; a change of platinum electrodes did not alter the observed voltage. All determinations were made at 25 ± 0.05°. The method was based upon the hydrolytic reaction of the base perchlorates, $B^+ + HOH \rightleftharpoons BOH + H^+$. The relation, readily deduced theoretically, for the calculation of the ionization constants is

$$K_I \text{ of Base} = K_w \cdot [B^+]/[H^+]^2$$

where K_w is the ionization constant of water. If the assumption is made that the $[B^+] = C$, the total salt concentration (an assumption very nearly true if the salt of a highly ionized acid, such as perchloric, is employed), the relation becomes

$$K_I \text{ of Base} = K_w \cdot C/[H^+]^2$$

This latter relation was used to calculate the ionization constants listed in the table. All materials were repurified for this investigation; after conversion into perchlorates, the salts were further purified by recrystallization from water.

---

(1) This investigation is a continuation of A. P. I. Project 20, under the general direction of Prof. J. R. Bailey. The work begun under this project is now being aided by the Union Oil Company, which is furnishing the nitrogen base concentrates.

[a] Products synthesized and purified in this Laboratory. [b] Products extracted from petroleum distillates, purified and identified in this Laboratory. [c] Products extracted from petroleum, purified, but constitution yet to be determined.

The correlation between activity (as expressed by the ionization constant) and the location of the methyl radical is not striking. In the monomethylquinoline series, the location of the methyl radical on the nitrogen ring seems to have a larger influence upon the ionization constant than does location on the benzene ring, the decreasing order locations being 2, 4, 3. In this series, also, the 7-position of the benzene ring seems to produce the largest activity. The 2,6-position produces the greatest activity of the dimethylquinolines.

The Adsorption of Gases on Palladium Oxide[1]

BY PAUL V. MCKINNEY

Palladium oxide is reduced readily at room temperature by hydrogen, reacting as rapidly as the gas comes into contact with it. However, the reduction proceeds slowly even at 100° when carbon monoxide is used[2] and is difficult to carry to completion short of 156°. This is unusual, for the heat of formation of water is less than the heat of formation of carbon dioxide from the monoxide, and the reduction of other oxides proceeds at a lower temperature with carbon monoxide.[2] Since adsorption of the gases is certainly one of the important steps in the rate of heterogeneous reactions, the adsorption of oxygen, carbon dioxide and carbon monoxide have been determined on palladium oxide and on partially reduced palladium oxide, *i. e.*, on an interface between the oxide and palladium. Adsorption on palladium itself has been previously investigated.[3] A series of less reducible oxides was studied by Benton,[4] who determined the adsorption of carbon monoxide only up to 0°, thus obtaining very little information concerning the relationship of adsorption to reduction.

Experimental

Preparation of Material.—The palladium oxide was prepared by the method of Shriner and Adams,[5] that is, from the chloride in fused sodium nitrate, washed and dried over phosphorus pentoxide. For the adsorption studies it was evacuated for three days at 256°, and washed twice with nitrogen. The sample weighed 47.0 g., equivalent to 40.8 g. of palladium or 0.383 mole. All gases were purified by the usual methods; volumes are given corrected to standard conditions.

Apparatus.—The apparatus is that described in another connection[6] and was constructed so that the adsorption could be followed either in a constant volume, or at constant pressure. In the present case the entire process was by the latter method at 350 mm. pressure. It was completely glass sealed, connecting directly with the gas purification train and with the collecting pumps and the system for analysis over mercury.

The adsorption vessel was surrounded by suitable constant temperature baths. The traps were cooled continually by a carbon dioxide–ether mush, to prevent the access to the active surface, of mercury vapor from the pumps and manometer as well as vapors from the stopcock grease. It was found necessary to keep this trap freshly packed with dry ice in order to maintain a constant temperature. The collecting pumps consisted of a Toepler pump and a Sprengel pump. The mercury vapor pump was placed in series just before the Sprengel pump and also connected to the oil pump. Thus removal of strongly adsorbed gas could be made at the speed and vacuum of the mercury vapor pump and yet the gas could be collected. The manometer was a constant vol-

ume instrument with electrical contact; however, the current was not used in the measurement with oxygen. The change in adsorption was observed by the change in level of the confining mercury in the buret. With this apparatus an adsorption isobar may be plotted directly.

Method.—The inert volume of the system was determined with nitrogen. There is sufficient evidence that it is not adsorbed. It had been previously shown to be inert to a palladium surface and it seemed reasonable to expect it to be inactive toward the oxide. The nitrogen was all recovered in the collecting system and a plot of the volume of the system against the temperature gives a smooth curve. The values obtained in three measurements with nitrogen spaced before and during the adsorptions are in agreement. Temperature equilibrium was attained rapidly over the entire range, with complete reversibility. The values are identical with the amount of oxygen required to fill the apparatus. The dead space of the apparatus to the master stopcock was 25.9 cc. with the bulb at 0°.

After the determination with nitrogen the order of study was oxygen, carbon dioxide and carbon monoxide. In each case the gas was admitted to the highly evacuated oxide at a low temperature and the rate of adsorption observed. The temperature was then changed and the process continued. Following a series of higher temperature measurements, the system was again cooled and the process observed for comparison with earlier results. The temperature range was from −78 to 218° for the adsorptions, with evacuation at 256° to recover the last trace of gas. In addition to the study of the adsorption isobar in the case of carbon monoxide, the rate of adsorption was measured at definite temperatures on a completely evacuated sample with analysis of the gas at suitable time intervals. Following each isothermal measurement the gas was collected until completely recovered, and the system pumped out at 256° with the mercury vapor pump for two to four hours.

Results

Adsorption of Oxygen.—This gas was measured over the temperature range −78 to 218° with a divergence of ±0.3 cc. from the nitrogen values. It is concluded that this is the order of accuracy of the individual measurement and that oxygen is not adsorbed by a palladium oxide surface. At each temperature there was no drift of the oxygen volume with time over a period of two hours. Actually 45.7 cc. of oxygen was admitted and 45.3 cc. recovered with less than 0.5% not adsorbed by alkaline pyrogallol solution.

Five adsorptions of oxygen were attempted, the first before the palladium oxide had been reduced differed by 0.3 cc. from the nitrogen volume, the last after the oxide was 2% reduced agreed within 0.05 cc. This is contrary to the results of Taylor and Burns,[3a] who found oxygen to be as strongly adsorbed as carbon monoxide on free palladium. However, the palladium they used had been reduced by hydrogen and it is difficult to remove all the hydrogen except by sintering the metal. The small amount of water would not have been observed since it is also strongly adsorbed by palladium.

Finally the partially reduced sample was heated in oxygen at 218°, and though ten minutes' contact showed no adsorption at this temperature, 2.13 cc. was adsorbed in four hours, and exactly this amount could not be recovered by the pumps, having reacted chemically. Metallic palladium reacts with oxygen at about 830°.[7]

Adsorption of Carbon Dioxide.—This gas, which Taylor and Burns have shown is not adsorbed by palladium black, is adsorbed normally by palladium oxide, Fig. 1. The adsorption is greatest at low temperatures and gradually evaporates with temperature increase becoming negligible at 218°. The observations are for a pressure of 350 mm. On a partially reduced surface, *i. e.*, one having perhaps Pd atoms and Pd–PdO interfaces, the adsorption of carbon dioxide is less as is shown by the lower curves.

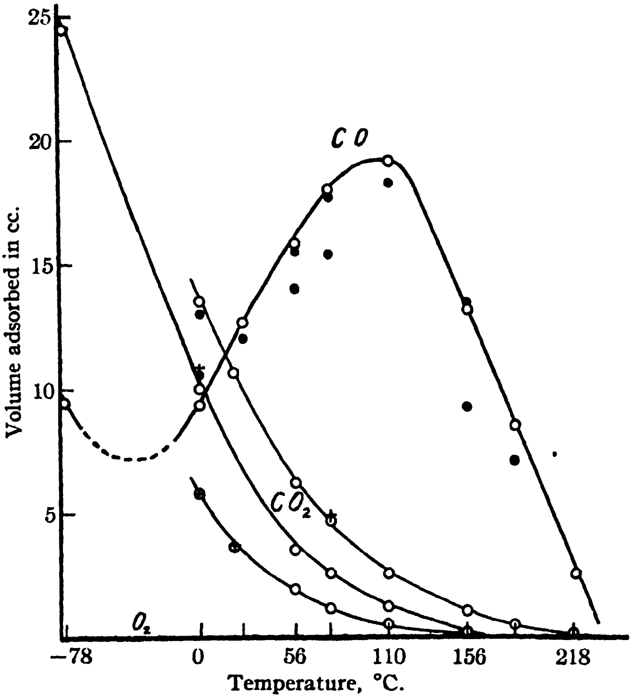

Fig. 1.—Adsorption on palladium oxide.

It is however similar in nature. Actually the original 0.383 mole of palladium oxide has been reduced by 0.0021 mole of carbon monoxide, *i. e.*, by only 0.5% before the second adsorption of carbon dioxide. Since the dioxide is not adsorbed by palladium itself, the decrease may represent either a decrease in the total extent of palladium oxide surface by the reduction or that the active palladium oxide spots have been removed to that extent. Values for the adsorption of carbon dioxide obtained on reducing the temperature are marked in Fig. 1 with +. Since it attains temperature equilibrium rapidly and is completely reversible, the adsorption of carbon dioxide by palladium oxide is entirely physical adsorption.

(7) Lunde, *Z. anorg. allgem. Chem.*, **163**, 345 (1927).

Carbon Monoxide.—As we should expect the adsorption isobar with this gas is widely different. There is a moderate adsorption at low temperatures, increasing from room temperature to a maximum at about 110° and then decreasing. The values plotted are not equilibrium values as in the case of carbon dioxide but are those for an adsorption of thirty minutes at each temperature. If the process is continued longer there is a slight but significant change in the location of the points. At −78° the two values are identical, between that and the maximum the values for an adsorption at one hour all lie higher than for the thirty-minute periods. Beyond the maximum these points are lower.

Analysis of the gas removed by the pump following this isobar of carbon monoxide on palladium oxide gave 94% of carbon dioxide, the remainder being carbon monoxide. This is equivalent to 0.5% reduction of the entire sample of palladium oxide. When carbon monoxide was admitted to the partially reduced sample the adsorption was very similar to the previous case. However, the gas desorbed analyzed only 73% carbon dioxide. These measurements for thirty-minute adsorption at each temperature are plotted as dark circles in Fig. 1. A third set of values was obtained by the isothermal rate measurements of Fig. 3, and these are also plotted with the former. Analyses of the gas removed from the isothermal adsorption are collected in Table I.

TABLE I

ANALYSIS OF GAS REMOVED FROM CARBON MONOXIDE–PALLADIUM OXIDE SYSTEM

Volume in cc.; Time in hours; Carbon Dioxide Content in %

Method of removal		Toepler				Hg vapor pump		By heating
Temp. °C.		Time		Time		Time		
−78	Vol.	3.5	43.6					7.4
	CO_2		0					77
25	Vol.	4	32.04				3.3	10.8
	CO_2		0.5				37	82
56	Vol.	3	7.3	21	15.2		5.9	21.1
	CO_2		6		20		52	62
76	Vol.	3	4.3	15	24.4		10.5	9.6
	CO_2		2		18		19	75
156	Vol.	15 min.	2.8	2	3.6	5	30.2	6.2
	CO_2		1.8		13		61	78

The adsorption of carbon monoxide is not reversible. On cooling to 0 from 218° the amount of gas adsorbed greatly increased. If one assumes that on cooling the amount of carbon dioxide readsorbed will be equal to that adsorbed at 0° in the preceding experiment and that the amount of carbon monoxide readsorbed is that originally adsorbed in the present experiment then the total readsorbed gas may be calculated.

Readsorbed: Expt. 4, 23.05 cc.; Expt. 5, 19.00 cc.
CO_2 13.46 CO_2 9.97
CO 9.30 CO 10.44
Calculated readsorption 22.76 20.41

Discussion

Physical Adsorption.—The low temperature adsorption on palladium oxide is certainly of the physical type. At −78° there is no drift of the amount of gas adsorbed with time, Fig. 2, temperature equilibrium being established in about fifteen minutes. When the oxide has been partially reduced there is a slight drift in the adsorption at −78°. This is probably due to adsorption of carbon monoxide by the free palladium.[3b,8] The gas removed with the Toepler pump at −78° analyzed free from carbon dioxide; 7.4 cc. could not be removed even with the mercury vapor pump at this temperature. It seems reasonable to suppose that this represents carbon monoxide held by activated adsorption to palladium atoms. When this gas was removed at a higher temperature it analyzed 5.7 cc. of carbon dioxide and 1.7 cc. of carbon monoxide.

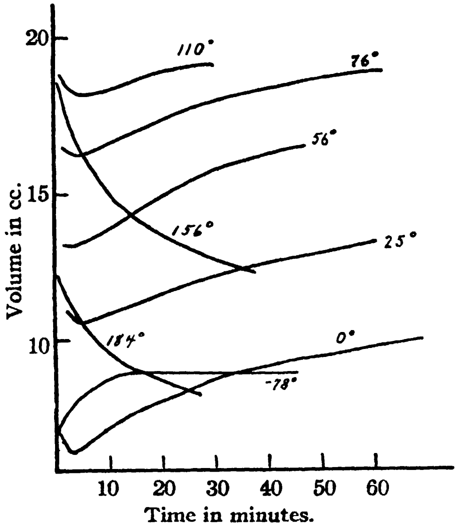

Fig. 2.—Rate of adsorption and desorption of carbon monoxide on palladium oxide.

Activated Adsorption and Reaction.—Between 0 and 100° the amount of carbon monoxide adsorbed increases with the temperature. Samples of the gas removed in this range showed varying amounts of carbon dioxide. On partial reduction the surface does not change much in extent and adsorption does not seem to penetrate the reduced material. However, certainly part of the adsorption in this case is on palladium. At 0° after each additional reduction the amount of adsorption increases, the dark circle lies higher, Fig. 1. At higher temperatures the values are not greater and in general less. This is reasonable since the maximum in the activated adsorption of carbon monoxide by palladium occurs at 0°, above which temperature the carbon monoxide rapidly evaporates from the free metal.

From the data of Fig. 3 activation energy of the process occurring in the rising portion of the curve of the adsorption of carbon monoxide may be calculated. The value of E for the volumes 8, 9 and 10 cc. between 0 and

---

(8) On palladium the adsorption of carbon monoxide exhibited the same type of maximum. The low temperature process reached an equilibrium rapidly and reversibly. All the carbon monoxide was recovered. The activated or chemical process approached equilibrium more slowly. Above the maximum, the carbon monoxide may be completely recovered, but below this temperature it cannot be removed in any reasonable time even with the mercury vapor pump. We note that this activated adsorption begins on palladium around −78° and reaches a maximum about 0°.

25° is 2600 calories. Between 25 and 56° for 10 to 15 cc. adsorbed it varies from 3600 to 4800 calories. In the temperature range 56 to 76° the activation energy has again increased, ranging from 7800 calories for 10 cc. adsorbed to 10,000 calories for 15 cc. and 16,000 calories for 18 cc. adsorbed. The process occurring here must be complex since in the case of a simple activated adsorption the value of E should be constant. There is the adsorption of carbon monoxide on free palladium with its maximum below 25° which is decreasing in amount above this temperature although increasing in rate, as well as the adsorption of the monoxide on palladium oxide with a maximum above 76°. Reaction is occurring with some of the adsorbed molecules evaporating as carbon dioxide from palladium atoms, which introduces the heat of reaction into the observed value of E.

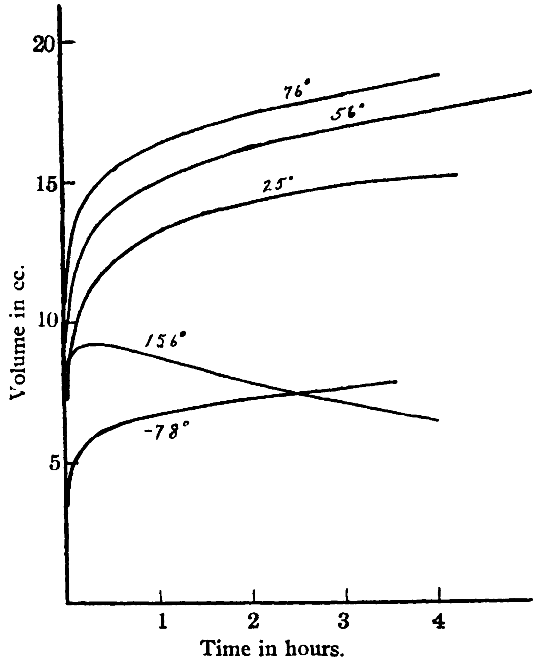

Fig. 3.—Rate of adsorption, carbon monoxide on palladium oxide.

Conclusion

The reduction of palladium oxide occurs through an adsorption step. However, unlike the case of most reducible oxides the process once begun is not autocatalytic and does not proceed to completion. The reduction in spite of the adsorption proceeds slowly. At −78° the carbon monoxide is adsorbed on palladium oxide physically and it may be recovered by evacuation. However, on a partially reduced sample even at this temperature the carbon monoxide is adsorbed strongly by the palladium atoms. Between room temperature and 110° the adsorption of carbon monoxide is chemical on palladium oxide. In this temperature range the analyses show that there is a slow evaporation of carbon dioxide but since the amount of adsorption continues to increase it is probably replaced by carbon monoxide, the dioxide being also adsorbed on palladium oxide but not on free palladium. In the higher temperature range the amount of adsorption decreases rapidly. Though the adsorption of carbon monoxide and carbon dioxide on palladium and of the dioxide on palladium oxide is negligible at 156° the carbon monoxide adsorbed on palladium oxide is quite strongly held at this temperature.

There are considerable data[9] which suggest that the reduction of platinum[10] oxide by carbon monoxide should be normal since it is adsorbed more strongly than hydrogen is by platinum, while the latter will displace carbon monoxide from palladium.[3a,11]

Summary

1. The adsorptions of oxygen, carbon dioxide and carbon monoxide on palladium oxide have been determined over the temperature range −78 to 218°.

2. Oxygen is not adsorbed by palladium oxide, nor by the oxide when partially reduced by carbon monoxide.

3. Carbon dioxide is adsorbed by palladium oxide reversibly, *i. e.*, by physical adsorption. The amount decreases with the extent of reduction of the surface of the oxide; on a sample only 2% reduced, the adsorption decreased by more than 50%.

4. The adsorption of carbon monoxide has a maximum about 100°. There is a physical adsorption at −78°. Activated adsorption increases slowly in amount between 0 and 100° and the gas is strongly held and evaporates only as carbon dioxide. Complete desorption occurs only above 218°.

5. The rates of adsorption on partially reduced samples and activation energies calculated from them indicate a complex process. Carbon monoxide is also adsorbed on the free palladium but so strongly that the further reduction of adjacent palladium oxide is not accelerated. The reaction does not occur at an interface, that is, it is not autocatalytic.

Preparation and Properties of Anhydrous Acetic Acid

BY WILLIAM C. EICHELBERGER AND VICTOR K. LA MER

Cryoscopic and solubility investigations with acetic acid as solvent require the preparation of anhydrous material of high purity in large quantities. The melting point must be highly reproducible without entailing undue labor.

The methods that have been employed may be summarized as follows: (1) repeated fractional crystallization,[1] followed by (a) distillation;[2] (b) drying with phosphorus pentoxide in the quantity calculated to react with the water present to form orthophosphoric acid and then distillation from the phosphorus pentoxide[3] (a small quantity of acetic anhydride is produced[3]); or (c) refluxing with the exact quantity of acetic anhydride required to convert the remaining water to acetic acid.[4] (2) Refluxing for one-half hour with two per cent. by weight of potassium permanganate and distilling from the residue.[5,6] We have found that such acid never melts above 16.55°. (3) Refluxing for ten hours with chromium trioxide[7] in an amount in excess of that calculated to react with the water present to convert it to chromic acid.[8]

The melting point is a good and frequently used criterion of purity but unfortunately only two laboratories[5,6] have reported how their thermometers were standardized, so that variations ranging from 16.4 to 16.60° may be due to inaccuracy in the temperature scale as well as to impurities.

We investigated methods (1a), (2) and (3). The first was very tedious when large quantities are needed. One fractional distillation with a good still yields acid of higher melting point than several recrystallizations. Potassium permanganate oxidized much of the acetic acid when applied to quantities of four liters or more. The chromic oxide method proved to be the most satisfactory.

Chromic Oxide Method.—Four liters of Niacet Chemical Company C. P. acetic acid (melting point 16.5°) was refluxed for about ten hours with an amount of chromium trioxide slightly in excess of that calculated to react with the water present to form chromic acid (about 1% by weight), assuming 16.60° to be the melting point of the pure acid and all the freezing point lowering to be due to water.[1] The acid was then distilled rapidly using an all-glass distilling apparatus protected by calcium chloride guards, followed by a careful fractionation with a two-foot Vigreaux column. After one liter had been distilled, the melting point of the distillate was 16.3°; it rose to 16.50–16.55° for the next liter, and to 16.57–16.60° for the remainder. Other workers[6,7,8] using this or the potassium permanganate method report a melting point of 16.55° for the second and third quarters of the distillate. One purification using two per cent. chromium trioxide yielded acid of the same purity but more of the low-boiling fraction, indicating that more water had been formed and hence more acid decomposed.

Triacetyl Borate Method.—Triacetyl borate[9] is an excellent dehydrating agent for purifying acetic acid which has apparently escaped attention. It reacts with water to yield acetic acid and insoluble boric acid which may be completely separated in the final distillation: $B(OCOCH_3)_3 + 3H_2O = 3CH_3COOH + B(OH)_3$.

Triacetyl borate was prepared according to the directions of Pictet and Geleznoff[10] by warming to 60° a mixture of boric acid (powdered) and acetic anhydride in the ratio of 1:5 parts by weight: $B(OH)_3 + 3(CH_3CO)_2O = B(OCOCH_3)_3 + 3CH_3COOH$. On cooling, most of the triacetyl borate precipitates and is removed on a suction filter. It is very hygroscopic.

The purified acetic acid was refluxed with the triacetyl borate in the all-glass apparatus and then carefully distilled. Two to four times the amount of triacetyl borate calculated to react with the water present was used. Acetic acid of the same melting point was always produced. If four liters of the acid was dried at one time, two and a half to three liters was collected with a variation of not over 0.02° in the melting point, that is, from 16.58–16.60°.

This value was determined with a thermometer calibrated against a copper–constantan thermocouple, standardized against the fixed points of 0°, 32.384 ($Na_2SO_4 \cdot 10H_2O$) and a platinum resistance thermometer certified by the Bureau of Standards. The specific conductance (κ) of the acid was measured at the Rockefeller Institute with apparatus placed at our disposal by Dr. D. A. MacInnes, and yielded a value of 1.4×10^{-8} mhos at 25°.

Conclusions

Methods of purifying pure, anhydrous acetic acid in large quantities are discussed. Oxidation with chromium trioxide to remove impurities followed by dehydration with triacetyl borate was found to be the most satisfactory method.

The melting point of pure anhydrous acetic acid is 16.60 ± 0.01° and the specific conductance is 1.4×10^{-8} mhos (25°).

The Analytical Determination and Conductance of Sulfuric Acid in Anhydrous Acetic Acid

BY WILLIAM C. EICHELBERGER AND VICTOR K. LA MER

An accurate method of analyzing very dilute solutions of sulfuric acid in anhydrous acetic acid is essential for cryoscopic studies of such solutions. The customary acid-base titration is impossible because of the acid nature of the solvent. Gravimetric determination as barium sulfate is not feasible because of the possibility of adsorption of acetic acid on the precipitate. The corresponding conductivity titration, however, yielded a satisfactory analytical method. To avoid the introduction of foreign ions which would disturb the conductivity, barium acetate was selected as the source of barium ion.

The specific conductances of acetic acid–water mixtures were investigated to find the most suitable dilution where the errors caused by absorption of moisture during titration are at a minimum. The specific conductances (Table I) when plotted against percentage of acetic acid (Fig. 1) yield a curve with a maximum at about 18% acetic acid, which falls off sharply on each side of this point, flattening out at about 80% acetic acid with an asymptotic approach to the abscissa. An 18% solution should therefore be least sensitive to variations in water content. Unfortunately, the conductivity titration curves for this solvent yielded a poorly defined intersection (Fig. 2A). For a solvent of 50% acetic acid and 50% water, the initial points obtained with small additions of the barium acetate solution when plotting the reciprocal of the resistance against the amount of solution, fell on a straight line (Fig. 2B), but after the equivalence point was passed all the points were on a curve. The conductivity titration curves obtained in 75% acetic acid to 25% water mixture yielded an intersection sufficiently well defined to give a precision of two or three parts per thousand (Fig. 2C).

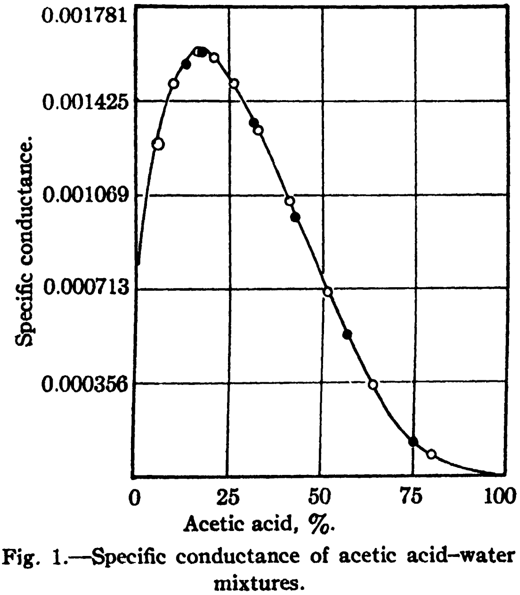

Fig. 1.—Specific conductance of acetic acid–water mixtures.

A conductivity cell of 200 cc. capacity with electrodes 1 sq. cm. in area is suitable for titrations of 0.005 molal sulfuric acid (the most dilute analyzed). The barium acetate solution was prepared by dissolving Kahlbaum C. P. barium hydroxide in the calculated amount of pure acetic acid and water, and was standardized conductimetrically in the same manner as it was to be used. The final procedure involved placing 50 cc. of 0.01000 *M* aqueous sulfuric acid in the conductivity cell, adding 150 cc. of pure acetic acid—a considerable contraction in volume occurs—and titrating the contents with 0.5 *M* barium acetate solution from a weight buret in approximately 100-milligram portions.

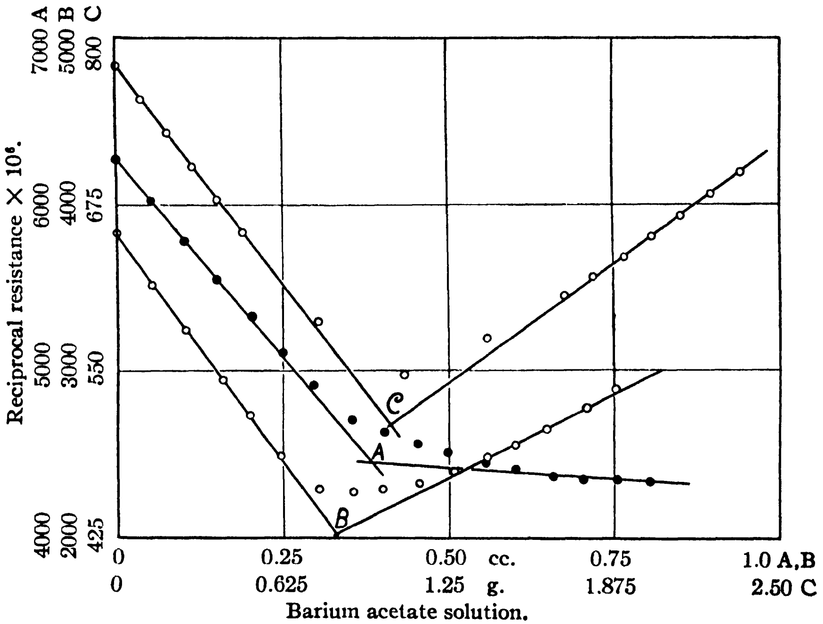

Fig. 2.—Conductivity titrations of sulfuric acid in: (a) 20% acetic acid–80% water; (b) 50% acetic acid–50% water; and (c) 75% acetic acid–25% water solvents.

The exact point of intersection was determined algebraically from the equations fitting the linear portions of the experimental curves of the type illustrated in Fig. 2C.

It is important that the determination of the unknown be carried out under approximately the same conditions as employed in standardizing the known solution, because of "electrolyte effects." Thus, if the concentration of the sulfuric acid was doubled, the barium acetate required would not be exactly twice that for the first solution. However, if the concentrations of sulfuric acid in duplicate experiments agreed to within 5%, the titers checked to 0.2%. The resistançes of the known and un-

known solutions must also agree within 10% of each other in order to obtain the precision desired. A preliminary determination is therefore necessary.

Conductance measurements also were carried out on solutions of sulfuric acid in anhydrous acetic acid. The results are given in Table II and plotted in Fig. 3. The curve follows the general type predicted by Walden[1] for solvents of low dielectric constant. A Washburn type of cell was used for these measurements.

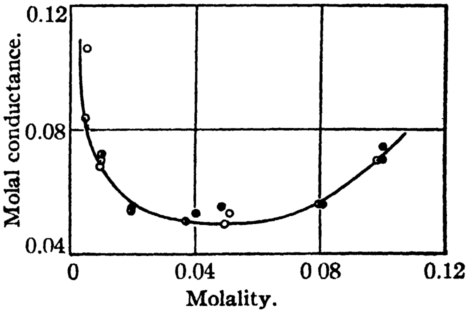

Fig. 3.—Molal conductance of sulfuric acid in anhydrous acetic acid.

Since completing this work (Spring, 1932), Hall and Voge[2] have published the complete conductance curve for the binary system H_2SO_4–CH_3COOH (m. p. 16.63° and $\kappa = 3 \times 10^{-8}$ mhos at 25°). Our curve parallels theirs very closely, but is displaced above it by an amount which would correspond to the presence

(1) Paul Walden, "Salts, Acids and Bases," McGraw-Hill Book Co., Inc., New York, 1929.

(2) Hall and Voge, THIS JOURNAL, 55, 239 (1933).

of only 0.02% water, if the source of the difference is attributed entirely to moisture. Our solutions stood for a few days in well-stoppered, ordinary glass bottles which had been used for acetic acid solutions for several months previously. They were protected by beakers sealed with paraffin.

The measurements were made on apparatus[3] of the a. c. bridge type consisting of the following parts: a 1000-cycle microphone hummer, a Kohlrausch slide wire (Leeds and Northrup Co.), non-inductive type resistance (Leeds and Northrup Co.), accurate to 0.05%, a variable air condenser across the resistance box to balance the capacity of the cell, and a two-stage audio amplifier with headphones matched to the frequency of the oscillator. The center of the bridge is grounded and all leads are shielded. The conductivity cell is placed in a thermostat which is constant to 0.005°.

Conclusions

1. A conductivity method is described for the precise determination of small quantities of sulfuric acid when dissolved in anhydrous acetic acid.
2. The specific conductances of the complete range of acetic acid-water mixtures have been determined.
3. The molal conductances of solutions of 0.005 to 0.10 *M* sulfuric acid in anhydrous acetic acid were determined. The data agree very well with the recent measurements of Hall and Voge.

The Ionization Constant of Monochloroacetic Acid, at 25°, from Conductance Measurements[1]

BY BLAIR SAXTON AND THEODORE W. LANGER

In sufficiently dilute aqueous solution the thermodynamic ionization constant of a weak acid, HA, is given by the equation

$$K = \gamma^2 C_i^2/(C - C_i) = \gamma^2 K' \qquad (1)$$

where γ is the geometrical mean activity coefficient, C_i is the concentration of the ionized portion, and C is the total concentration of the acid. K' is the usual concentration (or dilution) constant. Evaluating γ by means of the limiting law of Debye and Hückel,[2] taking the dielectric constant for water at 25° as 78.56 (the mean of the results of Drake, Pierce and Dow[3] and Wyman),[4] we may write

$$\log K = \log K' - 1.013\sqrt{C_i} \qquad (2)$$

---

[1] This paper contains material which represents part of the dissertation submitted by Theodore W. Langer to the Graduate School of Yale University in partial fulfilment of the requirements for the degree of Doctor of Philosophy, June, 1931. The authors wish to acknowledge their indebtedness to Lawrence S. Darken and Harry F. Meier, who contributed the measurements on hydrochloric acid and its sodium salt.

[2] Debye and Hückel, *Physik. Z.*, **24**, 185 (1923).

[3] Drake, Pierce and Dow, *Phys. Rev.*, **35**, 613 (1930).

[4] Wyman, *ibid.*, **35**, 623 (1930).

When C_i has been determined from conductance measurements, this equation has been verified by MacInnes and Shedlovsky[5] for acetic acid, Davies[6] for mandelic acid, and by our own results.

The ionic concentration can be determined from conductance data by means of the relation

$$C_i = \alpha C = \Lambda/\Lambda_{(H^+ + A^-)}\, C = 1000\, k\, (L/\Lambda_{(H^+ + A^-)}) \tag{3}$$

where k is the cell constant and α, L, Λ and $\Lambda_{(H^+ + A^-)}$ are the degree of ionization, the cell conductance, the equivalent conductance and the sum of the equivalent conductances of the ions of the weak acid, respectively. For a given value of C_i, the denominator can be determined by the relation

$$\Lambda_{(H^+ + A^-)} = \Lambda_{(HCl)} - \Lambda_{(NaCl)} + \Lambda_{(NaA)} \tag{4}$$

For very dilute aqueous solutions Λ for each of the strong electrolytes can be expressed as a function of C_i by means of the Debye–Hückel–Onsager[7] equation

$$\Lambda = \Lambda_0 - (0.2276\, \Lambda_0 + 59.88)\sqrt{C_i} \tag{5}$$

Shedlovsky[8] has empirically extended this to more concentrated solutions, obtaining the equation

$$\Lambda_0 = \frac{\Lambda + 59.88\sqrt{C_i}}{1 - 0.2276\sqrt{C_i}} - BC_i = \Lambda_0' - BC_i \tag{6a}$$

$$\Lambda = \Lambda_0 - (0.2276\, \Lambda_0 + 59.88)\sqrt{C_i} + BC_i(1 - 0.2276\sqrt{C_i}) \tag{6b}$$

in which B is an arbitrary constant. Using this equation for each strong electrolyte an equation of the type of (6b) for $\Lambda_{(H^+ + A^-)}$ results through substitution in equation (4). Values of C_i, K' and K can then be computed from equations (3), (1) and (2), respectively. This method has been used successfully by MacInnes and Shedlovsky[9] in their work on acetic acid. Since the conductance data for each of our strong electrolytes is represented by equation (6b), we have also used this method.

Apparatus

The Bridges.—Two bridges were used. The first was a modified Jones and Josephs[10] type constructed from apparatus at hand in the laboratory. The Wagner ground consisted of a Kohlrausch slide wire and a General Radio type 219 G condenser. The ratio arms were a Leeds and Northrup Kohlrausch slide wire of the older, marble drum type. An a. c.–d. c. calibration showed that the a. c. error was very small for readings near the center of the bridge. The standard resistances were a Curtis coil and a bifilarly wound decade box, both from Leeds and Northrup, which were calibrated against similar boxes certified by the Bureau of Standards. An air condenser and a General Radio type 219 G condenser, shunted across the standard resistance, produced the correct phase relations. Current from the bridge was led through a transformer, thence to a two-stage amplifier

and telephone. At all concentrations absolute silence was obtained. All measurements with cell A, the weak acid and its sodium salt, were taken with this bridge.

All measurements with cell B, hydrochloric acid and its sodium salt, were made with the new Leeds and Northrup bridge which has been described by Dike.[11] The ratio arms and all resistances were carefully calibrated against standard resistances certified by the Bureau of Standards. The condensers built into the bridge were sufficient to produce the correct phase relations.

Cells.—Two cells were used: cell A for the weak acid and its sodium salt, and cell B for hydrochloric acid and its sodium salt. A diagram of cell A, drawn approximately to scale, is shown in Fig. 1 (A). It is made entirely of Pyrex. The flask is two liters in capacity. The electrodes are heavy platinum disks, 3.8 cm. in diameter, and are sealed through the glass by means of platinum tipped tungsten rods. The opening at the top of the cell is ground to fit the collar of a weight buret. Cell B is made of Jena "Geräteglas." Figure 1 (B), giving the lower section of this cell, shows the other essential difference in the construction of the two cells. The electrodes are 2.5 cm. in diameter and are supported by thin-walled platinum tubing. A tube, provided with a stopcock, is sealed into the bottom of the electrode compartment. Through this tube air, freed from carbon dioxide and ammonia, was blown through the water at the beginning of a run until the conductance remained sensibly constant. Both cells were well annealed and sufficiently aged. The electrodes in both cells are unplatinized in order to facilitate the transfer from one concentration or electrolyte to another and to avoid any possible effect on the weak acids. Our results indicate that accurate conductance measurements can be made with such unplatinized electrodes. That there is no serious capacitance to earth is shown by the fact that no change was noticed when the quantity of solution in the cell was varied from the amount necessary to barely fill the electrode compartment to an amount which filled the flask more than half full. With cell B, the capacitance correction given in equation (7) was negligible in the range of concentrations of hydrochloric acid and sodium chloride used.

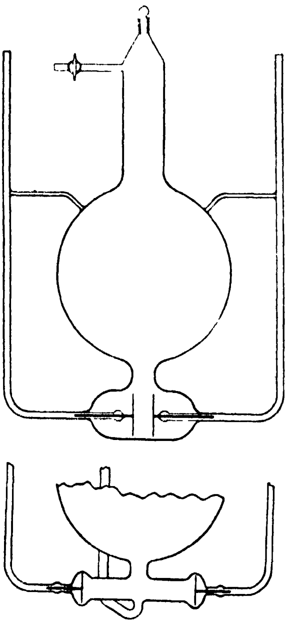

Fig. 1.—A, above; B, below.

Source of Power.—All recorded determinations were made at 1000 cycles generated by a shielded Vreeland oscillator situated about thirty feet from the bridge in another room. The low voltage secondary was connected to a potential divider, a manganin wire a meter long and of sixteen ohms resistance. By tapping about a millimeter from one binding post, a very low voltage was led directly to the first bridge. A somewhat greater voltage was sent through an intervening transformer to the second bridge.

Thermoregulation.—A rectangular porcelain thermostat, containing forty-five gallons of transformer oil, maintained a constant temperature. The bath was adjusted and its variation observed by a Beckmann thermometer which had recently been standardized against a platinum resistance thermometer. The temperature was 25.000 ± 0.005°.

Preparation of Materials

Conductivity Water.—For the measurements on the weak acid and its sodium salt, the water was obtained from a Barnstead automatic water still, electrically heated. The

---

(11) Dike, *Rev. Sci. Instruments*, **2**, 379 (1931).

cooling water was so regulated that less than one-half of the steam condensed. The first four liters after starting were discarded. The water was distilled directly into the vessel in which it was to be used. With care, the specific conductance was 10^{-6} mhos. Except for some of the most dilute solutions, the water conductance was less than 1% of the total conductance.

For the measurements on hydrochloric acid and its sodium salt the water was obtained by redistilling distilled water containing alkaline potassium permanganate in a Barnstead "Conductivity Water Still" which is a modified form of that described by Kraus and Dexter.[12] In general it was distilled directly into the vessels in which it was used, but for storage a properly protected 15-liter "Vitreosil" retort was used. The specific conductance of the water so stored was 3×10^{-7} mhos, while that of water collected directly in cell B and subsequently treated with air freed from carbon dioxide and ammonia was $1\text{–}2 \times 10^{-7}$ mhos.

Acids.—Baker C. P. Analyzed special arsenic free hydrochloric acid was distilled twice from an all Pyrex glass still by trapping the hydrogen chloride gas which was driven off in water whose volume was one-third that of the acid introduced into the flask. Eastman's No. 68 monochloroacetic acid was distilled twice under diminished pressure. The product was a white solid melting at 62°. The cold solution showed no immediate turbidity with silver nitrate.

Salts.—For the cell constant determinations, Kahlbaum "Kaliumchlorid zur Analyse" was recrystallized four times from water. After drying for a day at 110°, it was fused in a platinum dish, then it was ground to a fine powder in an agate mortar. It was stored in a weighing bottle kept in a desiccator. A saturated solution of Baker C. P. Analyzed sodium chloride was dropped slowly into ethyl alcohol which had been distilled from lime. The precipitate was dissolved in water and the solution evaporated partially to reprecipitate sufficient salt. All the crystals were semi-dried by pressing and aspirating dust-free air over them. To prepare sodium monochloroacetate, the required amount of sodium carbonate was added slowly and with constant shaking to a known amount of the acid. The solution was neutral to litmus. The sodium carbonate was made from Merck C. P. sodium bicarbonate according to the directions in Treadwell-Hall.[13]

After being made alkaline with sodium carbonate and acidified with nitric acid, all solutions remained perfectly clear on addition of barium chloride, and all, except the chlorides, remained perfectly clear on addition of silver nitrate. The acids left no detectable residue when evaporated in platinum.

Experimental Procedure

The Conductance Measurements.—All measurements were in concentration series. A weighed amount of conductivity water was introduced into the cell, brought to the temperature of the thermostat and its conductance measured. Successive samples of analyzed stock solution were added with a weight buret, the solution thoroughly mixed, and after reaching the temperature of the thermostat, the conductance of the solution was determined. In each measurement the cell and standard resistance were reversed and the ratio again taken. With the first bridge, the ratio arms were kept as nearly as possible equal to unity, with the second bridge

---

(12) Kraus and Dexter, THIS JOURNAL, 44, 2469 (1922).

(13) Treadwell-Hall, "Analytical Chemistry," John Wiley and Sons, New York, 1924, Vol. II, p. 475.

the ratio arms were always equal. The equivalent series resistance, R_4, of the cell was calculated from the equation[14]

$$R_4 = \frac{R_2}{R_1}\,\frac{R_3}{1 + R_3^2\,\omega^2\,C_3^2 + R_3\omega C_3\theta_3} \qquad (7)$$

where R_1 and R_2 are the resistances of the ratio arms of the bridge, R_3 is the standard resistance, C_3 is the capacity of the condenser shunting R_3, and ω is 2π times the frequency. The last term in the denominator including θ_3, the phase difference in the condenser, is negligible except in the case of a few of the more concentrated solutions when measured in cell A. No change in the value of R_4, calculated from this equation, resulted when the frequency was changed from 1000 to 500. The whole water conductance was subtracted for the salts and neglected for the acids. The cell constants were determined with one hundredth demal potassium chloride prepared according to the directions of Parker and Parker.[15] Taking their value of 0.0014078_9 as the specific conductance, the cell constants are 0.07308 and 3.8503 for cells A and B, respectively.[16]

Determination of Concentrations.—The analyses of the stock solutions were calculated as the true weight of electrolyte per gram of solution weighed in air. Chlorides were weighed as silver chloride. In the case of sodium chloride this was checked against the value determined by synthesis. Monochloroacetic acid was titrated against sodium carbonate with sodium alizarin sulfonate as indicator. From the amounts used in preparation, the concentration of sodium monochloroacetate was calculated. Estimating the densities by interpolation, the concentration, in moles per liter of solution, was calculated.

Results

The measured equivalent conductances of the necessary strong electrolytes are expressed in equations (8), (9) and (11), and from these expressions equations (10) and (12) are derived.

$$H^+ + Cl^-;^{17} \quad \Lambda = 426.01 - 156.84\sqrt{C_i} + 169.7\,C_i(1 - 0.2276\sqrt{C_i}) \qquad (8)$$

$$Na^+ + Cl^-;^{17} \quad \Lambda = 126.39 - 88.65\sqrt{C_i} + 94.8\,C_i(1 - 0.2276\sqrt{C_i}) \qquad (9)$$

$$H^+ - Na^+; \quad \Lambda = 299.62 - 68.19\sqrt{C_i} + 74.9\,C_i(1 - 0.2276\sqrt{C_i}) \qquad (10)$$

---

(14) This relation, easily derived from the theory of the alternating current bridge on the assumption that R_1, R_2 and R_3 are reactance free, is essentially the same as equations (23) and (24) of Jones and Josephs, THIS JOURNAL, **50**, 1049 (1928).

(15) Parker and Parker, *ibid.*, **46**, 312 (1924).

(16) Since this paper was written, Jones and Bradshaw [*ibid.*, **55**, 1780 (1933)] have reported new values for the specific conductances of potassium chloride. Their value for the 0.01 D solution is 0.062% higher than that given by Parker and Parker. If the new value be adopted, our cell constants and all our values of Λ should be increased by that amount, but our values of C_i, K' and K would be unaffected. The data of Shedlovsky, THIS JOURNAL, **54**, 1411 (1932), and of MacInnes and Shedlovsky, *ibid.*, **54**, 1429 (1932), with which we later compare certain of our measurements, would only be raised by 0.028%, since their cell constants were determined with 0.1 D potassium chloride. In general, the agreement for the dilute solutions is improved in the cases of sodium chloride and sodium acetate, but is not improved in the case of hydrochloric acid.

(17) Determined by Lawrence S. Darken and Harry F. Meier in this Laboratory.

$$\mathrm{Na^+ + A^-};\quad \Lambda = 90.02 - 80.37\sqrt{C_i} + 67.7\,C_i(1 - 0.2276\sqrt{C_i}) \tag{11}$$

$$\mathrm{H^+ + A^-};\quad \Lambda = 389.64 - 148.56\sqrt{C_i} + 142.6\,C_i(1 - 0.2276\sqrt{C_i}) \tag{12}$$

Our experimental results are compared with those calculated from equations (8), (9) and (11) in Table I.

Our results for hydrochloric acid and sodium chloride are in good agreement with those of Shedlovsky[18] but are higher than those of Jeffery and Vogel.[19] From equation (12) and the conductances of monochloroacetic acid given in Table II, the remainder of the table was constructed.

If log ($K' \times 10^3$) be plotted against $\sqrt{C_i}$, the first six points, excluding the first, fall on a straight line, the equation of which is

$$\log (K' \times 10^3) = 0.1449 + 1.011\sqrt{C_i} \tag{13}$$

From this it is apparent that nearly the theoretical slope has been obtained and that $K = 1.396 \times 10^{-3}$, which is the average of the first six values in Table II, again excluding the first value. Above 0.01 normal the curve falls below the limiting slope and the values of K decrease. This decrease

has been observed with acetic acid by MacInnes and Shedlovsky.[5] For both acids log K decreases approximately linearly with C_u, the concentration of the un-ionized acid. Further examples and a discussion of this relation will appear in a later paper from this Laboratory.

From a plot of log K' against $\sqrt{C_i}$ it is evident that equation (13) may be written

$$\log k' = \log K + a\sqrt{C_i} \tag{14}$$

where a in the dilute range approaches the theoretical value, 1.013, but decreases with concentration. Since $C_i^2/C_u = K'$, it follows that

$$\log K' = \log K + a(K')^{1/4}\, C_u^{1/4} \tag{15}$$

and since K' increases with concentration it may be expected that log K' should be a linear function of $C_u^{1/4}$, at least in the region of concentration in which the "medium effect" is not pronounced. This relation holds for monochloroacetic acid. If the acid is sufficiently weak, C_u may be replaced by C, the total acid concentration, and log K' and C_i may then be calculated from C. Even with an acid as strong as monochloroacetic the data can be represented by

$$\log (K' \times 10^3) = 0.1449 + 0.1794C^{1/4} \tag{16}$$

Excluding the first result, this equation reproduces the measured values of K' to within ±0.18% and the values of C_i to within ±0.07% and, therefore, gives a satisfactory method for calculating C_i from C. If this method be applied to MacInnes and Shedlovsky's[5] data on acetic acid, the results up to 0.01 N are given by the equation

$$\log (K' \times 10^5) = 0.24378 + 0.06074C^{1/4} \tag{17}$$

Above this concentration, the measured values of log K' fall below those calculated using equation (17) and the deviation is linear with C, which is to be expected if this is due to the "medium effect." Accordingly, a term in C was added to equation (17) giving

$$\log (K' \times 10^5) = 0.24378 + 0.06302C^{1/4} - 0.1256C \tag{18}$$

This equation reproduces K' to within ±0.10% and the values of C_i to within ±0.04%. It should be borne in mind that equations (16) and (18) reproduce the values of K' and C_i for the two acids, respectively, as measured by a conductance ratio in which $\Lambda_{(H^+ + A^-)}$ has been corrected for interionic forces but not for the presence of the un-ionized portion of the acid. More properly these are only apparent values except in the concentration range in which equation (2) is obeyed.

We have carried out similar measurements on acetic acid and its sodium salt in cell A. Our results agree with those of MacInnes and Shedlovsky[5] and not with those of Jeffery and Vogel.[20] Briefly, our results for sodium acetate are given by the equation

$$\Lambda = 90.91 - 80.57\sqrt{C_i} + 89.7C_i(1 - 0.2276\sqrt{C_i}) \qquad (19)$$

and our value of K is 1.759×10^{-5}. Our equivalent conductances for the acid are slightly higher than those of MacInnes and Shedlovsky.[5] This is probably due to the fact that our first conductivity water was not good enough for the measurements with such a weak acid. Their lower value, 1.753×10^{-5}, or 1.754×10^{-5} obtained by Harned and Ehlers[21] for electromotive force measurements is to be preferred.

Summary

Using a "flask" cell and bright platinum electrodes, the conductances of hydrochloric and monochloroacetic acids and their sodium salts have been measured and reported.

The results with all the strong electrolytes (those mentioned above and sodium acetate for which the equation only is given) confirm Onsager's equation as a limiting law, and up to our highest concentration, 0.03 N, agree with Shedlovsky's extension of Onsager's equation.

It has been shown that the theoretical constant of the limiting law of Debye and Hückel correctly represents the dependence of the activity coefficient of monochloroacetic acid upon its ionic concentration. Using this limiting law, the thermodynamic ionization constant of the acid is found to be 1.396×10^{-3}.

The values of the constant for acetic acid obtained by Harned and Ehlers and by MacInnes and Shedlovsky have been confirmed.

Notes

A Simple Automatic Pressure Regulator

By C. C. Coffin

One of the most satisfactory and convenient methods of obtaining constant temperatures in the laboratory is to use as a bath the vapor of a liquid boiling under a constant pressure. A pressure regulator is therefore necessary for accurate work with this type of thermostat particularly if the desired temperature corresponds to a vapor pressure much below one atmosphere. If the liquid is mercury, for example, a pressure change of 0.1 mm. at 200° (17.3 mm. Hg) corresponds to a temperature change of 0.17°. At 350° (697.8 mm. Hg) a pressure variation of 0.1 mm. produces a change of only 0.008°. The need of accurate pressure control at the lower pressures is obvious.

The purpose of this note is to describe a simple pressure regulator which has been found to be very satisfactory. It has been used particularly for obtaining constant temperatures between 210 and 280° with the vapor of boiling mercury[1] and would appear to the writer to possess certain advantages over some other regulators[2] which invariably involve the annoyance of mechanically operated valves to vacuum or pressure.

The operation of the regulator is made obvious by the accompanying diagram. The tube A connects with the space above the boiling mercury and with a 20-liter stabilizing volume the pressure changes in which move the manometer M to operate a relay R controlling the nichrome heating coil C. To set the apparatus in operation the pressure in the system is brought by means of tap B to a value slightly less than that desired and the amount of mercury in the manometer is adjusted by taps G and H until the surface on the vacuum side is slightly below the platinum point F. The switch S is then closed, C heats, and when contact is made at F the relay operates to break the heating circuit. The gas in D then cools, contact at F is broken and the cycle is repeated. The amount of mercury in M and the current in C should be adjusted to the rate of cooling of D so that the times of "make" and "break" are approximately equal. This

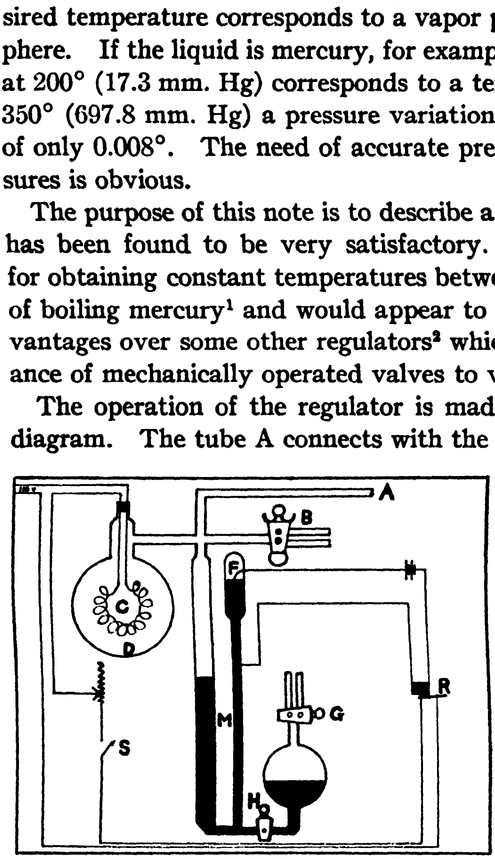

Fig. 1.—Automatic pressure regulator.

[1] C. C. Coffin, *Can. J. of Research*, **5**, 636 (1931); **6**, 417 (1932); **7**, 75 (1932).

[2] Mathews and Faville, *J. Phys. Chem.*, **22**, 3 (1918); D. F. Smith, *Ind. Eng. Chem.*, **16**, 22 (1924); Carroll, Rollefson and Mathews, This Journal, **47**, 1791 (1925).

time should be long enough (several seconds) to prevent the manometer from building up a periodic oscillation.

When in operation the movement of the mercury surface at F is too small to be observed. Temperature measurements on a platinum thermometer in the mercury vapor at about 200° indicated that the pressure remained constant to well within 0.01 mm. while the temperature of the stabilizing volume was varied some 5°. The maximum change in room temperature that the heater can compensate for is, of course, dependent on such factors as the coil dimensions, the power input and the fraction that D is of the total volume. The fact that the control manometer is influenced by changes in room temperature introduces a slight error which, in precision work, could be avoided by the use of a thermostat.

This simple regulator should prove to be useful in many cases where a constant high or low pressure is required.

Other applications of an electrically heated wire in the construction of automatic laboratory devices will be discussed elsewhere.

Adaptation of the Dimethylglyoxime–Benzidine Test for Cobalt to the Usual Scheme of Qualitative Analysis

BY ALFRED W. SCOTT

A. Chiarothino[1] states that a solution containing cobalt when treated with an alcoholic solution of dimethylglyoxime and benzidine gives an orange-red color. It is further stated that this test must be carried out in a neutral solution.

In nearly all schemes of qualitative analysis the cobalt and nickel precipitate, or the solution obtained from it, is divided into two parts in order to run confirmatory tests for these two cations. The author thought that if the dimethylglyoxime–benzidine test could be adapted to the usual scheme of analysis it might be of advantage since all of the cobalt and nickel precipitate could be used for each test. The following procedure, suitable for use in the ordinary scheme of qualitative analysis, was found to give satisfactory results even when the concentration of nickel was fifty times that of cobalt.

The precipitate of cobalt and nickel sulfides, after separation from the rest of the group three precipitate, is dissolved in hydrochloric acid containing a little nitric acid. The solution is filtered and the filtrate evaporated practically to dryness. The residue is dissolved in a few cc. of water containing 1 cc. of dilute acetic acid. To this solution is added 1 g. of solid sodium acetate, 0.5 cc. of a 0.5% alcoholic solution of benzidine and an excess of an alcoholic solution of dimethylglyoxime. If nickel is present the solution is filtered. In the absence of cobalt the filtrate will be colorless to yellow. If cobalt is present the filtrate will have a red coloration. Should the concentration of cobalt be so small that the red color is not very pronounced, it may be intensified by adding solid sodium acetate and allowing to stand for several hours.

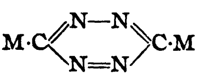
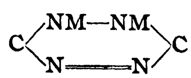
Tetrazine[1]

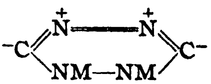
BY DENNISTOUN WOOD, JR., AND F. W. BERGSTROM

In connection with our attempts to prepare nitrogenous derivatives of divalent carbon,[2] we were interested by Müller's statement[3] that "1,2,4,5-tetrazine still contains two atoms of hydrogen which may be replaced by metals, and so have an acid character." In support of his statement, Müller has only his observation that tetrazine and silver nitrate form a precipitate of dark green needles,[4] but no analysis of this has been made.[5] On the other hand, Hantzsch and Lehmann[6] state that tetrazine forms no salts with either acids or bases, but that it reduces silver nitrate and mercuric chloride.

In view of these conflicting statements, it became desirable to see whether or not tetrazine[7] does form metallic salts corresponding to one or more of the formulas (M is a monovalent metal).







Preparation and Properties of Tetrazine.—Tetrazine was prepared from monochloroacetic acid through the following intermediates: glycine ethyl ester hydrochloride,[8] ethyl diazoacetate,[9] sodium bisdiazoacetate,[10] bisdiazoacetic acid,[8] tetrazine dicarboxylic acid.[11] Tetrazine[12] itself was prepared by heating an intimate mixture of its dicarboxylic acid with sand. A wad of glass wool is placed over the sand layer in the test-tube to prevent contamination of the tetrazine with undecomposed acid and sand. It is worthy of mention that we have found the yield of tetrazine to depend largely upon the length of time which the tetrazine dicarboxylic acid was dried in a vacuum, in conformity with the results of earlier investigators. The maximum amount obtained in this work was 16.8% of the theoretical. The total yield of tetrazine from 10 kg. of chloroacetic acid was only 7.9 g., or 0.18%, largely due to the fact that half of the dicarboxylic acid decomposed, apparently under the influence of radiant energy from a nearby muffle furnace.

Tetrazine itself is crimson colored, melting at 99° to a purple-red liquid. It is volatile even at room temperatures, and at higher temperatures is converted to a gas resembling iodine vapor in color. Its sharp irritating odor is also not unlike that of iodine. It has a bitter taste. Ethereal solutions of tetrazine cannot be concentrated even by vacuum distillation, because the solute volatilizes with the solvent. As will be shown later, liquid ammonia, maintained below −40°, is the only solvent from which tetrazine has ever been recovered. The solubility of tetrazine in water at 20° is roughly 6 g. in 100 cc. The solutions, even in great dilution, are pink.

As a general rule, it is essential to use tetrazine immediately after its preparation, but a pure specimen may be kept without decomposition for many months if sealed in a tube under its own vapor pressure. Left in air-filled tubes, even pure tetrazine becomes dark and pasty in a few hours, while the impure compound prepared from slightly moist tetrazine dicarboxylic acid, decomposes more rapidly. Much of the tetrazine may be recovered from the unpromising looking pasty mass by mixing it with barium oxide and resubliming. Dilute hydrochloric or sulfuric acid slowly decomposes tetrazine with evolution of gas (undoubtedly nitrogen) and conversion to a colorless solution. Very dilute ammonium or sodium hydroxide causes no apparent immediate change. In greater concentration, these alkalies together with potassium hydroxide turn tetrazine solutions brown, but ether extracts practically no color from them. Very little if any of the tetrazine is regenerated on acidification.

Tetrazine in its aqueous solution may best be recognized in the following manner. Hydrogen sulfide is passed through the ice cold solution until the pink color has changed to pale yellow, because of the formation of dihydrotetrazine.[13] Excess hydrogen sulfide is removed by a stream of nitrogen. A little ether and a few drops of sodium nitrite solution are added, the mixture is acidified with dilute acetic acid and shaken. The ether layer assumes a beautiful violet color from the regenerated tetrazine.

Reactions of Tetrazine outside of Ammonia.—Aqueous solutions of tetrazine produce no precipitate with picric acid, ferric chloride, lead dichloride or mercuric cyanide. With silver nitrate, an unstable explosive gelatinous precipitate of variable composition is formed. Auric chloride and tetrazine react in water to form a buff-colored precipitate, with evolution of gas and the occasional formation of metallic gold. The analyses of the precipitate are inconsistent. Hot aqueous mercuric chloride is reduced to mercurous chloride. Chloroplatinic acid does not form a precipitate with tetrazine, but when the reagents are sufficiently concentrated there is a rapid evolution of gas, indicating decomposition. It is evident that tetrazine may act as a reducing agent, as might be anticipated since it is a derivative of hydrazine. With a diethyl ether solution of methylmagnesium iodide, tetrazine forms a precipitate, apparently of an addition compound, since no methane is evolved.

The Behavior of Tetrazine with Ammonia.—Tetrazine is colored a deep purple by a small amount of ammonia at room temperature, but in a rapid stream of this gas it soon becomes pasty, occasionally hardening again in the ammonia atmosphere. The product, whose nature we have not been able to ascertain, explodes when rubbed with a glass rod. It dissolves readily in liquid ammonia, usually with a purple color, which may alter on standing. After evaporation of the solvent there remains a brick-red to purple imperfectly crystalline residue, a number of analyses of which are included in Table I.

---

[13] Curtius, Darapsky and Müller, *Ber.*, **40**, 86, 815–837 (1907).

Pure tetrazine dissolves readily in liquid ammonia at −40°. The more concentrated solutions are dark brown, the very dilute solutions pale buff, and the intermediate ones deep blood-red.

When a liquid ammonia solution of tetrazine which has been kept constantly at −40° or below is evaporated dry in a vacuum, a purple or copper-red substance is left in which are imbedded numerous small red crystals. These latter have been positively identified as unchanged tetrazine. The purple or copper-red material seems to be tetrazine coated with a thin film of the substances formed by the reaction of tetrazine with gaseous ammonia.

In Table I are summarized the analyses of a number of specimens of tetrazine, treated with gaseous or liquid ammonia at various temperatures. The extent of the decomposition of the specimens may be judged by an inspection of the analyses, since, theoretically, none of the nitrogen of tetrazine can be determined by the Kjeldahl method[14] (actually, see preparation 5).

TABLE I

Specimen Number	I	II	III	IV	V
% "Kjeldahl" Nitrogen	20.2	19.0	18.9	3.7	6.0

SPECIMEN I.—Tetrazine added to liquid ammonia at −40°, and solution allowed to stand at room temperature overnight.

SPECIMEN II.—Same as above, but solution allowed to stand at room temperatures for five to six hours.

SPECIMEN III.—Liquid ammonia distilled onto the purple product formed by the action of ammonia gas on tetrazine; solution allowed to stand for one day.

SPECIMEN IV.—Tetrazine added to liquid ammonia at −40°, and solution kept at this temperature until evaporated dry in a vacuum.

SPECIMEN V.—Pure tetrazine, not treated with ammonia.

The Reaction with Potassium Amide.—The reaction of tetrazine with potassium amide in liquid ammonia solution is carried out in Faraday tubes of the type described by Franklin[15a] and by Schurman and Fernelius,[16] in accordance with the technique first developed by Franklin and his co-workers.[15]

The addition of potassium amide to an excess (1.5 moles) of tetrazine causes the formation of a dark brown solution, from which nothing definite was isolated. The reverse addition of tetrazine to potassium amide in excess of 2 equivalents results in the precipitation of a substance approximating a dipotassium salt, $C_2N_4K_2$, in composition. If prepared in the customary manner from tetrazine that has reacted with liquid or gaseous ammonia at room temperatures, there are obtained gray-green to dark brown curdy or stringy precipitates, which usually can be hydrolyzed by water vapor without accident, giving solutions from which only relatively small amounts of tetrazine can be recovered. Since dilute sulfuric acid slowly decomposes these solutions with the formation of some hydrocyanic acid, it is concluded that the potassium salt, prepared in the described manner, is for the most part not a true derivative of tetrazine.

The decomposition of the dipotassium tetrazine is largely prevented if it is prepared and washed at a low temperature. To this end, tetrazine is dropped into liquid ammonia

maintained around −40° by an external bath. The ammonia is contained in one leg of a reaction tube described by Schurman and Fernelius,[16] the other leg containing a solution of an excess of potassium amide, likewise cooled to −40°. With the addition tube sealed shut, the tetrazine is slowly poured into the potassium amide solution, producing a blood-red finely divided crystalline precipitate. This is thoroughly washed with liquid ammonia, still taking care that the temperature of the solvent does not rise above its normal boiling point. The legs of the reaction tube are separated, the precipitate leg evacuated at room temperature, the substance moistened with dry benzene, then hydrolyzed with moist benzene, and finally with water. A trace of air or of the vapor of air-free water invariably explodes the compound, and even a slight shock may detonate it. The explosions are remarkably violent, and may prove disastrous out of all proportion to the small amount of material involved.

That the blood red crystalline precipitate obtained in this manner is a true derivative of tetrazine is shown by the addition to this salt of an excess of cooled ammonium bromide solution, all reactants necessarily being held at a temperature of −40°. The precipitate dissolves to form a dull red solution, from which the solvent is removed by evaporation under diminished pressure. From the reddish purple solid, crystals of tetrazine are sublimed and condensed on a portion of the tube cooled by a swab dipped in liquid ammonia; m. p. 96–97°. The reduction–oxidation test, previously described in this article, likewise shows the presence of tetrazine.

TABLE II

ANALYSES OF THE PRECIPITATES FORMED BY THE ACTION OF TETRAZINE ON AN EXCESS OF POTASSIUM AMIDE

Specimen No.	I	II	III	IV	V	VI	VII	VIII	IX	X
Moles KNH_2 per mole tetrazine[a]	2.79	3.30	3.34	3.50	7.4	3.30	2.40	2.5	3.75	3.75
% K	45.2	52.7	45.5	50.0	49.0	54.0 50.6	49.8	45.6	48.5	51.4
% "Kjeldahl N_2"[b]	14.9	15.3					23.6			

Average: K, 49.4. Calcd. for $K_2C_2N_4$: K, 49.4, "Kjeldahl Nitrogen" 0.0. Calcd. for $C_2H_2N_4 \cdot 2KNH_2$: K, 40.7.

[a] Reagents used in the reaction. [b] The Kjeldahl nitrogen is a quantity that cannot be calculated, since hydrolysis of the salt gives locally a high concentration of potassium hydroxide, which decomposes tetrazine in an unknown manner. Kjeldahl N is higher in the salts in which some previous decomposition is known to have occurred (No. VII).

Specimens I to VI were prepared from the cold solution of tetrazine in liquid ammonia. They were therefore all blood-red precipitates, except the second specimen VI. Specimen I was prepared with as great speed as possible at −40°. Specimens II to V stood overnight covered by liquid ammonia at room temperatures. Specimens VI were the products of continued washing of the precipitated salt with liquid ammonia. The upper analysis was of the red residue less soluble in ammonia, the lower analysis of the yellow substance left by evaporation of the wash liquid. Specimens VII to X were prepared from solutions of tetrazine which had reacted with ammonia, and so were brown or green precipitates. Specimen VII was made from tetrazine which had stood in liquid ammonia for seventy hours. Specimens VIII to X were made from tetrazine which had reacted with gaseous ammonia before being dissolved in the liquid.

The Reaction of Alkyl and Aralkyl Halides with Dipotassium Tetrazine.—The freshly prepared, and therefore reactive, salt of tetrazine explodes violently when exposed to methyl iodide vapor. Potassium cyanide is found among the reaction products.

Benzyl bromide reacts readily with the undecomposed salt in liquid ammonia solution, but no definite products were isolated.

Decomposition of Dipotassium Tetrazine under Liquid Ammonia.—When the blood-red dipotassium salt of tetrazine is allowed to stand for some hours under liquid ammonia at room temperature, the supernatant liquid becomes yellow, and the precipitate, while still explosive, has lost some of its sensitiveness. It may be safely hydrolyzed with water vapor. In the evaporation of a sulfuric acid solution of the substance some hydrazine sulfate appears to be formed.

In order to accelerate its decomposition, the dipotassium salt from 2.56 millimoles of tetrazine was heated for seven hours at 95–100° in liquid ammonia,[17] 2.50 millimoles of N_2 and 0.38 millimole of H_2 were obtained. The hydrolysate of the buff-colored precipitate could not be shown definitely to contain tetrazine, but a small amount of hydrazine was formed and identified by conversion to benzalazine. No N-aminotriazole was found.

Attempts to Synthesize Tetrazine by Other Methods.—Formimidoethyl ester hydrochloride, $H\cdot C(=NH)OC_2H_5\cdot HCl$, reacts with an aqueous solution of hydrazine hydrate and potassium hydroxide, or with a solution of hydrazine in liquid ammonia, to form small amounts of dihydrotetrazine, which are oxidized to tetrazine by atmospheric oxygen. The tetrazine was recognized by qualitative test, since it could not be isolated.

Dibenzyl- and Diphenyltetrazine.[18]—Both of these substances are sparingly soluble in liquid ammonia but dissolve readily in solutions of sodium or potassium amide at −40° or room temperatures to form, respectively, a deep red, and a lighter colored orange solution. Some nitrogen is evolved at the same time. The results will be reported at a later date.

Summary

1. Tetrazine reacts with aqueous solutions of silver nitrate, mercuric chloride, auric chloride and chloroplatinic acid, but without the formation of metallic salts or of definite addition compounds. The salt is often reduced to free metal.

2. Tetrazine dissolves in liquid ammonia and may be recovered from it unchanged, if the solution be kept at or below −40°. Otherwise, decomposition occurs. A number of new properties of tetrazine have been described.

3. Potassium amide reacts with tetrazine in liquid ammonia at −40° to form a red, highly explosive ammonia insoluble salt, approximately $K_2C_2N_4$, from which tetrazine may be recovered. At higher temperatures, the salt is slowly decomposed.

The Oxidation of 5-Keto-gluconic Acid with Nitric Acid in the Presence of Vanadium

BY W. E. BARCH

5-Keto-gluconic acid has been obtained by Boutroux and others[1] from glucose by means of certain oxidizing organisms (bacterium xylinum, bacterium gluconium, etc.). Kiliani[2] obtained it by chemical means from glucose, by mild oxidation with nitric acid. His method of preparation has been the source of the material used in the following.

Boutroux[2b] oxidized the acid with nitric acid and identified among the products of oxidation racemic acid, trihydroxyxyloglutaric acid, glyoxylic acid, and others.

It has been shown by Odell[3] that *d*-tartaric acid may be obtained by nitric acid oxidation, in the presence of vanadium, of common starch.

There will be an attempt to show, in future publications, that this means of oxidation offers certain advantages over that using nitric acid alone, or other oxidizing agents, in the study of the oxidative degradation of the monosaccharides, their acids, and other derivatives. A major portion of the original molecule may be recovered in the form of four carbon acids, (*d*-tartaric, *l*-tartaric, racemic or mesotartaric acids, dependent on the configuration of the starting material). These acids are readily followed analytically in the presence of each other and other products of oxidation which may be present.

5-Keto-gluconic acid was chosen as the subject of this preliminary paper because of the relative simplicity of the oxidation, and because of its application as a partial picture of the more complex oxidation of glucose itself.

It was the original intention to conduct the experiments with the free acid. It was found that the sirup obtained from the calcium salt of the acid by decomposition with oxalic acid was too unstable in the high concentration necessary for the oxidation. It rapidly turns black on standing a short time in the desiccator over sulfuric acid, swelling and evolving gas.

It was found, however, that the calcium salt itself was suitable for the purpose. It is quite easily obtained in the pure condition, and dissolves readily in the nitric acid used in the experiments. The calcium of the salt appears early in the oxidation as calcium oxalate and may be removed by simple filtration.

Discussion

The results of twelve oxidations are tabulated according to the analytical methods described in the experimental part.

The experiments are calculated on the basis of percentage of total carbon recovered from the original starting material as 100%.

It will be noted that as much as two-thirds of the original acid may be recoverable in readily determined non-gaseous products.

The main products are tartaric, racemic, trihydroxyxyloglutaric, and oxalic acids as shown. The column labeled carbon dioxide may be considered a rough estimation only, as it includes only that gas formed under the reflux and does not include that formed on evaporating off the nitric acid *in vacuo*. It is of interest chiefly in Part 1 in which the nitric acid was entirely consumed during the refluxing. One carbon of the six original carbons in the ketogluconic acid being 16.67%, it will be noted that the percentage of the gas with different molecular proportions of nitric acid closely approximates molecular proportions.

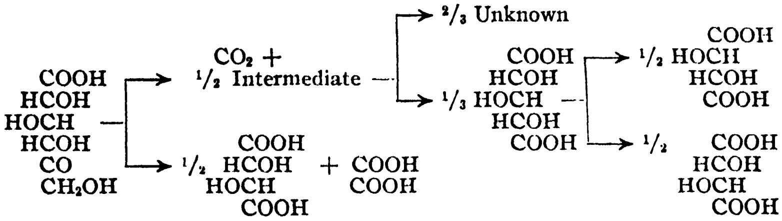
Referring first to Part 1, here the amount of available oxygen has been varied by varying the amount of nitric acid in each experiment. It has been a matter of observation, in this work, that at the boiling temperature nitric acid is deprived of oxygen by a simple reduction to nitrous acid, and therefore furnishes one molecular proportion of oxygen to one of nitric acid. This is true only at the higher temperatures, longer contact with the acid producing further reduction. In order to break the carbon chain at the keto group to tartaric and oxalic acids, or to trihydroxyxyloglutaric acid and carbon dioxide, three molecular proportions of oxygen are required. In this first series of four experiments, the following significant observations may be made. The greater bulk of the tartaric acid appears before any racemic or trihydroxyxyloglutaric acid can be detected. However, carbon dioxide, one-twelfth of the molecule (necessary for the postulation of one-half the original molecule breaking between carbon five and six) is formed at once. The amount shows no increase on increasing the molecular proportions of nitric acid from 2 to 2.5, indicating it as an early phenomenon. As tartaric acid continues to increase, the tryhydroxyxyloglutaric acid appears, oxidizing rapidly further to racemic acid. In the fourth experiment, with the splitting of the carbon chain presumably complete, the trihydroxyxyloglutaric acid has almost disappeared, the earlier formed tartaric acid has suffered by further oxidation, and the racemic acid is at its maximum point.

In Part 2, the available oxygen has been varied by time of contact with the nitric acid, using the same amount of nitric acid in each experiment. Here the peak for trihydroxyxyloglutaric acid is clearly shown, with its subsequent rapid disappearance.

All the products of the oxidation are themselves subject to further oxidation, making it probable that none of the observed results represent maxima. This is shown, to some extent, in Part 4, where the conditions of the oxidation are more mild than the foregoing. The amount of tartaric acid obtained here is near the maximum (33.3%) required by theory, and the trihydroxyxyloglutaric acid is also increased.

Summarizing, briefly, the following conclusions may be drawn on the breakdown of the carbon chain in 5-keto-gluconic acid on oxidation with nitric acid in the presence of vanadium.

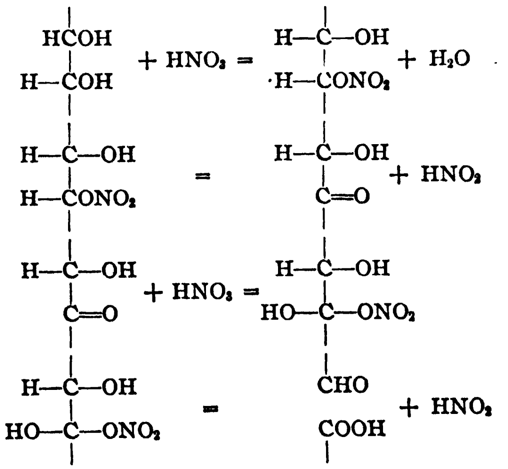
The chain breaks on either side of keto group, equally between the break between carbon four and five and the break between carbon five and six; 50% of the molecule appears as tartaric and oxalic acids. Only one-third of the five carbon fragment appears as trihydroxyxyloglutaric acid, which is subsequently further oxidized to racemic acid. In this way, two-thirds of the original keto-gluconic molecule has been accounted for, the fate of the remaining one-third being unknown.



²/₃ Unknown
COOH HCOH HOCH HCOH CO CH₂OH
CO₂ + ¹/₂ Intermediate
¹/₃ HOCH (COOH HCOH HOCH HCOH COOH)
¹/₂ HOCH (COOH HOCH HCOH COOH)
¹/₂ (COOH HCOH HOCH COOH)
¹/₂ HCOH (COOH HCOH HOCH COOH) + COOH COOH

It is probable that vanadium is catalytically manifested only by the early break of the carbon chain between carbon four and five. Although four-carbon acids have been reported as products of oxidation of hexose derivatives, without the use of this catalyst, it is probable that they are the result of a secondary oxidation of the first formed five-carbon acid, as illustrated by racemic acid in these experiments.

There is indirect evidence for the following hypothesis as to the reaction mechanism.



$$\begin{array}{c} | \\ \mathrm{HCOH} \\ | \\ \mathrm{H{-}COH} \\ | \end{array} + HNO_3 = \begin{array}{c} | \\ \mathrm{H{-}C{-}OH} \\ | \\ \mathrm{H{-}CONO_2} \\ | \end{array} + H_2O$$

$$\begin{array}{c} | \\ \mathrm{H{-}C{-}OH} \\ | \\ \mathrm{H{-}CONO_2} \\ | \end{array} = \begin{array}{c} | \\ \mathrm{H{-}C{-}OH} \\ | \\ \mathrm{C{=}O} \\ | \end{array} + HNO_2$$

$$\begin{array}{c} | \\ \mathrm{H{-}C{-}OH} \\ | \\ \mathrm{C{=}O} \\ | \end{array} + HNO_3 = \begin{array}{c} | \\ \mathrm{H{-}C{-}OH} \\ | \\ \mathrm{HO{-}C{-}ONO_2} \\ | \end{array}$$

$$\begin{array}{c} | \\ \mathrm{H{-}C{-}OH} \\ | \\ \mathrm{HO{-}C{-}ONO_2} \\ | \end{array} = \begin{array}{c} | \\ \mathrm{CHO} \\ \\ \mathrm{COOH} \\ | \end{array} + HNO_3$$

When glucose is oxidized under the conditions described in this paper, and the reaction slowed, by cooling, after the first violent phase, the unreacted nitric acid may be removed by repeated extraction with ether. The resulting liquor, free of nitric acid, when allowed to stand a short time in sunlight gradually warms until there is again a violent reaction with vigorous evolution of nitrogen oxides.

The hypothesis of successive formation of unstable nitrates and their decomposition by loss of nitrous acid is also supported by the predominance of nitrogen peroxide over nitrogen monoxide in the early stages of the reaction and the evolution of nitrogen monoxide only, in the latter stages when the free nitric acid has been consumed.

$$\text{(Early stage)}\quad HNO_2 + HNO_3 = H_2O + 2NO_2$$
$$\text{(Latter stage)}\quad 3HNO_2 = HNO_3 + H_2O + 2NO$$

Experimental

Preparation of Calcium 5-Keto-gluconate.—The method of Kiliani is repeated here, with some variation.

One hundred grams of glucose is dissolved in 28 cc. of water in a 300-cc. Erlenmeyer flask. To this is added 52 cc. of concentrated nitric acid (this is approximately

1.5 mole). Any number of these preparations as described may be placed in a slowly circulating shallow bath at 20 to 25°. Working with larger quantities in a single lot is not advisable because of difficulties in cooling.

Fumes of nitrogen peroxide appear slowly after twenty-four hours and continue to evolve for several days. In a week's time the reaction has practically ceased, and the flasks may be removed.

One hundred grams of solid sodium acetate is added and stirred into the acid solution, until it has dissolved more or less completely, and then 25 g. of calcium chloride dihydrate, dissolved in a little water. The solution becomes rapidly darker in color and may show a haze of calcium oxalate. Crystallization begins after four or five hours and continues almost indefinitely. The product obtained after long standing, however, contains large quantities of calcium saccharate. The subsequent purification is easier, if the precipitate is filtered off after forty-eight hours.

The brown amorphous precipitate is redissolved in sufficient hydrochloric acid to be equivalent to the calcium present in the precipitate. The calcium oxalate will remain undissolved in the cold, and is filtered off, after adding norite. The filtered and decolorized solution is then neutralized to 85% of its total acidity with aqueous ammonia, care being taken to avoid local alkalinity which will again color the solution. The calcium keto-gluconate appears rapidly as a coarse crystalline meal and may be filtered in a few hours.

After a second recrystallization in this manner, a product was obtained, pure white in color, containing 11.66% CaO, calcd. for $Ca(C_6H_9O_7)_2—3H_2O$, 11.67%. One gram dissolved in the theoretical amount of hydrochloric acid plus 5%, and made up to 25 cc., shows α^{20}_{D} of $-11.69°$, which calculated to the free acid is $-14.43°$. It shows no loss in weight on drying in the oven at 100°; yield, 10–12%.

Oxidation.—All experiments were conducted in the same manner, using 10 g. of the above prepared salt in a 250-cc. round-bottomed flask with a reflux condenser ground to fit the flask. The salt was covered with sufficient water to be equivalent, by volume, to 25% of the nitric acid used in the experiment. 0.001 g. of sodium orthovanadate was present in each experiment. The top of the reflux condenser was connected to two wash bottles containing concentrated sulfuric acid to absorb the bulk of the nitrogen oxides and then to a bottle containing 40% potassium hydroxide, protected from the atmosphere with a long tube coarsely packed with soda lime. This last was for a rough estimation of the carbon dioxide formed, which was determined on an aliquot of the potassium hydroxide solution by the usual volumetric method.

The flask containing the nitric acid, salt, water and sodium orthovanadate was immersed completely in a water-bath and heated to 100° (except where otherwise mentioned).

The reaction proceeds in three stages. The colorless solution very slowly turns green, a few desultory bubbles appear, increasing rapidly in number until a violent reaction ensues, with large quantities of red nitrogen peroxide evolving from the surface of the solution. The violent reaction is very brief and is succeeded by a slower reaction which continues for several hours. In this phase the nitrogen peroxide ceases to be evolved and is replaced by a slower evolution of nitrogen monoxide. The reaction is complete after all evolution of gas has ceased. Early in the reaction, soon after the violent phase, calcium oxalate begins to appear, in unusually coarse, granular crystals. To ensure the complete removal of the nitric acid, each experiment was evaporated to dryness in the vacuum without removing from the reaction flask.

Analysis.—The dry material is dissolved in a small quantity of hot water and the insoluble calcium oxalate filtered off. The filtrate is collected in a 10-cc. volumetric flask; 1 cc. is taken for titration with *N*/5 alkali. The same titration sample is then used for an oxalic acid determination. The remaining portion of the filtrate is then neutralized with the calculated quantity of a strong solution of potassium hydroxide (cooling) and rendered acid again with concentrated hydrochloric acid equivalent to exactly one-half the amount of the potassium hydroxide. The potassium acid salts of tartaric and racemic acids precipitate immediately and are filtered off after standing for forty-eight hours. The precipitate is washed with 60% alcohol.

The resulting precipitate is dried in the oven at 100° for twelve hours. A 1-g. sample is titrated with $N/5$ potassium hydroxide, then made up to 25 cc. and polarized. From the titration of pure potassium acid tartrate (26.58 cc.), and the specific rotation of potassium tartrate (α^{20}_{D} + 27.58°), the relative amounts of potassium acid tartrate and racemate may be calculated, together with inert material (potassium chloride). The weight of the equivalent potassium used in neutralizing is, of course, added to the original 1 g., in calculating the specific rotation of the unknown salt.

The filtrate from the potassium acid salts is evaporated to remove the alcohol, and sufficient calcium chloride added to be roughly equivalent to the oxalic acid as determined previously. This solution is immediately filtered hot and the filtrate neutralized. To this filtrate is added a solution equivalent to 5 g. of calcium chloride and allowed to crystallize for two days. The calcium trihydroxyxyloglutarate crystallizes rather slowly, and should only be filtered after no more crystals appear on the sides of the beaker after scraping down. The salt contains two molecules of water. It is not quite pure, but for purposes of analysis was considered as such because of the rather large loss on recrystallization: CaO determined, 21.87%; calcd. 22.06%. The free acid obtained by breaking up the salt with oxalic acid has no polarization and readily crystallizes from water; it melts at 142–144° and titrates 55.1 cc. of $^1/_5N$ KOH, calcd. 55.5.

Summary

1. The probable mechanism of the breakdown of 5-keto-gluconic acid on oxidation with nitric acid in the presence of vanadium is shown.

2. The application of the method as a means for the study of the oxidation of other carbohydrate derivatives is suggested.

Solubility of Inulin

BY E. YANOVSKY AND R. M. KINGSBURY

Such expressions as "insoluble" and "slightly soluble" applied to inulin are very common in the literature, but actual measurements recorded are very few. Some of the old fragmentary results on solubility of inulin in water and alcoholic solutions are recorded by Dragendorff,[1] von Lippmann,[2] and Prantl.[3] Wolff and Geslin[4] investigated the comparative solubilities of inulin from chicory and dahlia with the results in Table I.

TABLE I

t, °C.			15	30	40	45	50
Soly., grams in 100 cc.	Inulin from dahlia	I	0.045	0.185	0.305	...	0.558
		II	.333	.575	.920	...	1.490
	Inulin from chicory	I	.225	.400	.975	1.160	1.737
		II	1.445	1.859	2.400	...	...

The first line in each case represents inulin crystallized from water, the second, inulin precipitated with alcohol. Crystallization with the aid of alcohol increases the solubility of both; the chicory inulin, however, still remains the more soluble. Somewhat more detailed data on the solubility of inulin are presented in the following pages.

Materials Used.—Inulin was prepared from dahlia roots and chicory roots by the usual method[5] of extracting the roots with hot water, treating the solution with neutral lead acetate, removing the excess of lead with hydrogen sulfide, and evaporating the solution to the crystallization point. The inulin thus obtained was recrystallized four times by dissolving in hot water, treating with decolorizing carbon, and precipitating with alcohol. The final products, as used in the experiments described below, were white powders. Cursory microscopic examination showed that chicory inulin was the more crystalline of the two, consisting almost entirely of the typical spherocrystals, whereas dahlia inulin appeared to be largely amorphous with a few spherocrystals here and there. The specific rotation of dahlia inulin was found to be $[\alpha]^{20}_{D}$ −36.9°; that of chicory inulin was $[\alpha]^{20}_{D}$ −34.6°. Dahlia inulin contained 0.06% ash, chicory inulin contained 0.12%. Dahlia inulin had 0.45% reducing sugar, chicory inulin had 0.55%.

Analytical Procedure.—In analyzing inulin, or mixtures of inulin and levulose, two factors must be considered. First, that inulin is not hydrolyzed completely with acids at room temperature,[6] and second, that levulose gradually decomposes on heating with acids. The procedure used was as follows: a number of solutions of carefully purified inulin and levulose were brought to 99–100° (in boiling water). To 20 cc. of solution 5 cc. of 2.313 *N* hydrochloric acid was added. At frequent intervals (from one minute up) solutions were taken out, cooled quickly in ice water, neutralized, and brought to definite volume. Reducing sugar was determined by the Munson and Walker method. From several series of determinations it was found that heating for fifteen to sixteen minutes is sufficient to hydrolyze all the inulin; the correction for levulose decomposed is 3.0%.

In converting glucose values from the Munson and Walker tables into levulose a uniform factor 0.915 was used, thus admittedly introducing a small, for our purposes, rather negligible, error.[7] Likewise no correction has been made for glucose found by several investigators[6,8] after acid hydrolysis of inulin but apparently not formed (or formed only in small quantities) on hydrolysis by inulase.[9]

In view of the fact that the values for cuprous oxide in some of our results were very low the Fehling solution used was checked several times during the progress of experiments, but at no time did a blank determination with 50 cc. of water give more than one milligram of cuprous oxide.

Solubility of Inulin in Water at 20°.—Mixtures of water and inulin were kept at

20 ± 1° in tightly stoppered flasks and shaken by hand several times each day. Samples were removed at intervals of several days, filtered, and analyzed for reducing sugars and inulin. The results, given in Table II, indicate clearly that there is a substantial difference in the solubility of dahlia and chicory inulins, the latter being considerably more soluble. The findings corroborate the results of Wolff and Geslin, although their actual figures are somewhat different from ours. The most interesting fact brought out is that, although the solubility of dahlia inulin remained apparently constant during the period of experiment, the chicory inulin showed a very gradual but decided decrease in solubility.

TABLE II

SOLUBILITY OF INULIN AT 20 ± 1° IN GRAMS PER 100 CC.

Time, days	Dahlia inulin		Chicory inulin		Time, days	Chicory inulin	
	Expt. I	Expt. II	Expt. I	Expt. II		Expt. I	Expt. II
1	0.16	..	1.48	..	23	1.02	...
5	..	0.16	..	1.21	27	0.85	...
9	0.16	..	1.20	..	29		0.91
10	..	0.18	..	..	35		.94
13	..	..	..	1.09	40		.85
14	..	..	1.19	..	47		.80
20	0.16	0.15	1.00	1.01	54		.76

In the figures given above no correction has been made for the small amounts of reducing sugar found; there was no increase in reducing sugar during the course of the experiment. This statement applies to all subsequent results, unless otherwise stated. The rather low values for dahlia inulin solubility were checked by evaporating the solutions and drying *in vacuo* to constant weight. Two results (0.16 and 0.16) agreed well with those given in the table.

Since the results in Table II were obtained with inulin recrystallized with the aid of alcohol, and Wolff and Geslin obtained different results when inulin was recrystallized from water, we made similar experiments. Pure chicory inulin was recrystallized three times from water without the aid of alcohol. This inulin was soluble to the extent of 0.12 g. per 100 cc., and the value for solubility did not change during six weeks' observation. In a duplicate experiment a value of 0.13 g. per 100 cc. was obtained. The figures for similarly treated dahlia inulin were: 0.03 and 0.04 g. per 100 cc.

It appears therefore that there are two forms of inulin of entirely different degrees of solubility, and that the two forms of chicory inulin are different from the corresponding forms of dahlia inulin. The form of chicory inulin obtained by the usual method of recrystallization with the aid of alcohol seems to be the unstable modification, which gradually changes into the less soluble form.

That the stable less soluble modification of chicory inulin can be transformed into the unstable more soluble modification was shown by the following experiments. Chicory inulin having an unchanging solubility of 0.12 g. per 100 cc. was recrystallized (1) from water with an equal volume of alcohol added, and (2) from the same amount of water with four volumes of alcohol added. The solubility of the first product was found to be 0.52 g. per 100 cc., but it gradually decreased to 0.32 g.; the solubility of the second product was 1.17 g. per 100 cc. after four days, and this decreased gradually to 0.40 g.

Solubility at Other Temperatures.—Table III gives the results on solubility of inulin at 6°. The figures for dahlia inulin approach the limits of the accuracy of the method. The values for chicory inulin show a gradual decrease, but not as prominent, as was noted at 20°.

The data in Table IV show that at 39° the solubility of chicory inulin decreases in a shorter time than at 20°. The solubility of dahlia inulin remained stationary.

TABLE III

SOLUBILITY OF INULIN AT 6 ± 1°, IN G. PER 100 CC.

	Dahlia inulin		Chicory inulin	
Time, days	Expt. I	Expt. II	Expt. I	Expt. II
6	0.08	0.08	0.58	0.60
15	.02	.03	.52	.54
21	.02	.02	.51	.54
26	...	...	.49	.50

At this temperature a gradual increase in reducing sugar was noticed, and the figures of the table were corrected accordingly. The corrections were: for dahlia inulin, 0.17, 0.24 and 0.31; for chicory inulin, 0.33, 0.51 and 0.74.

TABLE IV

SOLUBILITY OF INULIN AT 39 ± 1°, in G. PER 100 CC.

12	.50	.48	3.00	3.28

Solubility in 50% Alcohol.—The usual laboratory procedure in the preparation of inulin requires precipitation of a water solution of inulin with alcohol. Knowledge of the solubility of inulin in alcoholic solutions is therefore of interest. Table V shows that only traces of dahlia inulin are dissolved in 50% alcohol. The gradual decrease in solubility of chicory inulin is not pronounced. The last column of the table represents results obtained by evaporating the solutions and drying to constant weight.

17.27	17.30	.62	17.17	1.06
24.56	24.42	.94	23.80	1.37

tions of different concentrations of levulose, and the results are given in Table VI. It appears that the solubility of dahlia inulin gradually increases with the increase of levulose in solution. In 25% levulose solution the solubility of dahlia inulin is practically equal to that of chicory inulin. On the other hand, the presence of levulose (up to 25%) does not seem to affect the solubility of chicory inulin.

Solubility in Presence of Soluble Inulin.—The yield of inulin prepared from a plant is considerably below the amount present in the plant as determined analytically. The uncrystallizable material represents either the degradation products of inulin or some form of soluble inulin. Therefore, we measured the solubility of inulin in solutions of soluble inulin prepared from camas bulbs.[10] The results given in Table VII show that the soluble inulin under the conditions observed is without any effect upon the solubility of either dahlia or chicory inulin.

Separation of Inulin from Supersaturated Solutions.—In common with other carbohydrates inulin easily forms supersaturated solutions. The knowledge of the extent of separation of inulin from its supersaturated solution is, of course, of utmost importance in the preparation of inulin. The existence of supersaturated solutions of inulin was known to early investigators.[1] Kiliani[11] noticed that if inulin is dissolved at higher temperature and then cooled, more inulin remains in solution than one would expect from the solubility data. Similar observation had been made by Tanret.[8] No data, however, were given by either investigator. We took a mixture of inulin and water, and after slightly warming it to produce a supersaturated condition kept the mixture at 20°. The supersaturated solution of dahlia inulin with an initial concentration of about ten times its normal solubility gradually deposited inulin, but it did not reach the normal solubility during the seven weeks of observation (Table VIII). The solution of chicory inulin, which had initially about twice the normal solubility, reached its solubility level at 20° in three to four weeks' time.

TABLE VIII

SUPERSATURATED SOLUTIONS OF INULIN IN WATER AT 20 ± 1°, IN G. PER 100 CC.

In another experiment with chicory inulin we used the mother liquor from recrystallization of inulin. Pure inulin was dissolved in boiling water, and the solution kept overnight in a refrigerator. The separated inulin was filtered off next day. The mother liquor, which contained 5.83% inulin, was kept at 20°. The gradual decrease in concentration of inulin in solution is shown in Table IX. The level of solubility at 20° was reached in four to five weeks.

Summary

The solubility of dahlia inulin differs considerably from that of chicory inulin. Each of the two inulins exists in two modifications having different degrees of solubility. One of the modifications of chicory inulin is unstable, gradually changing into the less soluble form. Solubility was measured at different temperatures and in alcoholic solutions. The presence of levulose increases the solubility of dahlia inulin, but has no effect on the solubility of chicory inulin. Soluble inulin has no effect on the solubility of either dahlia or chicory inulin. Inulin is slowly deposited from its supersaturated solutions until normal solubility is reached.

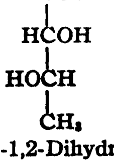
The C_4-Saccharinic Acids. VII. The Preparation and Resolution of *dl-threo*-1,2-Dihydroxybutyric Acid[1]

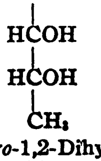
BY J. W. E. GLATTFELD AND JOHN W. CHITTUM

There are two theoretically possible *dl*-1,2-dihydroxybutyric acids. Both of these have recently been prepared in pure form and studied quite thoroughly.[2] One melts at 74–75° and the other at 81.5°. In still more recent work in this Laboratory[3] it has been shown that the acid of lower melting point probably has the *trans* configuration and the one of higher melting point the *cis* configuration. Braun has suggested the prefix *threo* for the *trans* acid and *erythro* for the *cis* acid. These suggestions are adopted in this paper.



$$\begin{array}{c} COOH \\ | \\ HCOH \\ | \\ HOCH \\ | \\ CH_3 \end{array}$$

dl-threo-1,2-Dihydroxybutyric acid, m. p. 74–75°



$$\begin{array}{c} COOH \\ | \\ HCOH \\ | \\ HCOH \\ | \\ CH_3 \end{array}$$

dl-erythro-1,2-Dihydroxybutyric acid, m. p. 81.5°

It is with the *dl-threo*-acid that this paper is concerned.

---

[1] This article is largely from a dissertation presented by John W. Chittum in partial fulfilment of the requirements for the degree of Doctor of Philosophy in the University of Chicago.

[2] Glattfeld and Woodruff, THIS JOURNAL, 49, 2309 (1927).

[3] Géza Braun, *ibid.*, 51, 228 (1929).

dl-threo-1,2-Dihydroxybutyric acid was prepared by Glattfeld and Woodruff by the oxidation of crotonic acid of m. p. 72° by means of potassium chlorate in the presence of osmium tetroxide and also by means of barium permanganate. The work with potassium chlorate was repeated and the results verified but an additional fact was established that may affect seriously the yield of acid if ignored, namely, the fact that the free *dl-threo*-acid forms a compound with its own potassium salt that is comparatively insoluble in cold alcohol. The formation of this compound was observed about the same time by Braun, who analyzed it[4] and showed it to have the composition corresponding to the formula $C_4H_8O_4{\cdot}C_4H_7O_4K$. We substantiated this formula further by preparing the compound from equal parts of the free acid and its potassium salt.

The chlorate method of preparation was greatly improved upon by Braun who used silver chlorate instead of potassium chlorate and thus avoided the complication due to the formation of the potassium double compound. We found this method to be by far the best one for the preparation of this acid.

The only report of work on the resolution of the *dl-threo*-acid is by Morrell and Hanson.[5] These workers prepared the acid by the oxidation of solid crotonic acid with barium permanganate. They failed to resolve the acid by the use of quinine, cinchonine, strychnine, morphine and brucine but reported partial success with quinidine. By the use of the last named alkaloid they obtained a *levo* acid whose specific rotation they report as −13.51°. Calculation of the specific rotation from the data they record, however, gives −19.08° instead of −13.51° and thus the correct rotation is left in doubt. Moreover, the free *dextro* acid was not obtained.

In the experimental work reported below the resolution of the acid was accomplished by means of brucine as well as quinidine. Both *dextro* and *levo* components were obtained in pure form in each case and found to have specific rotations of about −15.1 and +15.1° in the experiments in which brucine was used and −15.5 and +15.45° in those in which quinidine was used. The resolutions with the two alkaloids were made by different workers and at different times and the small differences in results are probably due to experimental error. It is probable that the true specific rotations at 20° lie somewhere between the figures recorded above.

Experimental Part

The Double Compound, $C_4H_8O_4{\cdot}C_4H_7O_4K$.—As the silver chlorate procedure has been found to be much more satisfactory than the one in which potassium chlorate is used, the latter will be discussed here only to record our work with the double compound formed by the acid and its potassium salt.

To a solution of 50 g. of crotonic acid (m. p. 72°) in 1 liter of water was added 95 g. of potassium chlorate and 20 cc. of a 0.3% solution of osmium tetroxide. After having stood for one week, the solution no longer decolorized bromine water. After extraction with benzene, it was concentrated at 60° at reduced pressure until the crystals which appeared caused bumping. The crystals (49 g. of practically pure potassium chlorate) were removed and the filtrate evaporated to dryness at reduced pressure and 60°. The residual sirup was dissolved in 150 cc. of absolute ethyl alcohol and the insoluble material separated by filtration while hot. As the filtrate cooled it deposited crystals. It was, therefore, thoroughly chilled and yielded 40 g. of white solid. This product was purified by solution in hot absolute alcohol, addition of ethyl acetate to turbidity, removal of turbidity with a little alcohol, and cooling of the solution. The crystals then deposited melted at 101–103° but still contained some chloride and chlorate.

---

[4] Braun, This Journal, 51, 244 (1929).

[5] Morrell and Hanson, *J. Chem. Soc.*, 85, 197 (1904).

These crystals were very soluble in water, almost insoluble in cold absolute alcohol, and insoluble in ethyl acetate and ether. The water solution was distinctly acid. With phenylhydrazine the substance gave a crystalline derivative of m. p. 132° and with brucine a salt of m. p. 229.5°. Authentic samples of the phenylhydrazide and the brucine salt of the *dl-threo*-acid melted at 130–131° and 232–234°, respectively, and mixtures of the corresponding compounds from the two sources melted over the same ranges as the pure individuals. These facts leave little doubt that the solid under discussion contained *dl-threo*-acid.

All doubt as to the identity of the compound was finally dispelled by its synthesis from its two constituents. Ten grams of crystalline *dl-threo*-acid was dissolved in 80 cc. of water. Half of this solution was carefully neutralized with a dilute solution of potassium hydroxide. The neutralized solution was then mixed with the untreated portion of the acid solution and the mixture evaporated to dryness at reduced pressure, water-bath at 70°. The sirup was dissolved in 25 cc. of hot absolute alcohol. The alcoholic solution yielded, on cooling, a quantity of fine white crystals which were collected on a filter, washed with ether and dried; yield 7.9 g., melting range 104–107°. A second crop of crystals was obtained by concentration at reduced pressure; weight 1.8 g.; melting range 95–106°. The total yield was, therefore, 9.7 g. or 83.6% of the theoretical amount.

The Silver Chlorate Method of Preparation.—Our procedure was practically that of Braun's second method,[6] except that we did not carry out the oxidation at zero degrees but at room temperature. To a solution of 100 g. of crotonic acid (m. p. 72°) in 5 liters of water which contained 0.25 g. of osmium tetroxide, was added 2.5 g. of silver chlorate twice daily until the reaction was complete (solution no longer turned brown even after standing for twenty-four hours); total amount of silver chlorate added 96 g., time required, three weeks. The solution was stored in the dark during the preparation. The silver chloride was then separated by filtration and washed with water, after which it was washed immediately with hydrochloric acid in order to destroy any silver oxalate that might have been present as this compound is explosive when dry. The water solution was extracted three times with 300 cc. of benzene to remove the osmium tetroxide and distilled to dryness at reduced pressure (bath at 60°). The residue was treated with sufficient ethyl acetate to dissolve the gum and the solution cooled. A small amount of material did not dissolve. Fresh ethyl acetate was then added to the solution until no more cloudiness was produced by further addition. The filtered solution was dried with sodium sulfate and then concentrated at reduced pressure to a small volume (150–200 cc.), transferred to a small flask and cooled in ice water for an hour. Crystallization was induced by scratching the walls of the flask with a glass rod. A crop of crystals which, after drying in a vacuum desiccator, weighed 80.5 g. was removed. The mother liquor was concentrated and two further crops of 7.5 g. and 4 g. obtained; total 92 g. of dry crystalline acid of m. p. 73.5–75.5° or 66%.

A repetition of this experiment with 80 g. of crotonic acid yielded 78 g. of crystalline acid or 70%.

---

[6] Braun, THIS JOURNAL, **51**, 245 (1929).

The acid thus obtained is of a very much higher degree of purity than when either potassium or barium chlorate is used. The reaction proceeds more slowly than when either of these reagents is used but, once it is finished, the rest of the procedure is shorter and easier to carry out, and the yields by the silver chlorate method are much higher.

If it is desired to obtain acid of the highest purity, the crystals obtained as outlined above may be dissolved in two parts of ethyl acetate at 60°, followed by chilling of the solution to 0°. The crystals are washed on the suction filter first with a little cold ethyl acetate, then with ether, and dried in a vacuum desiccator over phosphorus pentoxide and paraffin. Crystals obtained by the barium chlorate method and purified in this manner melted at 73-74° and titrated correctly.

Neither the *dl*-acid nor either of the active acids is at all hygroscopic when pure. We have exposed all three to the laboratory atmosphere for days with no evidence of absorption of moisture.

Resolution of the Acid with Brucine.—Contrary to the experience of Morrell and Hanson, we found brucine to be an excellent resolving agent when water is used as the solvent.

The brucine salt was made in the usual way.[7] A mixture of twenty-five grams of recrystallized *dl-threo*-acid (m. p. 73-74°) in 800 cc. of water and 85 g. of anhydrous brucine was kept on the boiling water-bath until the solution was permanently alkaline (several hours). The solution was cooled, extracted twice with 100-cc. portions of benzene, and distilled to dryness at reduced pressure (water-bath at 70°); wt. of residue, 127 g. This was dissolved in 150 cc. of hot water, the solution cooled and allowed to stand first at room temperature for two hours and then for one hour in an ice-bath. The solid was then collected on a suction filter, pressed dry and kept in an oven at 70-75° until constant in weight; wt. 43.5 g. The mother liquor from Crop I was evaporated to dryness at reduced pressure as before. The residue, which weighed 60 g., was crystallized from 1 part of water. This process was repeated until four crops of crystals had been obtained. The residue from the mother liquor from Crop IV weighed 12 g. The solvent was changed at this point; the material was crystallized from 12 cc. of 50% ethyl alcohol. This yielded 2.8 g. of dry salt, Crop V. The residue from the filtrate from Crop V weighed 6.0 g. It was crystallized from 6 cc. of 50% ethyl alcohol and yielded 1.3 g. of dry material.

Five such experiments were made in each of which 25 g. of the *dl*-acid was used. Six crops of crystals were obtained in each case. The specific rotations of these (sodium light) are recorded below.

Experiment	Crop I	Crop II	Crop III	Crop IV	Crop V	Crop VI
A	−32.5	−24.5	−21.0	Lost	−21.8	−22.5
B	−33.5	−21.2	−21.3	−22.2	−20.5	−22.0
C	−32.9	−21.2	−20.6	−21.9	−21.0	−18.6
D	Lost	−21.7	−24.5	−23.7	−21.5	−23.0
E	−32.8	−21.4	−21.0	−23.0	−21.2	−19.6

It is apparent from these data that a partial resolution had been accomplished. Each Crop I was now recrystallized six times from water and from the results of these recrystallizations it is concluded that the pure anhydrous brucine salt of the levo acid has a specific rotation in water solution between −34.4° and −35.6°.

Preparation of the Levo Acid from the Brucine Salt.—To a solution of 40.5 g. of recrystallized brucine salt (−34.4 to −34.6°) in 200 cc. of water was added a hot solution of 12.5 g. of hydrated barium hydroxide in 200 cc. of water. The mixture was cooled, the brucine removed and the filtrate extracted five times with 75-cc. portions of benzene. The barium was exactly precipitated with sulfuric acid, the barium sulfate removed and the filtrate evaporated to dryness at reduced pressure. The residual sirup weighed 9 g. Solution in a large volume (200–300 cc.) of ethyl acetate, filtration to remove gummy precipitate, and distillation of filtrate to dryness, gave 6 g. of gum which crystallized when seeded with racemic acid. The crystals were brought on a filter, washed with a little cold ethyl acetate and dried; m. p. 73.5–75°, $[\alpha]_D$ −15.0°.

---

[7] Glattfeld and Hanke, THIS JOURNAL, 40, 976 (1918).

A second portion of 75.2 g. of brucine salt (−35.1 to −35.7°) was treated in the manner outlined above. The rotation of the acid after three recrystallizations from ethyl acetate was −15.1°.

Preparation of the Dextro Acid from the Brucine Salt.—For the preparation of the dextro acid, various crops of brucine salt, −20.7 to −22.7°, were combined; weight 134.2 g. This salt was hydrolyzed in the manner outlined above for the levo acid and yielded 27 g. of crude crystalline acid; +11.3°. Fourteen grams of this material was subjected to five successive crystallizations from two parts of ethyl acetate and the specific rotation of the final product was found to be +15.1°.

Resolution of the Acid with Quinidine.—The work of Morrell and Hanson with quinidine was repeated. To a solution of 20 g. of the acid, m. p. 73.5–74.5°, in 400 cc. of hot water, quinidine was added until the solution was neutral (59 g. of alkaloid needed). The hot solution was filtered and deposited a crop of crystals which weighed 37.3 g. after three days in a vacuum desiccator over sulfuric acid; m. p. 117–117.5°; $[\alpha]_D$ +142.7°. Morrell and Hanson give 113–114° and +143.46° for the corresponding crop of crystals. They report the specific rotation as +142.2° after the material had been recrystallized six times. Our quinidine salt was recrystallized five times and then had a specific rotation of +147.5°. Further work with this salt showed it to be so much less soluble in water than the salt of the dextro acid that an almost complete separation of the two acids was found to be possible by the use of quinidine. The results recorded below support this statement.

A mixture of 60 g. of *dl* acid, m. p. 73.5–75°, in 2.5 liters of water, and 180 g. of quinidine was kept on the boiling water-bath for a half hour, cooled, filtered (2 g. of quinidine recovered) and the filtrate extracted three times with 500-cc. portions of ether. The solution was then concentrated at reduced pressure and brought to a weight of 1455 g. (1 part salt in 5 parts water), heated until all the solid was again in solution, then cooled rapidly and allowed to stand overnight. The crystals were then removed and dried in a vacuum desiccator over sulfuric acid for three days; wt. 90.3 g., $[\alpha]_D$ +147.5°; m. p. 116–122°.

It was found that it is the hydrated form of this salt which melts at 116–122° and that the m. p. must be taken rapidly to get this low value. If it is taken slowly, a very indefinite melting is observed with the last of the material liquefying at 159–162°. If the air-dry salt is extracted with boiling anhydrous ether (as is often done to avoid possible contamination with free alkaloid) it always melts at the higher value.

The filtrate from the first crop of crystals was concentrated and adjusted as before until it weighed 1395 g., cooled, seeded with crop 1 and allowed to stand for three days. The second crop was then removed; wt. 14 g., $[\alpha]_D$ +147.5°; m. p. (after ether treatment) 159–162°. A third crop of crystals was obtained by concentration of the filtrate to 1175 g. Crystals came very slowly this time even when the solution was stored for several days in the ice box; wt. crop 3, 6.8 g., $[\alpha]_D$ +149.5°; m. p. (after ether treatment) 159–162°.

The three crops of crystals were combined, wt. 106 g. (some material lost in tests of various sorts) and the filtrates and washings concentrated to dryness at reduced pressure, wt. residue 126 g. The acids were now set free from these two lots of material.

Active Acids from Quinidine Salts.—The two lots of salts were separately treated in 4–5 liters of hot water with an excess of barium hydroxide in hot solution, the mixtures cooled, the quinidine separated by filtration, the filtrates extracted with ether, the barium exactly removed as sulfate and the filtrates distilled to dryness at reduced pressure with water-bath finally at 100°; wts. of residues 24.5 g. from the crystalline salts, and 31 g. from the non-crystalline salts. Small samples of each were removed and the specific rotation determined. Then the residues were recrystallized from one and one-half parts of ethyl acetate and the specific rotation of the crystals obtained, again determined. This process was repeated five times with both levo and dextro acids. The results are recorded in the following table:

	Levo acid			Dextro acid		
	Weight, g.	$[\alpha]_D$		Weight, g.	$[\alpha]_D$	
Residue	24.5	−13.55°		31	+12.17°	
Crop 1	9	−15.9°	Av. −15.5	15	+13.4°	
Crop 2	7	−15.6°		11	+15.4°	Av. +15.45
Crop 3	5.5	−15.2°		10	+15.5°	
Crop 4	4	−15.1°		8	+15.1°	
Crop 5	2	−15.7°		6.5	+15.8°	

Summary

It has been shown that in the preparation of *dl-threo*-1,2-dihydroxybutyric acid by the method of Glattfeld and Woodruff (oxidation of solid crotonic acid by means of potassium chlorate) a compound of formula $C_4H_8O_4 \cdot C_4H_7O_4K$ is formed which may lower the yield of acid. The method of Géza Braun (use of silver chlorate instead of potassium chlorate) avoids this difficulty and was found to be much superior.

The acid prepared by Braun's method was successfully and completely resolved with brucine and with quinidine. The specific rotations of the acids obtained when brucine was used were −15.0 and +15.1°, and when quinidine was used −15.5 and +15.45°. It is probable that the correct rotations at 20° lie somewhere between these two figures.

The Reaction of Nitrogen Trichloride with Grignard Reagents

BY GEORGE H. COLEMAN, MARION A. BUCHANAN AND W. L. PAXSON

In a study of the reaction of boron trichloride and other chlorides with organomagnesium halides Strecker[1] tried the reaction of nitrogen trichloride with ethylmagnesium bromide and phenylmagnesium bromide and reported that only ammonium salts were formed. Le Fèvre[2] later obtained chlorobenzene but no amines from the reaction of phenylmagnesium bromide with nitrogen trichloride.

It has been shown in this Laboratory that monochloroamine[3] reacts with organomagnesium halides to form primary amines and ammonia. The similarity of nitrogen trichloride to monochloroamine suggested that it might also react with Grignard reagents to form amines.

The yields of amines obtained from Grignard reagents and monochloroamine vary greatly with the halogen present in the reagent, decreasing in the order, chlorine, bromine, iodine. It seemed probable, therefore, that if amines were formed in the nitrogen trichloride experiments mentioned they were formed in only small amounts and were overlooked in the relatively large amounts of ammonia. The results of the work here reported indicate that this was the case.

The reaction of nitrogen trichloride with Grignard reagents is similar to that of monochloroamine and was carried out in much the same manner. Primary amines, secondary amines, ammonia and nitrogen are the principal products. The reactions for the formation of the amines and ammonia may be represented by equations similar to those given for the reaction with monochloroamine. The results obtained with fifteen Grignard reagents are given in Table I. The percentage yields are based upon the nitrogen trichloride since the Grignard reagents were always used in excess.

The yields of primary amines are several times as large as the yields of secondary amines. This was to be expected in the light of the results of the reaction of alkyldichloroamines[4] with Grignard reagents in which the yields of secondary amines were never more than twenty-five per cent. In the products of only one reaction, that with benzylmagnesium chloride, was a tertiary amine definitely identified.

A variation in the yields of amines similar to that with monochloroamine with reagents prepared from chlorides, bromides, and iodides was observed in this work. It is probable that this variation is characteristic of the reaction of Grignard reagents with halogen derivatives of nitrogen com-

[b] In this reaction a trace of tribenzylamine was formed.

pounds in which the halogen is attached directly to nitrogen. The yields of amines are, in general, considerably smaller than the yields from monochloroamine. The formation of large amounts of nitrogen observed in this work is not characteristic of the reaction with monochloroamine.

A number of methods for the analysis of nitrogen trichloride have been used by the different investigators who have worked with this compound. Some have used more than one method. Noyes,[5] for example, has compared the hydrochloric acid method for nitrogen with the sodium sulfite method and reports that the former gives slightly higher results. There has been, however, no systematic comparison of several methods for both nitrogen and chlorine to determine their relative accuracy.

Both for the purpose of determining the best method for use in this work and because the same or very similar methods are used in the analysis of many halogen derivatives of nitrogen compounds in which halogen is attached directly to nitrogen, such a comparison has been made, the results of which are given in the experimental part.

Experimental

Preparation of Nitrogen Trichloride.—The solutions of nitrogen trichloride were prepared by a slight modification of the method previously described.[6] For the reactions with Grignard reagents ether was used as the solvent. For the comparison of methods of analysis carbon tetrachloride was the solvent. With ether as the solvent it was necessary on account of its volatility and solubility to add a little larger volume than that desired in the final solution. The reaction flask was also fitted with a reflux condenser. The tube through which the chlorine was introduced extended just to the interface between the aqueous and ethereal layers. A normal solution of ammonium nitrate was the source of nitrogen. Chlorine was either prepared as needed from sodium dichromate and hydrochloric acid or drawn from a cylinder.

(6) Coleman with Noyes, *ibid.*, **43**, 2211 (1921); Coleman and Howells, *ibid.*, **45**, 3084 (1923).

Reaction of Nitrogen Trichloride with Grignard Reagents.—Ethereal solutions of nitrogen trichloride containing about 0.10 mole in 300 cc. of solution were added slowly to the Grignard reagents containing about 0.40 mole in 400 cc. of solution. The reaction was very similar to that of monochloroamine or the alkylchloroamines with Grignard reagents. The procedure followed in carrying out the reaction and separating the products was the same as that used with alkylchloroamines.[4]

Comparison of Methods of Analysis of Nitrogen Trichloride.—In this comparison five methods were studied. The sodium sulfite method of Bray and Dowell[7] was followed very closely. The slightly modified[8] hydrochloric acid method of Noyes[8] was used for nitrogen together with the determination of chlorine in the same sample by passing the liberated chlorine into potassium iodide solution. The sulfur dioxide method of Chapin,[9] slightly modified, was used for both nitrogen and chlorine. Assuming that sodium bisulfite might combine the advantages of both sodium sulfite and sulfur dioxide, a method using this reagent was included. The method in which nitrogen trichloride is added directly to potassium iodide solution was tried but was found to give results so variable that they were not included.

In Table II are shown the results of a typical series of analyses in triplicate for nitrogen and chlorine by each of the four methods.

TABLE II

ANALYSIS OF A SOLUTION OF NITROGEN TRICHLORIDE BY FOUR METHODS

Results are expressed in milligram atoms per cubic centimeter of solution

Reagents	Nitrogen, mg. atoms	Chlorine, mg. atoms	Ratio Cl/N	Reagents	Nitrogen, mg. atoms	Chlorine, mg. atoms	Ratio Cl/N
HCl and KI	0.413	1.260	3.05	SO_2	0.418	1.259	3.02
	.415	1.264	3.04		.420	1.257	3.00
	.410	1.258	3.06		.417	1.262	3.00
Na_2SO_3	.404	1.261	3.09	$NaHSO_3$	.417	1.260	3.02
	.405	1.263	3.11		.417	1.265	3.03
	.406	1.263	3.09		.417	1.258	3.01

The fact that the chlorine to nitrogen ratio is not exactly three in each case is not necessarily significant. Solutions prepared as described sometimes have, shortly after preparation, a chlorine to nitrogen ratio which is slightly less than three. This usually increases due to slow decomposition and loss of nitrogen.

It is evident that all four methods are fairly satisfactory. The values for chlorine are practically the same throughout. The values for nitrogen by the sodium sulfite method are slightly lower than those obtained by the other three methods.

Summary

Nitrogen trichloride reacts with Grignard reagents to form primary amines, secondary amines, ammonia and nitrogen. In at least one reaction, that with benzylmagnesium chloride, a trace of a tertiary amine is formed.

---

(7) Bray and Dowell, THIS JOURNAL, **39**, 896 (1917).

(8) Coleman and Craig, *ibid.*, **50**, 1816 (1928); Noyes, *ibid.*, **42**, 2173 (1920); Noyes, *ibid.*, **50**, 2902 (1928).

(9) Chapin, *ibid.*, **51**, 2112 (1929).

The yields of primary amines are several times as large as the yields of secondary amines. The total yield of amines in any reaction is however less than the yield of primary amine in the reaction of monochloroamine with the same reagent.

The Course of Addition of Sodium Enol Alkylmalonic Esters to Phenyl Isothiocyanate

BY JOHN ROSS

It has been shown that sodium enol malonic ester adds readily to phenyl isothiocyanate to give the sodium enolate of the monothioanilide of methane tricarboxylic ester.[1] Ruhemann[2] found that on treating this sodium enolate with benzyl chloride, a thiobenzyl ether was obtained, and he considered that this fact supported the original formulation of the addition reaction in which Na- and -CH(COOEt)$_2$ were written as addendum components. According to this view of the reaction mechanism, Ruhemann expected that the sodium enolates of monoalkyl malonic esters would also add to phenyl isothiocyanate, but he found that benzylmalonic ester was recovered unchanged from the reaction between sodium enol benzylmalonate and phenyl isothiocyanate in alcoholic solution, the phenyl isothiocyanate being converted completely into the enolate of phenyl thiourethan by the addition of sodium ethoxide.

Worrall[3] states that by the action of sodium enol α-ethylacetoacetic ester on phenyl isothiocyanate he obtained an addition product, but he did not prove the composition of this compound.

Phenyl isocyanate readily combines with enolates such as sodium enol malonic ester, but addition of sodium enol alkylmalonic esters to phenyl isocyanate does not take place, and the phenyl isocyanate is polymerized under the conditions of the reaction.[4] Phenyl isothiocyanate does not polymerize under the conditions of these reactions and for this reason its action toward compounds of sodium enol alkyl malonic ester type was examined. Moreover, since the monothioanilide of methane tricarboxylic ester gives a stable thio ether, the possibility of alkyl group migration might be expected to exhibit itself in this reaction.

In alcohol-free ether, sodium enol malonate adds to phenyl isothiocyanate to give the theoretical yield of the sodium enolate of the monothioanilide of methane tricarboxylic ester. This sodium derivative with methyl iodide gives a thiomethyl ether, but this result of alkylation is no

evidence in itself as to the position of the sodium in the sodium enolate formed in the addition reaction. By the action of sodium enol methylmalonate upon phenyl isothiocyanate in dry ether there was obtained a 12–15% yield of the sodium enolate of the simple addition product (I), a 20% yield of phenyl thiourethan and there was recovered about 60% of unchanged reactants (methylmalonic ester and phenyl isothiocyanate). When the methyl ester of methylmalonic acid was used under similar conditions, no addition compound was formed, the products consisting of a small amount of methylphenyl thiourethan and unchanged reactants (80%). The addition of sodium enol methylmalonic methyl ester to phenyl isothiocyanate in methyl alcohol gave only methylphenyl thiourethan and the methylmalonic methyl ester was recovered unchanged. Attempted addition using a fraction of the molecular equivalent of sodium enolate in dry ether was likewise unsuccessful.

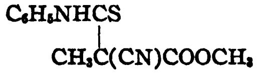
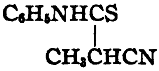
III

Sodium enol cyanacetic methyl ester in methyl alcohol with phenyl isothiocyanate gave the theoretical yield of the sodium enolate of the monothioanilide of cyanomalonic methyl ester. In contrast to this result sodium enol α-cyanopropionic methyl ester with phenyl isothiocyanate in methyl alcohol gave a small amount (6–10%) of the sodium enolate of the monothioanilide of α-cyanopropionic acid (V), phenylmethyl urethan and some unchanged α-cyanopropionic ester was recovered. The monothioanilide of α-cyanopropionic acid was apparently derived from the simple addition product, namely, the monothioanilide of α-cyano-α-carbomethoxypropionic ester (IV) by the loss of the —$COOCH_3$ group.



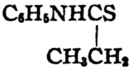
$$\begin{array}{l} C_6H_5NHCS \\ \quad\;\, | \\ CH_3C(CN)COOCH_3 \end{array}$$

IV



$$\begin{array}{l} C_6H_5NHCS \\ \quad\;\, | \\ CH_3CHCN \end{array}$$

V



$$\begin{array}{l} C_6H_5NHCS \\ \quad\;\, | \\ CH_3CH_2 \end{array}$$

In dry ether no addition product was formed from sodium enol α-cyanopropionic methyl ester and phenyl isothiocyanate, a small amount of phenylmethyl thiourethan being formed and unchanged reactants (80% of α-cyanopropionic methyl ester and phenyl isothiocyanate) being recovered.

The structure of the addition compounds was proved by saponification and elimination of the carboxyl groups to form thiopropionic anilide. The thiomethyl ether of the monothioanilide of methane tricarboxylic ester is stable toward sodium ethoxide in the cold, so that had this ether been formed in the reaction, it should have been possible to detect its presence. Therefore there is no evidence in these reactions with phenyl isothiocyanate of any migration of the alkyl group.

The whole subject of the mechanism of malonic ester addition reactions has been discussed recently[5,6] and it is necessary to consider the results described in this paper with reference to the views previously put forward.

Clearly, the simple ionic mechanism of the addition reaction would require yields of the same order of magnitude for the addition of sodium enol malonic as for sodium enol alkylmalonic esters. The question of ionization in this type of reaction with phenyl isocyanate has been discussed by Michael[4] and Dieckmann and others.[7] It has been shown that the yields of addition products are 100% for the addition of sodium enol malonates and less than 15% in the case of addition of sodium enol alkyl malonates. This disparity certainly does not support the ionic viewpoint and would appear to indicate a difference in the mechanism of addition of the two types of sodium enolates.

It has previously been stated[5] that sodium enol malonate adds by virtue of migration of the hydrogen atom so that addendum components are H and $-C(COOEt)=C(ONa,OEt)$. The results described in this paper are in agreement with the general ease and velocity with which such a reaction would be expected to proceed.

It has also been shown[5] that addition of malonic and alkylmalonic esters can be achieved by the aid of small amounts of alkaline reagents (*e. g.*, sodium ethoxide, nitrogen bases, caustic soda). When either of the reactants or the product is a relatively strong acid (*i. e.*, forms a relatively neutral sodium enolate), this catalytic reaction stops when the sodium or the base is neutralized.[8]

In the absence of conclusive evidence as to the migration of the alkyl group and the apparent small tendency of sodium enol alkyl malonate to combine directly with phenyl isothiocyanate, the only valid conclusion would appear to be that the addition of alkyl malonic esters to phenyl isothiocyanate proceeds solely by the above catalytic method. Explanations based upon the polar or steric effect of the alkyl group in sodium enol methylmalonate are rejected because previous work has not indicated that such effects would be of sufficient magnitude to account for the above results. Moreover, such explanations involve a simple ionic mode of reaction mechanism which is not experimentally supported.

In the preparation of sodium enol malonic esters it is almost impossible to exclude completely the presence or production of alcohol (as sodium ethoxide). In the reaction between methylmalonic ester and phenyl isothiocyanate the catalytic chain of addition is rapidly stopped, (a) because the sodium ethoxide reacts with the phenyl isothiocyanate to give the sodium enolate of the thiourethan and also (b) because the enolized

primary addition product is a relatively strong acid and forms an unreactive neutral sodium derivative. The phenyl isothiocyanate and sodium enol methylmalonate remain together in dry ether (in the presence of small amounts of the sodium enolates of phenyl thiourethan and monothioanilide of ethane tricarboxylic ester) and no further reaction takes place. In this way the formation of a small amount of addition product and the non-production of a large yield can be explained.

Experimental

Addition of Sodium Enol Malonate to Phenyl Isothiocyanate.—A suspension of sodium enol malonate in dry ether was prepared by the addition of 16 g. of malonic ester to 2.3 g. of pulverized sodium, and 13.5 g. of phenyl isothiocyanate in dilute ether solution was added. After standing for twenty-four hours the sodium derivative was rapidly filtered off and freed from ether in a vacuum desiccator; yield approximately theoretical (31.5 g.). Upon acidifying with mineral acid it gave the thioanilide of methane tricarboxylic ester, m. p. 60°.[1]

Alkylation.—To a suspension of 15 g. of the above powdered sodium enolate in dry ether, 8.0 g. of methyl iodide was added and the mixture left to stand for twenty-four hours cooled in ice water. The product was washed with water and dried. Upon removal of most of the ether and the addition of ligroin, almost the theoretical yield of the S-methyl ether was obtained. It crystallized in large flat prisms of m. p. 58°.

Anal. Calcd. for $C_{15}H_{19}O_4NS$: C, 58.25; H, 6.05; S, 10.38. Found: C, 58.42; H, 6.10; S, 10.28.

When boiled with hydrochloric acid the ether hydrolyzed, giving methyl hydrosulfide and aniline. The methyl hydrosulfide was absorbed in mercuric cyanide and identified by the crystalline compound of m. p. 175° so formed.[9] To a suspension of alcohol-free sodium ethoxide prepared from 0.8 g. of sodium a solution of 10 g. of the above S-methyl ether was added. After standing for twenty-four hours the mixture was acidified and worked up as usual. There was recovered unchanged 9.5 g. of the S-methyl ether. A trace of yellow oil was left which smelt strongly of phenyl carbylamine.

Addition of Sodium Enol Methylmalonic Ester to Phenyl Isothiocyanate.—To a suspension in ether of sodium enol methylmalonic ester prepared from 17.4 g. of methylmalonic ester and 2.3 g. of pulverized sodium, 13.5 g. of phenyl isothiocyanate was added. A faintly yellow solution was obtained. After standing at room temperature for two days, the mixture was acidified, washed with water and the ether extract dried and distilled under reduced pressure; 19 g. of a mixture of methylmalonic ester and phenyl isothiocyanate distilled over at 85–100° (3 mm.) and then the distillation was stopped. The unchanged material represented 60% of the total reactants. The residue in the flask was taken up in the minimum of ether and ligroin added until crystallization began.

Monothioanilide of ethane α,α,α-tricarboxylic ester crystallized out first in large faintly yellow prisms which were recrystallized and melted at 92°. The yield of 4.0 g. represented about 12% of the total reactants.

Anal. Calcd. for $C_{15}H_{19}O_4NS$: C, 58.25; H, 6.05; S, 10.38. Found: C, 58.36; H, 6.12; S, 10.25.

The residue in the mother liquor after removal of the above thioanilide proved to be almost entirely phenyl thiourethan. This crystallized in large flat needles, m. p. 71°. The yield was 6.0 g., approx. 20% of the total reactants.

Monothioanilide of Methylmalonic Acid.—The monothioanilide of ethane α,α,α-

---

(9) S. P. Mulliken, "Identification of Organic Compounds," Vol. III, 1922, p. 216.

tricarboxylic ester dissolved immediately in a slight excess of 10% caustic potash and after standing for three days was carefully acidified with cold dilute hydrochloric acid. There was immediate evolution of carbon dioxide and an oil was precipitated which rapidly solidified. The latter proved to be the monothioanilide of methylmalonic acid. It crystallized in faintly yellow prisms and melted at 118° with the evolution of carbon dioxide.

Anal. Calcd. for $C_{10}H_{11}O_2NS$: C, 57.42; H, 5.26; S, 15.33. Found: C, 57.65; H, 5.30; S, 15.18.

Thiopropionic anilide was obtained by heating a small amount of the above monothioanilide of methylmalonic acid above its melting point. It crystallized in large cubes melting at 67° and was shown by analysis and direct comparison to be identical with a sample of thiopropionic anilide prepared through the action of magnesium ethyl iodide upon phenyl isothiocyanate.[10]

Addition of Sodium Enol Cyanoacetate (Methyl Ester) to Phenyl Isothiocyanate.—To a solution of 1.2 g. of sodium in absolute methyl alcohol 4.8 g. of cyanoacetic methyl ester was added and followed by 6.7 g. of phenyl isothiocyanate. The solution became very warm but was quickly cooled in ice water. After standing for twenty-four hours, the mixture was acidified and the monothioanilide of cyanomalonic methyl ester crystallized out and was filtered off. It was recrystallized from a mixture of methyl alcohol and ether as small prisms which melted at 135° with decomposition. The yield was almost the theoretical.

Anal. Calcd. for $C_{11}H_{10}O_2N_2S$: C, 56.41; H, 4.27; S, 13.73. Found: C, 56.65; H, 4.34; S, 13.49.

Alkylation.—To a solution 1.2 g. of sodium in 15 cc. of methyl alcohol was added 4.8 g. of cyanoacetic methyl ester and 6.7 g. of phenyl isothiocyanate in order. After standing for several hours, 8.0 g. of methyl iodide was added and the mixture stood in the cold for twenty-four hours. The product was washed with water and the ether extract dried. Upon removal of most of the ether and adding ligroin, approximately the theoretical yield of the S-methyl ether was obtained. It crystallized in large prisms, m. p. 83°.

Anal. Calcd. for $C_{12}H_{13}O_2N_2S$: C, 56.74; H, 4.83; S, 12.93. Found: C, 56.50: H, 4.95; S, 12.75.

When boiled with hydrochloric acid, the ether hydrolyzed to give methyl hydrosulfide.

Addition of Sodium Enol α-Cyanopropionic Methyl Ester to Phenyl Isothiocyanate.—To a solution of 1.2 g. of sodium in 15 cc. of methyl alcohol was added 5.7 g. of α-cyanopropionic methyl ester followed by 6.7 g. of phenyl isothiocyanate, the mixture being cooled in ice water. After standing for twenty-four hours the product was acidified and the ether extract dried. After removal of most of the ether there crystallized out approx. 1.0 g. of the monothioanilide of α-cyanopropionic acid (representing about 10% of the reactants). This was filtered off and the residue distilled under reduced pressure; 4.5 g. of unchanged α-cyanopropionic methyl ester distilled over at 75–90° (3 mm.), then the distillation was stopped. The residue (7.0 g.) solidified completely and proved to be the methyl ester of phenylthiocarbamic acid (methylphenylthiourethan), m. p. 95°.

Monothioanilide of α-cyanopropionic acid was recrystallized from a mixture of methyl alcohol and ether. It melted at 126° without decomposition.

Anal. Calcd. for $C_{10}H_{10}N_2S$: C, 63.16; H, 5.9; S, 16.87. Found: C, 63.37; H, 6.15; S, 16.78.

---

(10) Sachs and Loevy, *Ber.*, 36, 587 (1903).

A solution of this monothioanilide in excess caustic potash did not hydrolyze upon standing in the cold for three days, since upon acidification the original material was recovered unchanged. Upon boiling a solution in excess caustic potash some hydrolysis with formation of aniline occurred but the main product was the potassium salt of the monothioanilide of methylmalonic acid, m. p. 118°. This upon melting gave thiopropionic anilide, m. p. 67°, which further confirmed the structure of the original addition compound.

Summary

1. Whereas the sodium enolates of malonic and cyanoacetic esters combine readily with phenyl isothiocyanate to form approximately 100% yields of the sodium enolates of the corresponding monothioanilides, the sodium enolates of methylmalonic and α-cyanopropionic esters give only very small yields (5–15%) of the simple addition products and the major portion of the reactants is unchanged.

2. A modification of the theory of the mechanism of this addition reaction is consequently necessitated and an explanation is offered.

The Resin Acids of American Turpentine Gum. The Preparation of the Pimaric Acids from Pinus Palustris[1]

BY S. PALKIN AND T. H. HARRIS

The resin acids of *Pinus maritima*, the principal French gum, have been given considerable study by Vesterberg,[2] Aschan,[3] Dupont[4,5] Ruzicka[6] and others.

The acids of the American gums, *Pinus palustris* and *Pinus carribea*, from which the bulk of the world's supply of rosin and turpentine are obtained, have received less attention.[7,8]

Pinus maritima[5,9] contains two general types of isomeric acids of the empiric formula $C_{20}H_{30}O_2$—the sapinic and the pimaric acids. The sapinic, of which two have been described (α and β), have been estimated by Dupont to represent about 70% of the total acids. These are levorotatory, very susceptible to oxidation, and easily isomerized by heat and

mineral acids to abietic acid, and they do not form crystalline salts. The pimaric, of which two also have been prepared, one levo (β) and the other dextro-(α)-rotatory, do possess the property of forming crystalline salts, a property which has thus far served as the principal means for their isolation from the complex acid mixture.

While the actual steps involved in the preparation of the resin acids are relatively simple, their isolation in a reasonable state of purity is rendered exceedingly difficult by a number of factors including the physical character of the gum, close similarity of their properties, their instability, and their great tendency to form isomorphous crystals.

Considerable advance in the methods of preparation was made by Dupont,[4] and later by Ruzicka and Balas,[10] and by Aschan,[3] over those of the earlier investigators. But even their improved procedures when applied to *Pinus palustris* were found to lead to certain difficulties, indicating the need for a more dependable working scheme in which greater flexibility of method as applied to acid mixtures of varying composition is provided.

By extending the observations of Ruzicka, data on the behavior of the sodium salts on fractional crystallization under certain conditions of temperature, concentration and alkalinity have been worked out. These data, together with an improved technique for obtaining the original crude acids and for liberating the acids from the sodium salts, have made possible a more expeditious separation of the pimaric and the sapinic, and the α- and β-pimaric acids from one another, than by previous means.

As shown in this paper, levo-pimaric acid from *Pinus palustris* agrees well in properties with that derived from *P. maritima*, but dextro-pimaric acid from the two sources differs markedly in rotation and melting point.[11]

The *P. palustris* gum was found to contain appreciable quantities of the two pimaric acids.

Their relative proportions, as indicated by calculations from the rotation of the mixture, was about two parts of levo to one part of dextro, a ratio similar to that observed in the French gum.[5]

Experimental Part

Treatment of the "Galipot."—The thick sirupy character of the gum turpentine medium, containing the settled crystalline acids or so-called "galipot," renders the ordinary laboratory filtration apparatus and processes inapplicable. Since the task of removing the crystalline mass from this medium is in this case attended with such extraordinary difficulties and constitutes an unavoidable step in the preparation of initial mixed acids, a convenient device providing a large filtering surface is here shown in detail in Fig. 1. A small quantity of turpentine gum spread evenly over the surface of the cloth before suction is applied will serve to seal the rim and the hood. The "galipot" mass is distributed evenly over the filter cloth in a layer about 5 cm. thick, and

---

(10) L. Ruzicka, Fr. Balas, and Fr. Vilim, *Helv. Chim. Acta*, 7, 458 (1924).

(11) The latter, unless that from *P. palustris* is found to be a new isomer, has been prepared by this means in a higher state of purity than hitherto obtained from any other source, or by other means.

smoothed over with a wide spatula to insure uniform suction. Where the crystalline "galipot" is relatively coarse, the filtration proceeds rapidly. The product obtained is relatively dry to the touch.

Preparation of the Mixed Acids.—Two extractions of the filtered product with 80% alcohol, and one crystallization from 95% alcohol, were found adequate to provide white crystalline pimaric acids in sufficient concentration to give a crystalline ammonium salt.[12]

The white crystalline acids yielded a pearly mass of sodium salts in one crystallization, as described later.[13]

Fig. 1.—Large filter.

The extractions with the 80% alcohol were carried out at room temperature, 500 cc. per kilogram being used each time. The "galipot" acids were thoroughly disintegrated in these two extractions and filtered by suction.

The acids so obtained (containing also chips, bark, etc.) were then crystallized once from 95% alcohol, the alcohol being warmed 50° to effect the solution. This was carried out in several stages, treating with the alcohol, filtering by suction and re-treating the residue each time with fresh alcohol to bring it into solution with a minimum of solvent. About one liter per kilogram of acids was required. The chips, bark, etc., were thus eliminated in this step.

Preparation of Crystalline Sodium Salt.—The resulting white crystalline acids were converted to the salt with warm $N/2$ sodium hydroxide (not over 50°). After cooling somewhat, the soap was precipitated with an excess of alkali (using 2 or 3 normal)

---

(12) Unless the sapinic acids have been sufficiently removed, the ammonium salt test cannot be obtained and subsequent preparation of the crystalline sodium salt is much more difficult.

(13) This preparatory treatment of the acid may be compared with the ten treatments of the pressed "galipot" found necessary by Dupont as follows: four extractions with 75% alcohol; one crystallization from 75% alcohol; three crystallizations from 80% alcohol; two crystallizations from 95% alcohol.

more or less as described by Dupont[5] in connection with the preparation of sapinic acids. The soap was either centrifuged or filtered by suction, a filter cloth disk being used instead of paper. The resulting white soap, thus freed from oxidation products, was redissolved in a minimum quantity of warm water (about 50°), diluted with about one-half the volume of additional water and allowed to crystallize in cold storage (about 0°) for twenty-four hours. The mass of pearly crystalline pimaric acids thus obtained was either centrifuged or filtered by suction.[14]

12.03 Kilograms of "galipot" yielded in this manner 2375 g. of crystalline sodium salt having a rotation $[\alpha]_D$ −173° in terms of its corresponding acids. In another experiment 6.78 kilograms yielded 1265 g. having a rotation $[\alpha]_D$ −164.6° in terms of its acids. Assuming the pure acids to have the specific rotations $[\alpha] = -279°$, and $+73°$, respectively, their relative proportions would be about 71% levo and 29% dextro in the first instance, and 68% levo and 32% dextro in the second.

Separation of Levo from Dextro Pimaric Acid.—In the following scheme for the separation of the respective pimaric acids, due consideration is given to the composition of the acid mixtures or fractions in question, rotation being the criterion as to the applicability of any particular method used. Actual composition of any given fraction (assuming only the two compounds dextro and levo pimaric acid present) may be calculated from Biot relationship as follows: $Px(\mathrm{LR}) + (1-P)x(\mathrm{DR}) = \mathrm{OR}$ where P is % levo pimaric acid; LR is specific rotation of pure levo pimaric acid; $1-P$ is % dextro pimaric acid; DR is specific rotation of pure dextro pimaric acid; OR is observed rotation of mixture.

Two general procedures were found useful for effecting a concentration of the respective acids: (1) one leading in a few steps to levo pimaric acid and applicable to pimaric acid mixtures having a rotation of −160° or above. This was found more convenient and effective than fractionation from acetone as described by Ruzicka, *et al.*[10] The resin acids were liberated (quantitatively) from the sodium salts in an alcoholic solution in the cold with an equivalent of acetic acid in alcohol. (2) Another procedure leads more or less rapidly to dextro pimaric acid and is applicable to pimaric acid mixtures having rotations below −160°. In this method the sodium salts were subjected to a systematic crystallization in a manner similar to that described by Ruzicka,[10] modified to include fractionating advantages incident to low temperature and alkalinity. This scheme was found particularly useful for acid mixtures in which fractionation of the free acids from organic solvents was ineffective.

Method 1.—The sodium salt was dissolved in warm alcohol (about 45°), filtered by suction (paper washed with alcohol) and brought to a concentration (in a volumetric flask) of not more than 500 g. per liter. The calculated equivalent of 2 *N* acetic acid in alcoholic solution (using 3 or 4 cc. excess), ice cooled, was added to the previously cooled solution of sodium salt. This quantity was calculated from analytical determination of an aliquot. Crystallization (aided by stirring) soon took place. The acid filtered by suction was washed with a little ice cold 75% alcohol, and finally with water to remove all traces of acetic acid. Successive crops were obtained by progressive dilution with water. The yields and rotations of the acids so obtained are shown in Table I.

Method 2. Systematic Fractional Crystallization of the Sodium Salts.—The sodium salts were dissolved in warm water (about 50°) and diluted with cool water, the dilution depending upon the relative proportions of the respective acids as determined by the rotations of the fractions treated. In these experiments the temperature was generally not allowed to go above 50° to avoid isomerization.[8]

The progress of the fractional crystallization is indicated in the diagram (Fig. 2A). The approximate dilutions (volume of water per gram of sodium salt) are shown on the continuous lines of the chart. Except as indicated three fractions were generally ob-

[a] Numerical portions of fraction numbers also represent weights of fractions. [b] Spec. rotation in terms of the corresponding acid. [c] Used *N* acetic instead of 2 *N* acetic acid for neutralization.

tained, (1) at room temperature, (2) by cooling, (3) by the slow addition of alkali (about 5 *N*) until precipitation was fairly complete. These crops are indicated by the designations "r. t.", "ice," "alk.," respectively. The numerical part of the experiment numbers (just preceding the letters), represents the approximate weights of the respective fractions. Specific rotations are given directly below each experiment number. Various fractions, whose rotations were not markedly different, were combined in the usual way for further fractionation, such combinations being indicated by dotted lines connecting them. In order to render the diagram less confusing, some of the intermediate fractions are not shown.

Rotations of the various crops of sodium salt are given in terms of their corresponding acids. These we determined as follows. A weighed quantity of sodium salt (1 or 2 g.) was dissolved in a minimum quantity of alcohol and to this solution (ice cooled) was added slightly more than an equivalent of a cool alcoholic solution of 2 *N* acetic acid. (Approximately 1.2 cc. to 1.4 cc. of 2 *N* acetic acid per gram of sodium solution is generally sufficient.) A fine granular crystalline precipitate formed on stirring. Cool water was then added, drop by drop, with stirring, to effect a complete precipitation. This product, after filtration by suction and washing with water, was dried in the air and then in vacuum (at 45°). The specific rotation was generally made on a 1% alcoholic solution in a 2-decimeter tube.

This procedure was generally preferred to the liberation of the acids by way of carbon dioxide, as the latter, even when heated to 60° during precipitation, as suggested by Ruzicka, were frequently found to filter poorly.

There was virtually no isomerization by the acetic acid under the special conditions described above, as may be seen by the following determinations (Table II).

TABLE II

Experiment		1	2	3
Acids liberated with	AcOH $[\alpha]_D$	−207°	−286°	−251°
	CO_2 $[\alpha]_D$	−205°	−286°	−250°

In Experiment 3 an excess of acetic acid, over 60% more than the required equivalent, was used without any apparent isomerization.

Enrichment of the sodium salts in terms of dextro pimaric acid proceeds fair rapidly with fractions of rotation below −100°, as may be seen from fractions 158C$_{400}$, 80CCD and 92CCD, etc. (Fig. 2A).

High concentration of dextro acid tended markedly to hydrolyze. Gradual addition of a small quantity of $N/2$ alkali to the suspension in the hot water generally cleared the solution. The progress of the purification of the levo and dextro acids may be seen from the diagram in Fig. 2B.

Fig. 2.—Fractional crystallization scheme for sodium salts (A, upper part) and preparation of the pure acids (B, lower part): fractions of sodium salt are shown in rectangles; fractions of free acid are shown in ovals; fractions that were combined are shown by dotted lines; fractions obtained at room temperature by cooling and by addition of alkali are indicated by "r. t.," "ice," "alk.," respectively; concentrations of sodium salt in water are given on continuous lines; numerical part (to left) of experiment numbers indicates approximate weights of fractions; specific rotation given for each fraction.

The properties of the purified levo and dextro pimaric acids obtained from longleaf pine (*Pinus palustris*) are given in Table III.

Catalytic Hydrogenation

Dihydro-levo-pimaric Acid.—Ten grams of the pure levo-pimaric acid in 85 cc. of ethyl acetate with 0.5 g. of palladium–barium sulfate catalysts,[15] absorbed 820 cc. of hydrogen in a total of two and one-half hours, 800 cc. having been absorbed in the first half hour. (Calculated volume for the dihydro compound is approximately 810 cc.)

The hydrogenated product, after removal of the catalyst and solvent, was crystallized several times from diluted alcohol (85%) as described by Ruzicka, Balas and Vilim.[10] Several isomers were apparently formed as reported by these authors, of which only one was obtained in pure form, as indicated by constancy of the melting point (m. p. 144–146°).

Dihydro-dextro-pimaric Acid.—Four grams of dextro-pimaric acid in 110 cc. of

[a] Levo pimaric acid isomerizes rapidly as the melting temperature is approached. Softening takes place before substance melts to an oil. Ruzicka and Frank,[16] prepared a dextro pimaric acid, melting at 215°, by way of the dihydromethyl ester. No rotation for this is given.

[b] Crystallographic data were furnished by G. L. Keenan of the Food and Drug Administration.

---

(16) L. Ruzicka and M. W. Frank, *Helv. Chim. Acta*, **15**, 1925 (1932).

ethyl acetate with 0.1 g. of palladium–barium sulfate catalysts (warmed somewhat), absorbed a total of 340 cc. of hydrogen in five hours, 270 cc. having been absorbed in the first two hours (calculated volume for dihydro compound, 325 cc.).

The reaction product after removal of the catalyst and solvent was recrystallized from ether to a constant melting point which was over 10° higher than that reported by Ruzicka and Balas[17] (m. p. 249–250°).

Anal.[18] Calcd.: C, 78.88; H, 10.60. Found: C, 78.87; H, 10.63.

The authors wish to express their appreciation to Mr. R. R. Long, of Atmore, Ala., for his coöperation in furnishing the turpentine gum.

Summary

An investigation of the pimaric acids in *P. palustris*, an improved systematic procedure for their preparation from the "gum," as well as the preparation of catalytic hydrogenation products of these acids are described.

Carbon Syntheses with Malonic and Related Acids. I

BY ARTHUR MICHAEL AND JOHN ROSS

In 1879[1] it was shown that mixtures containing benzoic, or cuminic, aldehyde with phenylacetic acid and sodium acetate heated in sealed tubes gave stilbene, or propylstilbene, evidently by loss of carbon dioxide from the first-formed cinnamic acid derivatives. Subsequently,[2] this modification of the Perkin synthesis, using an acid instead of an acid anhydride, was extended to malonic acid, when, with benzoic aldehyde, cinnamic acid was obtained without use of acetate. This synthesis was not extended, as, simultaneously, Claisen and Crismer[3] found that benzalmalonic acid was formed on heating malonic acid with benzoic aldehyde in acetic acid solution, with or without acetic anhydride, and Komenos[4] that replacement of aromatic by fatty aldehydes led to the formation of aliphatic α,β,Δ-dibasic acids, or corresponding monobasic acids through loss of carbon dioxide. A large literature now exists on the use of malonic acid for the preparation of mono- and dibasic α,β,Δ-acids.[5]

Komenos[4] was unable to condense malonic acid with acetone, using acetic anhydride, but Meldrum[6] observed that addition of a little sulfuric acid to the mixture caused an immediate reaction to form the β-lactone of β-hydroxyisopropylmalonic acid. This interesting synthesis of a β-lactone has been used besides with acetone and methylmalonic acid,[7] and with several homologous ketones and malonic acid.[8] Malonic acid also has been condensed with certain aryl carbinols, yielding arylmalonic acids. Notwithstanding the extensive use of the malonic acid reaction for C-syntheses, its applicability is far from exhausted. We have undertaken a systematic investigation of the chemical behavior of this reagent and derivatives toward mono- and polycarbonyl compounds, including the enol–keto group, to determine the scope of the reaction and the relations of the products formed in the Claisen–Komenos, Meldrum and Knövenagel methods to the structures of the components of the systems.

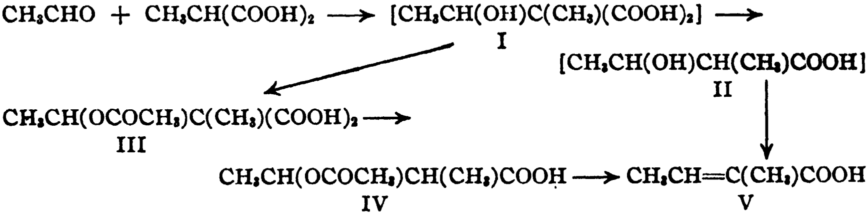
[5] Beilstein, Vol. II, p. 245; Suppl., Vol. II, p. 235 (1920). Thirty researches are listed. Knövenagel used pyridine instead of acetic acid and anhydride to induce the reaction.

[6] Meldrum, *J. Chem. Soc.*, **93**, 605 (1908).

Tiglic acid has been synthesized by a number of methods, but the preparations are difficult and poor yields are obtained. A mixture of methylmalonic acid with an excess of paraldehyde, acetic anhydride and acetic acid was heated on the water-bath for several hours. There were formed tiglic acid (V) and β-acetoxy-α-methylbutyric acid (IV). The latter distilled unchanged in a vacuum, but at ordinary pressure lost acetic acid to give tiglic acid which, by these simple methods, may be obtained in a 70% yield. In this synthesis the following processes apparently occur



$$\begin{tikzcd}
CH_3CHO + CH_3CH(COOH)_2 \arrow[r] & \underset{\text{I}}{[CH_3CH(OH)C(CH_3)(COOH)_2]} \arrow[r] \arrow[dl] & {} \\
\underset{\text{III}}{CH_3CH(OCOCH_3)C(CH_3)(COOH)_2} \arrow[r] & {} & \underset{\text{II}}{[CH_3CH(OH)CH(CH_3)COOH]} \arrow[d] \\
 & \underset{\text{IV}}{CH_3CH(OCOCH_3)CH(CH_3)COOH} \arrow[r] & \underset{\text{V}}{CH_3CH{=}C(CH_3)COOH}
\end{tikzcd}$$

The stability of I toward elimination of water to form an α,β, Δ-acid is evidently due to the absence of an α-hydrogen. Compound III upon loss of carbon dioxide would form α-methyl-β-acetoxybutyric acid (IV) and tiglic acid (V) may now be formed by loss of acetic acid. This must take place with difficulty under the experimental conditions, since IV remains as a considerable proportion of total products of the reaction. It might be considered, therefore, that tiglic acid is formed solely through II by elimination of water, but this simple interpretation has been shown to be improbable.

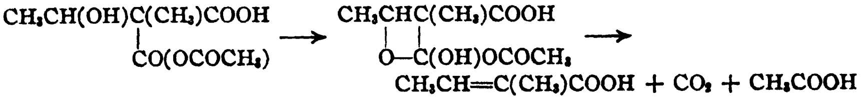
α-Methyl-α-carboxy-β-hydroxybutyric acid (I) was prepared by a method described later in this paper. On pyrogenic decomposition at 135°, under atmospheric or reduced pressure, it gave acetaldehyde and methylmalonic acid and no appreciable amount of tiglic or α-methyl-β-hydroxybutyric acid. Therefore it seems probable that methylmalonic acid in the

---

(7) Ott, *Ann.*, 401, 159 (1913).

(8) Kandhiah, *J. Chem. Soc.*, 1215 (1932).

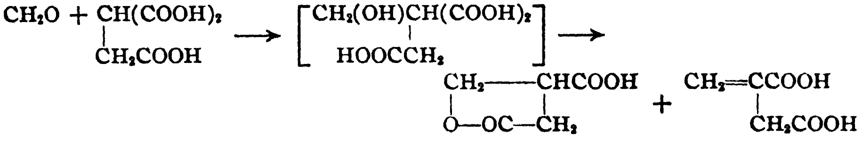
presence of paraldehyde, acetic anhydride and acetic acid follows a different course of reaction. Dimethylmalonic acid warmed with acetic anhydride gives a mixed malonic–acetic anhydride and methylmalonic acid undoubtedly reacts similarly. From this point of view, the formation of tiglic acid, besides through IV, may take place through a β-lactone derivative



$$\begin{array}{l}CH_3CH(OH)\underset{\displaystyle CO(OCOCH_3)}{C}(CH_3)COOH \longrightarrow \begin{array}{l}CH_3CHC(CH_3)COOH\\ \;\;|\quad\;\;|\\ \;O{-}C(OH)OCOCH_3\end{array} \longrightarrow\\ \qquad\qquad CH_3CH{=}C(CH_3)COOH + CO_2 + CH_3COOH\end{array}$$

This very negative β-lactone should undergo facilely such a decomposition and all malonic acid syntheses of α,β, Δ-acids, that require the use of acetic anhydride, may proceed through a mixed acid anhydride.

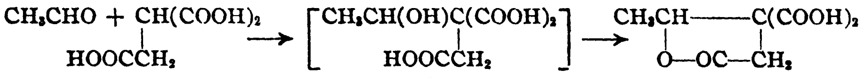
In the above manner, paraformaldehyde and ethinyl tricarboxylic acid gave a good yield of paraconic acid (VI) with itaconic acid (VII) in a small proportion



$$\begin{array}{l}CH_2O + \underset{\displaystyle CH_2COOH}{CH}(COOH)_2 \longrightarrow \left[\begin{array}{l}CH_2(OH)CH(COOH)_2\\ \quad HOOCCH_2\end{array}\right] \longrightarrow\\ \qquad \begin{array}{l}CH_2{-}{-}CHCOOH\\ |\qquad\quad |\\ O{-}OC{-}CH_2\end{array} + \begin{array}{l}CH_2{=}CCOOH\\ \qquad\;\; |\\ \quad\;\; CH_2COOH\end{array}\end{array}$$

VI VII

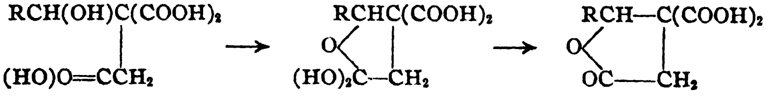
By the same method there was produced from paraldehyde and the tricarboxylic acid in the cold an almost theoretical yield of α-carboxy-β-methylparaconic acid (IX)



$$CH_3CHO + \begin{array}{l}CH(COOH)_2\\ HOOCCH_2\end{array} \longrightarrow \left[\begin{array}{l}CH_3CH(OH)C(COOH)_2\\ \qquad HOOCCH_2\end{array}\right] \longrightarrow \begin{array}{l}CH_3CH{-}{-}{-}C(COOH)_2\\ \quad\;\; |\qquad\qquad |\\ \quad\;\; O{-}OC{-}CH_2\end{array}$$

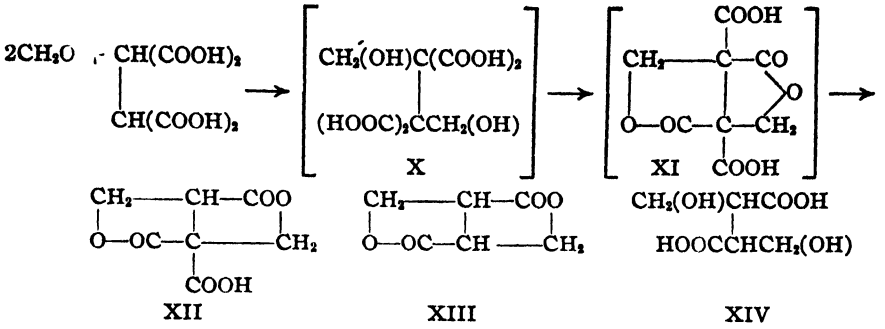
VIII IX

It is evident that when a mono-substituted malonic acid contains a carboxyl in the β-position to the dicarboxylic group, the elimination of water from the first-formed aldol derivative (*e. g.*, VIII), occurs solely, or almost entirely, by way of intramolecular esterification to form a γ-lactone

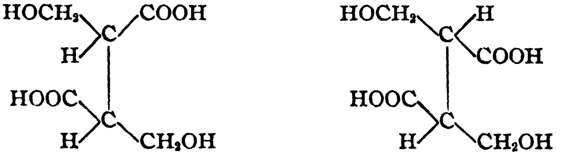


$$\begin{array}{l}RCH(OH)C(COOH)_2\\ \qquad\qquad\;\; |\\ (HO)O{=}CCH_2\end{array} \longrightarrow \begin{array}{l}RCHC(COOH)_2\\ O\langle\quad |\\ (HO)_2C{-}CH_2\end{array} \longrightarrow \begin{array}{l}RCH{-}C(COOH)_2\\ O\langle\qquad |\\ \;OC{-}{-}CH_2\end{array}$$

This course of reaction is again illustrated in the case of symmetrical ethane tetracarboxylic acid. That acid and paraformaldehyde, by the Claisen–Komenos method, gave with loss of carbon dioxide the γ-dilactone of dimethylolethinyl tricarboxylic acid (XII) as the main product. Upon fusion acid XII lost carbon dioxide and gave the bicyclic γ-dilactone of dimethylolsuccinic acid (XIII), the simplest possible aliphatic member of this class of dilactones. It dissolved in warm caustic soda to form the neutral sodium salt of *sym*-dimethylolsuccinic acid (XIV)



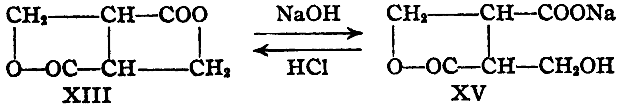
This dihydroxy dicarboxylic acid (XIV) contains two asymmetrical carbon atoms and may exist in the racemic and meso form



A Racemic B Meso

From the property of γ-hydroxy acids to condense to γ-lactones, when the involved interacting groups are uniplanar, each of these stereostructures may yield a corresponding racemic and meso form of a mono-lactonic acid and a dilactone. According to Reis,[9] in the meso or "centri" form the hydrogen atoms at the asymmetrical carbon atoms are in *trans* relationship. but no chemical evidence is known to confirm this view. The dissymmetry of the hydrogen atoms should cause a decided increase of free chemical energy in the meso over the racemic stereo form This does not agree with the relative properties of the members of these groups of compounds and it is not improbable that B would pass over voluntarily into A.

The dilactone (XIII) is soluble in water and in the cold it slowly neutralizes one equivalent of alkali, with fission of one lactone ring, giving the mono-sodium salt (XV). This upon acidifying yields the original dilactone (XIII)

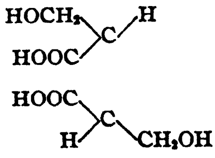


When boiled with two equivalents of caustic soda, both lactone rings are opened and approximately equal amounts of the two stereomeric sodium salts of XIV were obtained. One of the salts appeared as an octahydrate, which separated as a highly crystalline solid from the solution of the other, very soluble compound. The latter upon acidifying gave the original dilactone. On the other hand, the less soluble sodium salt gave a mono-hydroxy-γ-lactonic acid (XVI).

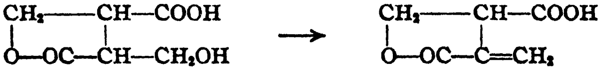
---

[9] Reis, *Ber.*, **59**, 1551 (1926).

The formation of the mono-lactonic acid from the less soluble salt can be explained only by racemization of A, when one of its COONa groups undergoes a positional interchange with the hydrogen atom attached to the same asymmetrical carbon atom. The respective methylol and the carboxyl group of the corresponding free acid are no longer in the same plane and therefore cannot undergo lactonization (C Meso). These properties of A and C are of theoretical interest as they offer a rigorous chemical proof that racemization proceeds with rearrangement at one of the asymmetrical carbon atoms. Upon treatment with a dehydrating agent the meso mono-lactonic acid XVI might be reconverted into the racemic acid (A), when it would condense to the dilactone; lose water from the methylol and carboxyl groups in *trans* position to each other, when it would undergo retrogression with elimination of carbon dioxide; or, water might be eliminated from the carbinol hydroxyl and the hydrogen atom at the same asymmetrical carbon atom, when an unsaturated lactonic acid would be formed. As the last process would occur in a β-hydroxy acid group, which always loses water very readily, it is not surprising that treatment of the meso lactonic acid XVI with acetic anhydride proceeded in this direction

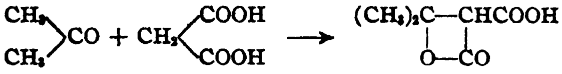


C Meso



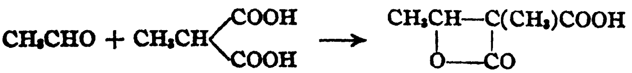
XVI XVII[10]

Related to the γ-lactone reaction is the Meldrum[6] synthesis of the β-lactone of β-hydroxyisopropylmalonic acid (XVIII) from a mixture of malonic acid, acetone and acetic anhydride with a small amount of concentrated sulfuric acid



XVIII

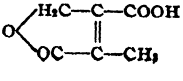
Similarly, Ott[7] obtained from methylmalonic acid the α-methylated derivative (XIX) of XVIII. We have found that aldehydes may be used in place of ketones in the Meldrum β-lactonic acid synthesis. Thus, aldehyde reacts with methylmalonic acid to give β-lactonic acid XX



XX

---

(10) The structure of XVII is uncertain. Itaconic acid, and its anhydride, give citraconic anhydride on distillation, which points to the isomeric



as a possible formula.

Until recently, the interpretation of Erlenmeyer[11] has been accepted that alkene formation from salts of β-halogen acids proceeded through a β-lactone. However, Einhorn[12] obtained the β-lactone of the three nitrophenyllactic acids, which decomposed in this manner only at the melting points, and Baeyer and Villiger[13] the β-lactone of β,β-dimethylmalic acid from the corresponding β-halogen acid, which on distillation did not undergo the olefin decomposition. Johansson and Hagman[14] attributed the isolation of these β-lactones that their insolubility in the surrounding media resisted conversion into hydroxy derivatives. By dissolving liberated β-lactones in chloroform as they are formed, they showed that aliphatic β-halogen salts on decomposing in aqueous solution yield mixtures of β-lactones and alkenes. These fatty β-lactones boiled in a vacuum without decomposition and, in some of the reactions, were formed in much larger proportion than the corresponding alkenes. They concluded from these results that such β-bromo salts yield simultaneously a mixture of β-lactone and olefin, but gave no reason for this double mode of decomposition. This is to be sought in the stereostructures of the β-bromo salts. There are good grounds to accept favored, comparatively stable, stereostructures, which represent the maximum degradation of energy, for all saturated aliphatic compounds[15] from the second carbon series on, but, according to the partition principle, the other possible configurations may occur in more or less minor proportions. From this point of view, the β-lactone formation proceeds from the stereostructure in which the halogen and the metallic atom of the salt are in *cis* position to each other. In configurations where these atoms are *trans* to one another, the lactone rings would be formed under such strain that rupture to alkenes and carbon dioxide would occur.

The pyrogenic decomposition of the alkylated β-propiolactonic acids is complicated. Ott[7] showed that β,β-dimethylpropiolactonic acid (XVIII) gave acetone with dimethylketene; its α-methyl derivative (XIX) gave acetone with high boiling products. Although that β-lactonic acid decomposes above its melting point, we found that it can be distilled unchanged in a vacuum. The introduction of an α-methyl into XVIII has increased decidedly the stability of the β-lactone ring toward heat. In striking contrast to the ketonic mode of decomposition, is that of β-lactonic acid XX, whose structure may be derived from that of XVIII by replacing one of the β-methyls by hydrogen. The thermal decomposition of this β-lactonic acid involves merely the elimination of carbon dioxide from the carboxyl, leaving α,β-dimethylpropio-β-lactone (XXI); a fairly stable compound toward heat, since it boils without decomposition

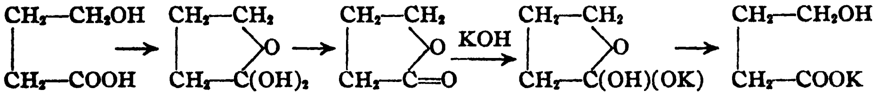
XX XXI

This shows that the unusual fission at the saturated linkages between the α- and β-carbons of XVIII and XIX cannot be ascribed wholly to the lessening of their affinity to each other by the negative influence of the COOH- and COO-groups, since then this influence should be somewhat greater in these lactones than in XX. These reactions further illustrate that if strain in the sense of the Baeyer hypothesis[16] functions it can be only one of the energy factors which enter into the thermal stability of rings.

Upon treatment of β,β-dimethylpropiolactonic acid (XVIII) with cold, aqueous alkali, Meldrum[6] found that it functioned monobasic and when heated with baryta water it decomposed into acetone and malonate. Kandiah[8] stated that β,β-dipropylpropiolactonic acid titrated monobasic with cold alkali and dibasic with the reagent at 100°. We examined the α,β,β-trimethyl derivative XIX toward aqueous caustic soda and observed a still greater stability of the β-lactone ring. With two equivalents at 100° only the mono-sodium salt was produced and from the evaporated dry residue the original monobasic lactonic acid could be recovered. The existing observations on the relative stability of β-lactone rings toward heat and toward alkali with reference to chemical structures show that they run parallel to each other and that they are developed constitutive properties.[16a]

The γ-butyrolactone formation from γ-hydroxybutyric acids,[17] and rupture of the lactone ring by alkali, should be represented as follows



The primary phase of the internal esterification proceeds at the energetic Δ-CO of the acidic group. This carbonyl possesses the chemical potential at the Δ-C and Δ-O atoms for the carbinol O and H atoms to overcome the slight hindrance to the formation of the hydrated pentacyclic lactone

---

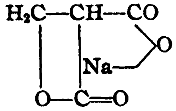
(16) Baeyer, *Ber.*, **18**, 2277 (1885). This chemist [*ibid.*, **23**, 1275 (1890)] made a curious error in endeavoring to interpret the "Strain Theory" in terms of mechanical energy. The tension in a cyclic chain was compared to that in a bent elastic spring, it increasing in each case with the magnitude of the pressure. Baeyer overlooked that the strain in the spring is due to energy exerted externally, while spontaneous ring-formation is caused by internal, intramolecular energy, in a large measure to the free chemical energy and the chemical affinity, *i. e.*, the chemical potential, between the two groups that react directly to form the cyclic system. It can occur only with a decrease of the free chemical energy of the corresponding compound with the open-chain form. The more of the free chemical energy used to complete the closure, the less must be available to hold the terminal groups that unite to form the ring together by bound chemical energy and, therefore, the less will be chemical hindrance to ring-fission. Evidently, this interpretation is the reverse of that implied in the bent spring explanation, where the free energy increases with closure. The magnitude of this chemical hindrance to ring-fission must be one of the major energy factors that determine the stability of rings.—A. M.

(16a) In opposition to the "Strain Theory" the tetracyclic ring of XIX shows greater stability toward alkaline reagents than the pentacyclic ring of any lactone that has been examined.

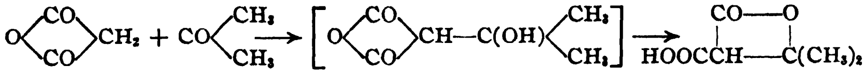
(17) Michael, *J. prakt. Chem.*, **60**, 338 (1899); THIS JOURNAL, **40**, 1694 (1918).

ring. The alkali hydrolysis of the lactone ring proceeds through the intermediate addition of alkali at the Δ-CO[18] to pass over into the γ-hydroxy salt. In these reactions the formation of the neutral lactone and hydroxycarboxylate evidently determine the maximum degradation of chemical energy of the systems.

These theoretical standpoints permit an insight into several of the above β-lactone reactions. If the primary phase of the action of caustic alkali upon a β-lactone consists in its addition to the ring carbonyl, then the introduction of any chemical influence into the lactone molecule, acting directly or through space, that increases or decreases this additive capacity, must result in a greater lability or stability, respectively, of the lactone ring. The replacement of an α-hydrogen of a lactone by carboxyl should augment the chemical potential of the ring carbonyl for water and alkali, and, accordingly, should lessen the stability of the lactone ring toward aqueous mineral acid and alkali. Toward acid this conclusion holds for β-lactones, but not toward alkali. However, in this case the primary product is the corresponding carboxylate and the not wholly neutralized positive chemical energy of the alkali atom must decrease the facility of addition, depending more or less upon the extent of the free positive energy remaining in the alkali atom. In all cases, the retardation should be noticeable, for the natroxyl group is in the *cis* position to the lactone carbonyl and the metal in the spatially near 5–6 places to the carbon and oxygen of that group. The configuration of the β-propiolactonate may be represented by the formula shown.



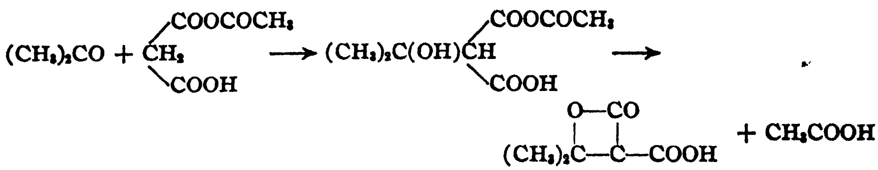
According to Ott,[7] malonic acid with acetic anhydride and a little sulfuric acid may give the mixed malonic–monoacetic anhydride. He assumed that malonic anhydride, formed from it by loss of acetic acid, may react with aldolization upon acetone with subsequent rearrangement



It should be stated that the "malonic anhydride" here assumed contained acetyl and that it was also considered a mixed anhydride. Since there is no evidence that sulfuric acid had been entirely removed from the preparation, and the composition of the latter as malonic anhydride is not established, it is evident that the interpretation has no experimental basis. The comparison with the malic β-lactonic acid change is not applicable; if they rearranged similarly the anhydride of isopropylmalonic acid should be formed and not a β-lactone derivative. A simpler and more probable interpretation is that the synthesis of the β-lactone proceeds through a mixed anhydride

---

(18) Analogous alkali addition derivatives have been isolated [Michael, *Am. Chem. J.*, **5**, 93 (1883); Michael and Lamb, *ibid.*, **31**, 552 (1906)].



The probable function of sulfuric acid is to facilitate the formation of the mixed anhydride[19] and to catalyze intramolecular esterification as it does the intermolecular process. In the mixed anhydride the hydrogen attached to the α-carbon becomes more reactive, through replacement of COOH by the more negative radical $COOCOCH_3$, and that replacement of hydroxyl hydrogen by acetyl favors cyclization has been long known.[20]

Experimental

Preparation of Tiglic Acid.—A mixture of 50 g. of methylmalonic acid, 37 g. of paraldehyde, 43 g. of acetic anhydride and 25 g. of acetic acid was heated under a condenser for forty-eight hours, then gently boiled on a sand-bath for four hours. The liquid was distilled with a 15-cm. column until the thermometer read 140°. The residual liquid was then fractionated under reduced pressure, two main fractions being collected; tiglic acid (19 g.), distilling at 90–115° (15 mm.), solidified in the receiver, and a second fraction (13 g.), distilling at 147–150° (10 mm.), which was β-acetoxy-α-methylbutyric acid.

β-Acetoxy-α-methylbutyric acid is a colorless liquid of not unpleasant odor.[21] It readily decomposed into acetic and tiglic acids on distillation at ordinary pressure.

Anal. Calcd. for $C_7H_{12}O_4$: C, 52.5; H, 7.5. Found: C, 52.4; H, 7.3.

This method will give a total yield of tiglic acid of approximately 70% of the theoretical. The tiglic acid upon recrystallization melted at 65° and was identical in all other respects with tiglic acid.

Preparation of α-Ethylcrotonic Acid.—A mixture of ethylmalonic acid (38 g.), paraldehyde (22 g.), acetic anhydride (26 g.), and acetic acid (15 g.) was heated as in the preparation of tiglic acid. Upon fractionation there was obtained 20 g. of liquid which distilled at 100–120° (20 mm.), and upon cooling almost completely solidified to large crystals of α-ethylcrotonic acid melting at 42°. There was also obtained a small amount (3.0 g.) of liquid boiling at 156–160° (10 mm.), presumably β-acetoxy-α-ethylbutyric acid.

Action of Aldehydes on Carboxysuccinic Acid. Formaldehyde.—A mixture of 4.0 g. of paraformaldehyde, 8.0 g. of the tricarboxylic acid, 7.0 g. of acetic anhydride and 7.0 g. of acetic acid stood at room temperature for two weeks. The mixture was heated on a water-bath for six hours and boiled under a condenser for an hour. The excess acetic anhydride and acetic acid was removed by distillation under reduced pressure, the flask being placed in a water-bath. There remained a thick sirup containing some unchanged paraformaldehyde, which was removed by warming with excess caustic soda and the acid extracted with ether upon acidifying. On removal of the solvent the sirupy residue deposited crystals (1.0 g.) of an acid (m. p. 161°), which was proved by analysis and a direct comparison to be itaconic acid.

---

[19] Fittig and Stuart [*Ber.*, **16**, 1436 (1883); *J. Chem. Soc.*, **44**, 403 (1883)] obtained cinnamic and α-methylcinnamic acids from the products of the action of benzaldehyde on sodium malonate, sodium methylmalonate, respectively, and acetic anhydride at room temperature. Under these conditions the aldehyde does not act on the anhydride and sodium acetate mixture and they therefore contended that the syntheses must proceed through the aldehyde and malonate, a view which was practically universally accepted. The writer [*Am. Chem. J.*, **5**, 14 (1883)] gave reasons to show that this interpretation was not tenable and that the reaction proceeded through the primarily formed, mixed malonic–acetic anhydride. Later [*J. prakt. Chem.*, **60**, 366 (1899); *Ber.*, **34**, 918 (1901)], it was proved experimentally that the synthesis with monobasic derivatives takes place through the aldehyde and acid anhydride. The recent preparation and properties of mixed malonic–acetic anhydrides now show unmistakably that the synthesis with malonic derivatives proceeds by action of the aldehyde on mixed anhydrides, not on malonates.—A. M.

[21] Blaise and Herman, *Compt. rend.*, **146**, 1327 (1908); *Ann. chim.*, [8] **20**, 189 (1910).

Anal. Calcd. for $C_5H_6O_4$: C, 46.16; H, 4.6. Found: C, 46.26; H, 4.8.

The residual sirup in a desiccator gradually crystallized and was found to be paraconic acid (m. p. 57°); yield 5.0 g.

Anal. Calcd. for $C_5H_6O_4$: C, 46.16; H, 4.6. Found: C, 46.05; H, 4.7.

Acetaldehyde.—A mixture of 3.0 g. of paraldehyde, 5.4 g. of ethinyl tricarboxylic acid, 4.0 g. of acetic anhydride and 5.0 g. of acetic acid stood at room temperature for two weeks. After heating gently on a water-bath for six hours, the excess paraldehyde, acetic anhydride and acetic acid was distilled off under reduced pressure. On cooling, the residue crystallized almost completely and the solid was filtered from the adhering liquid. Recrystallization from a mixture of ether and ligroin gave large prisms of β-carboxy-γ-methylparaconic acid, melting at 165°.

Anal. Calcd. for $C_7H_8O_6$: C, 44.68; H, 4.75. Found: C, 44.52; H, 4.43.

This acid on melting lost carbon dioxide to give γ-methylparaconic acid,[22] melting at 84° after recrystallization from ether–ligroin mixture.

Anal. Calcd. for $C_6H_8O_4$: C, 50.0; H, 5.5. Found: C, 49.81; H, 5.61.

An excellent yield of β-carboxy-γ-methylparaconic acid (approximately 80%) was also obtained from the above mixture by adding a drop of concentrated sulfuric acid and allowing to stand at room temperature for one week. The acid crystallized from the reaction mixture.

Sym-ethane tetracarboxylic acid was prepared by saponifying the ethyl ester with caustic potash and acidifying the dry potassium salt suspended in ether with concentrated hydrochloric acid while cooling well in an ice–salt freezing mixture. The aqueous solution was extracted in the cold with ether in a continuous extractor. The solid acid was obtained from the concentrated ether extract by evaporation in a vacuum desiccator. The crude acid melted at 181° and crystallized from acetone–chloroform solution as fine needles, melting at 183°. By this method a very pure acid can be obtained in excellent yield.

Action of Formaldehyde on Sym-Ethane Tetracarboxylic Acid.—A mixture of 20 g. of the tetracarboxylic acid with 20 g. of acetic anhydride was added to a solution of 7.0 g. of paraformaldehyde in 20 g. of acetic acid and left at room temperature for two weeks. Some evolution of carbon dioxide occurred and after a few days nearly all the solid acid dissolved. The mixture was then warmed on the steam-bath for six hours when evolution of gas almost ceased. The excess acetic acid and acetic anhydride were distilled off under reduced pressure and the residual sirup was taken up in ether and ligroin added. On standing there was deposited 4.5 g. of a mixture of crystalline compounds. Upon fractional crystallization from acetone–ether it gave a compound which melted at 178° with decomposition, to give a second compound melting at 138°. The analysis and properties of the first substance correspond to the dilactone of dimethylol ethinyl tricarboxylic acid (XII).

Anal. Calcd. for $C_7H_6O_6$: C, 45.16; H, 3.28. Found: C, 45.34; H, 3.28.

The compound, melting at 138°, crystallized in large prisms, was soluble in water and analyzed for the γ-dilactone of dimethylol succinic acid (XIII).

---

(22) Fittig, *Ann.*, **256**, 1 (1889).

Anal. Calcd. for $C_6H_6O_4$: C, 50.7; H, 4.72. Found: C, 50.72; H, 4.43. *Neutral equivalent.* Calcd. for $C_6H_6O_4$: 142. Found: 140.5.

On treatment with *N*/20 baryta water slow neutralization occurred; 0.06 g. of dilactone was neutralized, added dropwise, in approximately thirty minutes.

After separation of the above acid considerable sirupy material remained. When this was heated under 20 mm. pressure about 5.0 g. distilled over at 210°; the residual resin in the distilling flask decomposed upon further heating. The distillate solidified upon cooling and was separated by fractional crystallization into the dilactone, m. p. 138° (2.5 g.), and an isomeric compound melting at 165°. The latter, an unsaturated acid, crystallized from chloroform in fine needles and gave the following analysis.

Anal. Calcd. for $C_6H_6O_4$; C, 50.7; H, 4.22. Found: C, 50.48; H, 4.34. *Neutral equivalent.* Calcd. for $C_6H_6O_4$: 142. Found: 145.2.

It dissolved immediately in bicarbonate solution with evolution of carbon dioxide and the solution decolorized permanganate solution instantaneously. However, in chloroform solution, it did not readily take up bromine. In analysis and properties it corresponds to the γ-lactone of β-methylol-itaconic (XVII), or -citraconic acid.

Racemization of Dimethylolsuccinic Acid.—The dilactone melting at 138° was dissolved in the calculated amount of 2 *N* caustic soda and the solution boiled for fifteen minutes. Upon cooling there separated large prisms of an hydrated sodium salt. These crystals were filtered off and, after drying on a porous plate, were analyzed.

Anal. 0.5130 g. of the salt lost 0.2042 g. on drying at 110°, and the dry salt gave 0.1990 g. of anhydrous Na_2SO_4. Calcd. for $C_6H_8O_6Na_2 \cdot 8H_2O$: H_2O, 39.35; Na, 12.57. Found: H_2O, 39.8; Na, 12.51.

This octahydrate was not formed on standing of the alkaline solution of dilactone for two days in the cold. The mother liquor from the octahydrate was evaporated to dryness and acidified, when the original dilactone (m. p. 138°) was obtained.

γ-Monolactone of Meso Dimethylolsuccinic Acid (XVI).—The disodium salt octahydrate was dried at 110°, the anhydrous salt suspended in ether and acidified with the theoretical amount of hydrogen chloride. Upon evaporation of the ether extract, there was obtained large crystals of the meso hydroxy-lactonic acid, m. p. 122°.

Anal. Calcd. for $C_6H_{10}O_5$: C, 44.44; H, 6.17. Found: C, 44.18; H, 5.95. *Neutral equivalent.* Calcd. for $C_6H_{10}O_5$: 160. Found: 159.3.

Upon boiling with acetic anhydride and distilling under reduced pressure this acid gave the unsaturated γ-lactonic acid (XVII) (m. p. 165°).

α-Methyl-α-carboxybutyrolactone.—To a mixture of 20 g. of methylmalonic acid, 20 g. of acetic anhydride, 10 g. of acetic acid and 10 g. of paraldehyde was added one drop of concentrated sulfuric acid. There was an immediate evolution of heat and all the solid acid dissolved. After standing overnight, 0.2 g. of anhydrous sodium acetate was added, in order to convert the sulfuric acid to sodium sulfate, and the excess paraldehyde and acetic acid was removed by heating under reduced pressure, the flask being kept in water at about 80°. The sirupy residue was taken up in ether and ligroin added. Upon standing large crystals of α-methyl-β-hydroxy-α-carboxybutyric acid separated; yield 4 g.

This acid melted at 135° with decomposition. It crystallized in large prisms from chloroform–ligroin.

Anal. Calcd. for $C_6H_{10}O_5$: C, 44.44; H, 6.17. Found: C, 44.67; H, 6.44.

When heated at its melting point, under reduced or at atmospheric pressure, it decomposed into acetaldehyde and methylmalonic acid, both of which were identified. There was no identifiable amount of tiglic acid or the β-lactone of β-hydroxy-α-methylbutyric acid obtained in this pyrogenic decomposition.

The β-lactone of α-methyl-α-carboxy-β-hydroxybutyric acid remained as a sirup after removal of crystalline acid.

α-Methylbutyro-β-lactone.—When the sirupy residue was heated above 100° under reduced pressure, decomposition occurred with elimination of carbon dioxide and the above β-lactone distilled over. The original reaction mixture distilled directly gave 70% of this lactone. It is a colorless liquid boiling at 80° (15 mm.)[23] and has a pleasant odor. It is insoluble in cold sodium carbonate but dissolves on warming; it is also soluble in warm caustic soda.

Anal. Calcd. for $C_5H_8O_2$: C, 60.0; H, 8.0. Found: C, 59.84; H, 8.15.

Preparation of Tiglic Acid from α-Methylbutyro-β-lactone.—Seven and one-half grams of the lactone was mixed with 38 cc. of 2 *N* caustic soda and the mixture warmed on a steam-bath. The major part of the lactone rapidly dissolved but there was formed a small amount of deep, yellowish brown resinous material, which had an unpleasant odor, and which was filtered off. The clear, colorless filtrate was evaporated to dryness and the cold sodium salt, suspended in ether, acidified with concentrated hydrochloric acid. The ether extract, which contained β-hydroxy-α-methylbutyric acid, was concentrated and the hydroxy acid distilled under reduced pressures, when it lost water to give almost the theoretical yield of tiglic acid.

Summary

1. The preparation of α-alkyl-α,β-olefinic acids, by the action of aliphatic aldehydes upon mono-alkylmalonic acids, has been described.

2. The method with ethinyl tricarboxylic acid gave γ-lactonic acids; from paraformaldehyde and *sym*-ethane tetracarboxylic acid a γ-dilactonic acid was obtained, which upon heating gave the simplest aliphatic γ-dilactone.

3. The racemic dimethylolsuccinate, obtained from this γ-dilactone upon warming with alkali, reformed the γ-dilactone with mineral acid. On longer heating it racemized partially to the meso salt, which yielded a mono-γ-lactonic acid upon acidifying. These relations offer a rigorous chemical proof that the racemization took place by a rearrangement between a methylol group and a hydrogen atom at one of the asymmetrical carbon centers.

4. It has been shown that aldehyde may replace acetone in the Meldrum malonic synthesis of β-lactonic acids.

5. The thermal and chemical properties of β-lactonic acids in relation to structure have been examined. It has been shown that an intramolecular strain in β-lactone rings can be only one of the energy factors that determine their physical and chemical stability. The relations deduced solely from Baeyer's "Strain Theory" are therefore erroneous.

6. The β-lactone of α-methyl-β-hydroxy-α-carboxybutyric acid has been examined and the preparation of tiglic acid from this acid described.

Hydrogenation of Aromatic Compounds at Temperatures Close to their Decomposition in the Presence of Catalysts

BY VLADIMIR IPATIEFF

The hydrogenation of aromatic compounds in the presence of mixed catalysts at temperatures close to their decomposition points was first studied by Ipatieff and Klukvin in 1924.[1]

The results of this work led to conclusions which were later confirmed by Ipatieff and Orlow[2] and Kling and Florentin.[3]

However, the work done up to this point did not explain the main problems of destructive hydrogenation in the presence of catalysts. The first question which remained unanswered concerned the hydrogenation of aromatic compounds in the presence of molybdenum oxide catalysts. It is not yet known whether monocyclic aromatic compounds can be hydrogenated under high pressure with other catalysts than nickel or nickel oxide. The first experiments, therefore, concerned the hydrogenation of benzene and xylene under pressure at high temperature (450°F.) in the presence of molybdenum oxide catalysts (MoO_3). It was found that neither benzene nor xylene hydrogenated in the presence of a molybdenum catalyst, while xylene decomposed under these conditions to benzene and toluene.

A second series of experiments dealt with the hydrogenation of naphthalene in the presence of NiO, CuO, Fe_2O_3 and MoO_3 catalysts as well as in their absence, the iron walls of the autoclave acting catalytically.

Since preliminary experiments with fluorene and phenanthrene also resulted in hydrogenation at high temperature in the presence of a molybdenum catalyst, it was concluded that polycyclic aromatic compounds differ from monocyclic compounds under these conditions of hydrogenation.

In the case of naphthalene, it is possible to explain why hydrogenation occurs under the influence of weak catalysts. Naphthalene has two carbon atoms, common to both rings, which differ from the others. One can assume that a molecule of hydrogen is first added to the common carbon atoms (I); the product is immediately isomerized into 1,4-dihydronaphthalene, forming an ordinary double bond in the ring, (II). This compound is easily hydrogenated further to give 1,2,3,4-tetrahydronaphthalene (III).

This assumption is supported by the fact that sodium amalgam causes the hydrogenation of naphthalene to 1,4-dihydronaphthalene (II), which may be transformed into 3,4-dihydronaphthalene with sodium ethoxide.

If the temperature of naphthalene hydrogenation does not exceed 450° tetrahydronaphthalene is obtained almost exclusively. Above 450° the

III

tetrahydronaphthalene formed decomposes into benzene hydrocarbons. It must be noted that decomposition of the tetrahydronaphthalene into benzene hydrocarbons causes the occurrence of naphthenes in all fractions of the product only when using a nickel catalyst. This shows that some molecules of the monocyclic aromatic compounds are hydrogenated during this decomposition.

Another series of experiments was concerned with the hydrogenation of phenol at high temperature in the presence of various catalysts. The investigations of Tropsch,[4] Orlow[2] and Kling and Florentin[3] showed that several hydrocarbons can be obtained under such conditions. Our experiments indicated that at high temperature and pressure (with NiO or MoO_3), hydrogenation of the aromatic ring also occurs, yielding cyclohexane in amounts depending upon the nature of the catalyst used.

The possible hydrogenation of the aromatic ring under such conditions can be explained in the same way as it was in 1905[5] when the hydrogenation of phenol under pressure in the presence of nickel oxide was carried out for the first time. The reaction was explained on the basis of the two *tautomeric forms* of phenol: "true" phenol (enol) and *keto* form. During hydrogenation, "true" phenol is reduced to benzene, with the separation of water. The reaction proceeds at high temperatures without catalysts, under the influence of the iron walls of an autoclave. If a strong hydrogenation catalyst, such as nickel oxide, is present, much cyclohexane is obtained. It should be noted that, at 450–490° under high pressure, cyclohexane is isomerized to methylcyclopentane.[6]

When the hydrogenation of phenol is carried out with MoO_3, Fe_2O_3 or CuO, 10 to 30% cyclohexane is always obtained. Its formation, then, is caused more easily by hydrogenation of the second tautomeric form of phenol—the ketone form—for which a less active catalyst is needed.

My investigations[7] showed that alumina, when not very highly heated

and therefore containing water of hydration, is an active dehydrating catalyst. This fact has been contradicted by the work of Kling and Florentin,[8] who state that alumina prepared at 750° gives high yields of benzene in the hydrogenation of phenol at 490° under high pressure. I can explain this fact that alumina does not act as promoter, but as a porous substance.

Special experiments were made on the hydrogenation of aromatic hydrocarbons in the presence of active catalysts poisoned by thiophene. It was found that although one-ring aromatic hydrocarbons are not hydrogenated at high temperature, naphthalene can be hydrogenated in the presence of thiophene, as well as in its absence. Phenol is hydrogenated in the presence of thiophene, but the action is accompanied by the formation of high-boiling products, presumably esters, etc. Thiophene decomposes completely under these conditions.

Experimental Part

The Hydrogenation of Monocyclic Aromatic Hydrocarbons.—The hydrogenation was carried out in a rotating bomb of the type described by Ipatieff, at 450°, in the presence of catalysts. The data are summarized in Table I.

TABLE I

Expt.	Subs.	Catalyst	Time, hours	Temp., °C.	Pressure, atm.		Anal. of gas	Index of ref.	Prod. of reaction
					start	end			
4	Benzene	MoO_3	3	430	100	99	H_2	1.5036/17	Benzene
6	Benzene	MoO_3 50% Al_2O_3 50%	3	400	65	65	H_2	1.5030/18	Benzene
7	Benzene	MoO_3 50% Al_2O_3 50%	3	450	65	64	H_2	1.5029/18	Benzene
9	Xylene	MoO_3	3	450	90	75	H_2 95% Par. 5	....	Benzene Toluene Xylene
19	Xylene	MoO_3 50% Al_2O_3 50%	3	450	100	80	....	....	Benzene Toluene Xylene

As shown in Expts. 4, 6 and 7, benzene cannot be hydrogenated in the presence of molybdenum catalysts. Xylene also fails to hydrogenate under these conditions in the presence of molybdenum catalysts, but decomposes to benzene and toluene (Expts. 9 and 19). The product of reaction dissolves entirely in fuming sulfuric acid and distils at 80–140°. It was separated into: (1) fraction boiling at 80–81° which solidified at 0°, and (2) fraction boiling at 108–112° (with nitric acid forms dinitrotoluene).

The Hydrogenation of Naphthalene.—The experiments on the hydrogenation of naphthalene in the presence of different catalysts were carried out in the rotating autoclave at 450–475°. The data obtained are shown in Table II.

Catalyst MoO_3 was precipitated from solution of ammonium molybdate by addition of nitric acid, and dried for thirty-six hours at 210°. $MoO_3Al_2O_3$ consists of a mechanical mixture of the precipitated MoO_3 and Al_2O_3.

$Fe_2O_3Al_2O_3$ and $CuOAl_2O_3$ were precipitated from a solution of mixed nitrate salts of these metals by addition of ammonium hydroxide and dried at 250°.

$NiOAl_2O_3$.—The precipitation (nitrate salts) was made by addition of ammonium carbonate, the product dried for seventeen hours at 210° and in a stream of air for five hours at 400°. All catalysts were used in amount of 10% of the substance.

From Table II one can see that $NiOAl_2O_3$ catalyst (Expt. 21) gave 38% of the fraction boiling at 196–208°. The analysis and properties prove the presence of *tetralin*. Found: C, 90.76; H, 8.78. Other products were identical with those obtained by Klukvin and myself, *i. e.*, consist of aromatic hydrocarbons—benzene, toluene, etc. In order to ascertain whether other hydrocarbons are present in the aromatic fractions they were treated with 15% fuming sulfuric acid. The hydrocarbons insoluble in sulfuric acid are *naphthenes;* they did not react with the nitrating mixture and analysis gave: boiling point 76–104°, d_4^0 0.7630; n_D^{26} 1.4215; C, 85.82; H, 14.78.

Contacting with MoO_3 as catalyst for a short time, the yield of tetralin increased to 76% (Expt. 24). In this case benzene hydrocarbons are obtained in small amount. When hydrogenation is carried out for a long time the first fraction (80–120°) contains about 10% of naphthenes (after treatment with fuming sulfuric acid), confirmed by analysis: boiling point 72–78°, d_4^0 0.7547, n_D^{26} 1.4070; C, 85.25; H, 14.78.

Analysis showed that methylcyclopentane had been formed by isomerization of cyclohexane.

Experiments 17, 25, 8, 9 and 23 showed that the same results were reached when catalysts MoO_3 or $MoO_3Al_2O_3$ were used and when the time of hydrogenation was extended. At 475° very little tetralin remained; the aromatic hydrocarbon fractions do not contain other hydrocarbons.

Experiments 12 and 13 (catalyst $CuOAl_2O_3$) and Experiments 9, 10 and 11 (catalyst $Fe_2O_3Al_2O_3$) showed that the formation of tetralin also takes place and aromatic hydrocarbons are obtained. Analysis of different fractions (catalyst $Fe_2O_3Al_2O_3$) gave: Fraction 80–110°, C, 91.03; H, 8.76; corresponding to C_7H_8. Fraction 125–150°, C, 90.61; H, 8.83; corresponding to C_8H_{10}. Fraction 175–190°, C, 89.63; H, 8.63; corresponding to C_9H_{12}.

Experiment 26 shows that at 475° in the absence of a catalyst we have the same picture of hydrogenation.

The Influence of Thiophene upon the Hydrogenation of Naphthalene.—It was found that, at high temperatures of hydrogenation, the thiophene does not affect the reaction appreciably. Thus in the hydrogenation of naphthalene ($NiOAl_2O_3$) 38% of tetralin was obtained whereas in the presence of thiophene 33% was obtained.

The Hydrogenation of Phenol.—The hydrogenation of phenol proceeded under the conditions as described in the case of naphthalene. The data are summarized in Table II. Experiment 8 showed the reaction with $NiOAl_2O_3$ proceeded within two hours only when the temperature was 400°. After-treatment of hydrocarbons (95%) with 15% fuming sulfuric acid yielded 90% cycloparaffins—cyclohexane and methylcyclopentane.

Experiments 12, 13, 16 and 17 showed the hydrogenation of phenol in the presence of catalysts $MoO_3Al_2O_3$ and MoO_3; MoO_3 is a more active catalyst and the amount of naphthenes obtained increased slightly.

Analysis of fractions (Experiment 13) after treatment with sulfuric acid proves that we have naphthenes: Fraction 74–77°, C, 85.37; H, 14.30. Fraction 81–83°, C, 84.94; H, 14.60. Calcd. for C_nH_{2n}: C, 85.62; H, 14.38.

Analysis of fractions (Experiment 16) after treatment with sulfuric acid gave: Fraction 73–76°, C, 85.05; H, 14.70. Fraction 79–80°, C, 84.87; H, 14.56.

Experiments 22 and 23 (catalyst $Fe_2O_3Al_2O_3$) showed that the amount of phenol decomposed is considerably smaller (about 25%).

If phenol is hydrogenated *without a catalyst*, almost the same result is obtained as when iron oxide was used. After treatment of the fractions (Expt. 20) boiling 75–81° and 81–84° with 15% sulfuric acid, a hydrocarbon was obtained which did not react with the nitrating mixture. Its analysis showed that it was cyclohexane: C, 84.92; H, 14.61.

Experiments 25 and 27 Catalyst Al_2O_3.—The formation of an unsaturated hydrocarbon becomes noticeable, since the hydrocarbons obtained decolorize permanganate solution. After treatment with fuming sulfuric acid (15%) a hydrocarbon is obtained which does not react with the nitrating mixture and is a mixture of cyclohexane and methylcyclopentane.

The Hydrogenation of Phenol in the Presence of Thiophene.—If the hydrogenation of phenol is carried out in the presence of MoO_3 and 1% thiophene, the same results are obtained. From 200 g. of phenol at 450° for two hours, 160 g. of a product was obtained which contained only 12 g. of unchanged phenol, and hydrocarbons distilled at 69–84°; 26% hydrocarbons remained. They distil at 77–81°, n_D^{26} 1.4215. The hydrocarbons do not react with the nitrating mixture and must be cyclohexane with a small amount of methylcyclopentane. With catalyst $NiOAl_2O_3$ and addition of 1% thiophene the hydrogenation of phenol also takes place but the yield of hydrocarbons decreases to 50%. The rest consisted of unchanged phenol and a small amount of high boiling products. It may be supposed that they consist of phenyl ether and cyclohexylcyclohexanol.

Summary

1. The hydrogenation of monocyclic benzene hydrocarbons cannot take place in the presence of molybdenum catalysts prepared by precipitation in the usual way.

2. During destructive hydrogenation with catalysts, the combination of hydrogen with aromatic compounds occurs first, followed by the decomposition of the hydrogenated product.
3. Active catalysts may hydrogenate the benzylene ring, at the time of its formation, and during the decomposition of a hydrogenated product.
4. The destructive hydrogenation of phenol is due to its tautomeric form.
5. The presence of thiophene does not change the rate of destructive hydrogenation of naphthalene.
6. Thiophene decreases the yield of hydrocarbons during the hydrogenation of phenol.

The Oxidation of Sym-Triiodophenol[1]

BY W. H. HUNTER AND MARY L. MORSE

The present research upon the oxidation of *sym*-triiodophenol was undertaken for the purpose of ascertaining further facts concerning the nature and relative stability of triiodo Type A and diiodo Type B radicals.

A preliminary qualitative survey was made of the oxidation of *sym*-triiodophenol in non-aqueous or in aqueous media by several oxidizing agents.

The oxidation of *sym*-triiodophenol in alkaline solution by potassium ferricyanide was then chosen for further study. The products of this reaction were a large quantity of Lautemann's Red, a small quantity of the dinuclear quinone, 2,6,2′,6′-tetraiododiphenoquinone,[2] and an unstable compound which was not isolated. No phenoxyquinones were found.

Experiments were also carried out for the purpose of showing the relative oxidizing power of the crude oxidation products obtained from the respective oxidations of *sym*-trichloro-, tribromo-, and triiodophenols in glacial acetic acid by a large excess of chromium trioxide. The crude oxidation from the trichlorophenol showed the presence of about 97% of the mononuclear dichloroquinone, which has long been known to be the chief oxidation product formed under these conditions, whereas the crude

---

(1) The work described in this paper formed a part of a thesis submitted to the Graduate Faculty of the University of Minnesota by Mary L. Morse in partial fulfilment of the requirements for the degree of Doctor of Philosophy, August, 1929. The manuscript was written by the junior author after the death of Dr. Hunter.—L. I. SMITH.

(2) Kammerer and Benzinger [*Ber.*, **11**, 557 (1878)] assigned this formula to a substance which they obtained by the action of potassium tri-iodide solution on a boiling solution of phenol in sodium carbonate. However, the work of Hunter and Woollett indicated that the material obtained by Kammerer and Benzinger was Lautemann's Red. In this case, 2,6,2′,6′-tetraiododiphenoquinone is a new compound.

oxidation product of triiodophenol showed the presence of only 86% of mononuclear diiodoquinone. The crude oxidation product of tribromophenol, with 74% of mononuclear dibromoquinone, proved to be more similar to the oxidation product of triiodophenol than to that of the trichlorophenol.

The results of this research upon the oxidation of *sym*-triiodophenol indicate a pronounced tendency toward the rapid formation of Type B radicals, when this compound is treated with reagents capable of disengaging the hydrogen of the phenolic hydroxyl group. Since no phenoxyquinones were isolated, it is assumed that an iodinated Type A radical is very much less stable than its trichloro and tribromodimethoxy analogs. On the other hand, a comparison of the relative oxidizing power of the crude oxidation products of *sym*-trichloro, tribromo and triiodophenols indicates that polymerization of Type B radicals, proceeding concurrently with oxidation, is a more pronounced property of diiodo Type B radicals than of dichloro Type B radicals.

Another characteristic of the diiodo Type B radical is brought out by a comparison of certain of the products isolated in this study, with the oxidation products of pyrogallol dimethyl ether, as reported by Graebe and Hess,[3] and of tribromoresorcinol studied by Davis and Hill.[4] All of these products may be considered to be derivable from the polymerization of Type B radicals, although it is noteworthy that the mode of polymerization is apparently capable of variation, for from the diiodo Type B radicals there result both carbon to carbon and carbon to oxygen ties, the latter type predominating, whereas the dimethoxy Type B radical and the dibromoreso Type B radical exhibit a carbon to carbon type of polymerization.

No compounds ascribable to a carbon to carbon polymerization of Type B radicals were isolated in the work of Hunter and Levine[5] on the oxidation of tribromopyrogallol dimethyl ether, or in that of Hunter and Minerva Morse[6] on the oxidation of *sym*-trichlorophenol. All of the compounds isolated in these investigations must be looked upon as resulting from the carbon to oxygen type of polymerization.

The variation in the mode of polymerization evidenced by the types of polymers described above may be considered as due in part at least to the character of the Type B radicals involved. Thus, if a Type B radical of a given kind were more stable in a benzenoid than in a quinoid form, the corresponding polymer would be of the carbon–oxygen type, whereas if a Type B radical existed predominantly in the quinoid form, the carbon–carbon type of polymerization would occur.

---

(3) Graebe and Hess, *Ann.*, **340**, 232 (1905).

(4) Davis and Hill, This Journal, **51**, 500 (1929).

(5) Hunter and Levine, *ibid.*, **48**, 1608 (1926).

(6) Hunter and Morse, *ibid.*, **48**, 1615 (1926).

The results of this investigation indicate that: (1) if the triiodo Type A radical is capable of existence, it is less stable than the Type A radicals previously studied in this Laboratory; (2) the diiodo Type B radical, on the other hand, is more stable and exhibits a greater tendency toward polymerization than its dichloro analog; (3) diiodo Type B radicals are capable of polymerizing both carbon–carbon and carbon–oxygen, the latter representing the predominating tendency.

Experimental Part

The Effect of Various Oxidizing Agents on Sym-Triiodophenol.—The attempted oxidation of triiodophenol in glacial acetic acid by sodium nitrite resulted in the replacement of one of the iodine atoms by a nitro group. Nitro compounds of this type also resulted from the reaction between triiodophenol in carbon tetrachloride and nitrogen trioxide. No oxidation products were isolated in either case. The results of this investigation were in agreement with those reported earlier by Raiford and Heyl.[7]

In the oxidation of triiodophenol in benzene by lead dioxide a buff colored amorphous material, presumably polydihalogenophenylene oxide resulting from the catalytic decomposition of the salts of *sym*-triiodophenol, was the only product formed in appreciable amount. About 50% of the triiodophenol was recovered unchanged after a twenty-four hour reaction period. This reaction was not studied further.

The oxidation of triiodophenol in glacial acetic acid by chromium trioxide resulted in the formation of a large quantity of *m*-diiodo-*p*-quinone, some amorphous material and a small quantity of tetraiododiphenoquinone.

Triiodophenol was oxidized in neutral solution by potassium permanganate. The chief product of this reaction was a reddish amorphous mixture. This was reduced by treatment with sulfur dioxide, and extracted with acetone. The insoluble amorphous material amounted to about 75% of the theoretical yield calculated on the basis of the exclusive formation of the Type B radical. This material was probably the amorphous oxide. It was not investigated further. The acetone extract was evaporated to a small volume. A gum-like material was left which was purified by repeated crystallizations from ethyl acetate. The crystalline product melted at 260–263°, although some decomposition and evolution of iodine were noticeable at around 245°. This compound was found to be identical with the 2,6,2′,6′-tetraiododiphenol to be described below.

Anal. Calcd. for $C_{12}H_6O_2I_4$: I, 73.62. Found: (Carius) I, 73.56, 73.52.

Oxidation of Sym-Triiodophenol in Alkaline Solution by Potassium Ferricyanide

Preparation of the Oxidation Product or "Red Mixture."—A solution of 70 g. (10 equivalents) of potassium ferricyanide in 300 cc. of water was added in one lot with stirring to a solution of 10.00 g. (1 equivalent) of *sym*-triiodophenol dissolved in 15 cc. of 2 *N* potassium hydroxide (1.5 equivalents) and 200 cc. of water. A heavy reddish brown precipitate appeared immediately. The mixture was filtered, and the residue washed thoroughly with water. The filtrate contained some iodine but no organic material.

The precipitate, which will be called the "red mixture," was dried to constant weight at 60°. The average weight of the product at this point (for several runs) was 7.56 g. The theoretical weight calculated on the basis of the exclusive formation of Type B radicals, and the compounds which might result from subsequent polymerization of these, was 7.29 g.

Reduction of the "Red Mixture" and Isolation of 2,6,2′,6′-Tetraiododiphenol.—Ten lots of "red mixture" prepared as described above were combined while still moist

---

(7) Raiford and Heyl, *Am. Chem. J.*, **43**, 393 (1910); **44**, 209 (1910).

and suspended in a liter of water. A solution of 14.4 g. of hydrazine sulfate in 400 cc. of 2 *N* potassium hydroxide was added to this suspension and the mixture was placed on a steam-bath. After thirty to forty minutes the solution was decanted from the residue and the latter was thoroughly extracted with warm 1 *N* potassium hydroxide. The filtrate and washings were combined and acidified with acetic acid. A white precipitate was formed, which amounted to 4.3 g. or 5.6% yield of alkali soluble product.

This material was difficultly soluble in most organic solvents, but was purified by several crystallizations from ethyl acetate. It melted at 260–265° with noticeable decomposition at 245°. A molecular weight determination was impossible due to insolubility of the substance.

Anal. Calcd. for $C_{12}H_6O_2I_4$: I, 73.62. Found: (Carius) I, 73.64, 73.50.

2,6,2′,6′-Tetraiododiphenoquinone.—Two hundred cc. of a saturated solution of 2,6,2′,6′-tetraiododiphenol in glacial acetic acid was treated with 0.5 g. (50 equivalents) of chromium trioxide in 1 cc. of water and 25 cc. of glacial acetic acid. A drop of concentrated sulfuric acid was added to the mixture which was stirred for five minutes and filtered; 0.12 g. of a dark green crystalline product was obtained. The mother liquor was diluted with water but no further precipitation occurred. The crystalline product could not be purified further, due to its insolubility. It did not melt.

Anal. Calcd. for $C_{12}H_4O_2I_4$: I, 73.82. Found: (Carius) I, 73.09, 73.13.

Anal. (Hydrazine method for quinoid oxygen). Calcd. for $C_{12}H_4O_2I_4$: O, 4.65. Found: O, 4.66, 4.58.

Evidence for the Presence of an Unstable Compound in "Red Mixture."—A sample of freshly prepared "red mixture" was extracted with dry ether and filtered rapidly. The residue, a clean, red powder, was extracted with dry benzene, yielding a deep red solution. Gradual evaporation of the solvent at room temperature and atmospheric pressure gave deep red crystals, with a gold sheen. This substance decomposed without melting, and all attempts to purify it by recrystallization failed as the dry material changed rapidly to a reddish brown amorphous powder. A solution of the red crystals left a varnish-like deposit upon evaporation of the solvent, and no crystalline material could be obtained after this change had occurred. Several attempts were made to determine the quinoid oxygen content of this substance. The results were variable, but the highest value obtained was roughly 5.4%. The calculated quinoid oxygen content of tetraiododiphenoquinone is 4.65%, of *m*-diiodo-*p*-quinone, 8.88%, and of the as yet unknown triiodophenol iodide, 5.38%.

Comparison of the Quinoid Oxygen Content of the Crude Oxidation Products of Sym-Trichloro, Tribromo and Triiodophenols

Preparation of the Oxidation Product of the Sym-Trihalogenated Phenol.—1.00 gram of the *sym*-trihalogenated phenol was dissolved in a small quantity of glacial acetic acid at 50°. A solution of 19 equivalents of chromium trioxide in an equal weight of water was added to this solution all at once. After a few seconds (5–10 in the case of the trichlorophenol, 20 in the other two cases) the mixture was poured with

[a] Average of four or five determinations.

stirring into 200 cc. of water. The crude oxidation product which separated was filtered by suction within one half hour, and dried in a desiccator over concentrated sulfuric acid for about eighteen hours. The experimental data are given in Table I.

Summary

1. The oxidation of *sym*-triiodophenol results in the formation of mononuclear quinone, dinuclear quinone of the cedriret type, chromopolydihalogenophenylene oxide (Lautemann's Red) and an unstable compound which has not been isolated.

2. 2,6,2′,6′-Tetraiododiphenol and 2,6,2′,6′-tetraiododiphenoquinone have been isolated for the first time.

3. The crude oxidation product formed in the oxidation of *sym*-triiodophenol in glacial acetic acid by an excess of chromium trioxide is poorer in mononuclear quinone than that obtained under the same conditions by the oxidation of *sym*-trichlorophenol.

Some Tolyl Derivatives of Germanium[1]

BY J. K. SIMONS, E. C. WAGNER AND J. H. MÜLLER

Numerous phenyl but relatively few tolyl derivatives of germanium are known.[2]

No ortho or meta tolyl germanium compounds have been reported. A number of para tolyl compounds, mostly of mixed types, have been described by Tabern, Orndorff and Dennis,[3] Schwarz and Lewinsohn,[2] Bauer and Burschkies,[2] and Shelton.[4] Most tetraarylgermanes have been prepared from germanium tetrahalide by arylation either with Grignard compounds or with aryl halides and sodium,[2] both methods giving low yields.[5]

In the present study the interaction of germanium tetrachloride and arylmagnesium bromide led to incomplete arylation, with formation of triarylgermanium halide; a similar result was reported by Morgan and Drew[5] in the preparation of tetraphenylgermane. This procedure was tried unsuccessfully also for the preparation of triphenyl-*m*-tolylgermanium from triphenylgermanium bromide and *m*-tolylmagnesium bromide. The interaction of germanium tetrachloride and *p*-tolylmagnesium bromide further afforded an interesting example of exchange of halogen, the major product being tri-*p*-tolylgermanium bromide. An analogous result was obtained by Bauer and Burschkies[2] for the reaction between cyclohexylmagnesium bromide and germanium tetrachloride.

[5] Morgan and Drew, *J. Chem. Soc.*, **127**, 1760 (1925). No other investigators report yields on tetraaryl compounds.

A much more satisfactory procedure is that first used for tetraphenyltin by Chambers and Scherer[6] and extended by Kraus and Foster[7] to the preparation of tetraphenylgermanium, the first-formed Grignard compound being treated with zinc chloride, and the resulting zinc aryl (without isolation) treated with germanium tetrahalide. By this method there were obtained tetra-*p*-tolyl-, tetra-*m*-tolyl-, and tetra-*o*-tolylgermane in yields of 65, 75 and 30%, respectively. In each case some of the corresponding di-tolyl was isolated. No tri-*p*-tolylgermanium chloride was found, but both tri-*m*-tolyl- and tri-*o*-tolylgermanium chlorides were isolated as by-products due to incomplete arylation. The zinc aryl procedure was used also for the preparation of triphenyl-*m*-tolylgermanium.

The dearylation of tetraarylgermanes by bromine was effected for tetra-*p*-tolylgermanium by Schwarz and Lewinsohn[8] and for the tetra-*o*- and tetra-*m*-tolyl compounds in the present study. In each case the main product was triarylgermanium bromide, some nuclear bromination occurring with the *o*-tolyl compound. Hydrolysis of tri-*m*-tolyl- and tri-*p*-tolylgermanium bromide by aqueous alkali or by alcoholic silver nitrate yielded the corresponding tritolylgermanium oxide, $(Ar_3Ge)_2O$. Similar treatment of the *o*-tolyl chloride gave the hydroxide, Ar_3GeOH.

Controlled dearylation by the action of gaseous hydrogen bromide upon tetraaryl compounds, in preliminary experiments with tetraphenyl- and tetra-*p*-tolylgermanium, effected replacement of one aryl group by bromine, yielding triarylgermanium bromide and aromatic hydrocarbon, both of which can be isolated. It is the purpose of work now in progress to attempt the use of this reaction in a study of the relative reactivities of various aryl groups when attached to germanium, analogous to the work of Kharasch, Bullard, Gilman and others,[9] on organic compounds of other elements.

Experimental

General

Germanium Tetrachloride.—Winkler[10] found that dry distillation of a mixture of mercuric chloride and germanium sulfide yields germanic chloride. Trials showed that recovery of germanium is high but the product somewhat impure. The results of dis-

tillations of mixtures of germanite and mercuric chloride showed that ordinary distillation from a flask transposed as high as 73% of the germanium to chloride; heating the mixture in a sealed tube at 260–290° transposed 97% of the germanium to chloride. This reaction might be used to prepare large quantities of the chloride and for analytical purposes is even more promising.

The germanium tetrachloride needed for the work described was prepared from 4.2 kg. of 100-mesh germanite (6.45% GeO_2) by decomposition with concentrated nitric acid, digestion of the dried insoluble residue with concentrated hydrochloric acid and distillation. The distillate of crude chloride was washed with concd. hydrochloric acid to remove arsenious chloride[11] and distilled through an all glass eight-ball Snyder column. The product (490 g., 87.5% recovery) boiled 83.0–83.8° corr. and gave no test for arsenic in the last fraction.

Bromotoluenes were obtained from Eastman Kodak Co. Anhydrous zinc chloride (Baker U. S. P.) was fused and then crushed and kept in a desiccator over phosphorus pentoxide. Eastman anhydrous ether was kept over sodium just before use. Tetraphenylgermane and triphenylgermanium bromide were prepared according to Kraus and Foster.[12] Grignard reagents were prepared in the usual way and in an atmosphere of nitrogen.

Analysis.—After a consideration of the available methods for the determination of germanium in organic compounds,[13] it seemed preferable to estimate carbon and hydrogen rather than germanium. Trials of a modification of the usual wet oxidation methods, using concd. and fuming sulfuric acid with solid ammonium persulfate followed by evaporation to GeO_2 in a silica beaker heated laterally by a ring-burner, gave results in three to five hours which were reproducible but low by about 0.6% due to mechanical loss during expulsion of fumes. Accordingly carbon and hydrogen were determined by the micro-method of Pregl.[14] Both a porcelain and a platinum boat were used, combustion occurring more readily in the latter. It was found advisable to cover the sample with a layer of previously ignited finely ground copper oxide. The compounds were with one or two exceptions difficult to burn, the last traces of carbon being extremely resistant to combustion, so that it was necessary to heat the tube until it just began to soften. Some of the substances with lower melting points ignited with a flash when too rapidly heated, but even with these all of the carbon could be burned only on strong ignition. The analyses reported below are in each case the average of three acceptable determinations.

Preparation of Tolyl Compounds of Germanium

Tetratolylgermanes—General Procedure.—Interaction of germanium tetrachloride, aryl bromide (*o*-bromotoluene), and sodium yielded unsatisfactory results. Interaction of the Grignard reagent and germanium tetrachloride yielded triarylgermanium bromide as the main product. The modified zinc aryl procedure described below, essentially that of Kraus and Foster,[15] was found satisfactory. The Grignard reagent dissolved in ether in a three-necked one liter flask equipped with a stirrer, reflux condenser and dropping funnel, reacted in an atmosphere of nitrogen with an ether suspension of zinc chloride. After refluxing for one-half to one hour the ether was replaced by toluene (or xylene). To the cooled mixture was added a solution of germanium tetrachloride in the same solvent. After standing overnight the mixture was heated on the water-bath for three hours and then stirred and refluxed for fifteen to twenty hours. Mechanical stirring was used throughout and was found to be noticeably more efficient than agitation by a stream of nitrogen. Ammonium chloride and dilute hydrochloric acid were used for the hydrolysis and yielded cleaner products than did 2 *N* sulfuric acid. The upper layer was dried by calcium chloride and distilled to a residue under reduced pressure. Further details are recorded in the descriptions of the individual compounds.

p-Tolyl Derivatives

Tetra-*p*-tolylgermanium.—*p*-Bromotoluene (100 g.), zinc chloride (33 g.) and germanium tetrachloride (13 g.) were treated as outlined above. The residue was dissolved in 50–60 cc. of benzene. To the warm solution was added an equal volume of 58–70° ligroin, the whole chilled strongly, and the separated solid washed with cold ligroin. The mother liquors yielded more crystals by the same procedure. The yield of pure product was 65%. It melted at 229° on the Dennis "melting point bar" and at 227° corr. in the usual apparatus.

Anal. Calcd. for $C_{28}H_{28}Ge$: C, 76.92; H, 6.46. Found: C, 76.5; H, 6.47.

Tri-*p*-tolylgermanium Bromide.—Germanium tetrachloride (10.8 g.) was treated in ether solution with the Grignard reagent from 50 g. of *p*-bromotoluene. The mixture, after standing for two days, was refluxed for four hours. The ether was then distilled off and the residue heated at 110° for three hours.[16] The mass was taken up in benzene, decomposed with 2 *N* sulfuric acid, and the benzene layer dried with calcium chloride. The oily residue after distilling off the benzene was diluted with 20 cc. of 58–70° ligroin and the tetra-*p*-tolylgermanium filtered off; yield, 3.2 g.; 14.6%.

The mother liquors on vacuum distillation yielded (a) a small amount of *p*-bromotoluene, b. p. (760 mm.) 160–190°, (b) di-*p*-tolyl, b. p. (1–2 mm.) 100–125°, m. p. 117–121° from ligroin, and (c) a viscous oil of b. p. (1 mm.) 229–234° which after five recrystallizations from 90–120° ligroin was obtained as a crystalline solid of m. p. 130° corr. Mixed with a specimen of tri-*p*-tolylgermanium bromide (m. p. 127–128°) made according to Schwarz and Lewinsohn,[17] the melting point was 128–129°. This with the analytical and molecular weight values reported below identified the product as tri-*p*-tolylgermanium bromide. The yield after the first crystallization was 10.3 g. or 48%.

Anal. Calcd. for $C_{21}H_{21}GeBr$: C, 59.20; H, 4.97; mol. wt., 426. Found: C, 59.5; H, 5.24; mol. wt. (cryoscopic in benzene), 403, 404.

Tri-*p*-tolylgermanium Oxide.—Slightly impure tri-*p*-tolylgermanium bromide (1.9 g. from the Grignard reaction) was refluxed for ten hours with 40 cc. of 0.5 *N* aqueous sodium hydroxide. The resulting solid was filtered off and the filtrate titrated with 0.5 *N* hydrochloric acid. (Bromine found by titration, 18.3; calcd., 18.8.)

The white solid after drying and several crystallizations from 90–120° ligroin, and from a mixture of ligroin and methyl alcohol, melted at 147–148° corr.

Anal. Calcd. for $C_{42}H_{42}Ge_2O$: C, 71.23; H, 5.98; mol. wt., 708. Found: C, 70.6; H, 6.09; mol. wt. (Rast), 753; (cryoscopic in benzene), 714.

Tri-*p*-tolylgermanium oxide is a white densely crystalline solid, crystallizing in well-developed very small anisotropic prisms. It is insoluble in water; very slightly soluble in methyl and ethyl alcohol; and soluble in hot ligroin and cold benzene.

This compound was also made by the action of alcoholic silver nitrate on the bromide. The crystals obtained melted at 148–150° corr.

---

(16) Kraus and Flood showed this procedure to be advantageous in the preparation of tetraethylgermanium [This Journal, 54, 1636 (1932)].

(17) R. Schwarz and Lewinsohn, Ref. 2, p. 2354.

m-Tolyl Derivatives

Tetra-*m*-tolylgermanium.—The Grignard reagent from *m*-bromotoluene (75 g.), zinc chloride (30–33 g.), and germanium tetrachloride (10–11 g.) reacted as described above. The ether was removed by gentle heating (below 80°). After the usual further procedure there was obtained a final residue which was purified by crystallization from 58–70° ligroin; yield, 75%. Repeated crystallizations from 58–70° ligroin or a mixture of 90–120° ligroin and alcohol yielded the pure compound of melting point 146° corr.

Anal. Calcd. for $C_{28}H_{28}Ge$: C, 76.92; H, 6.46; mol. wt., 437. Found: C, 76.5; H, 6.61; mol. wt. (cryoscopic in benzene), 405.

Tetra-*m*-tolylgermanium is a white solid crystallizing from ligroin in long thin needles, which exhibit parallel extinction. It reacts with bromine to form tri-*m*-tolylgermanium bromide. It is insoluble in water; very slightly soluble in hot or cold methyl alcohol; soluble in ligroin or carbon tetrachloride, and very soluble in benzene or toluene.

Tri-*m*-tolylgermanium Chloride.—The mother liquors from crystallization of several preparations of tetra-*m*-tolylgermanium were vacuum distilled. Di-*m*-tolyl was isolated boiling at 120–125° at 1–2 mm. and at 280–290° at atm. pressure. The only other isolable product was a viscous oil boiling at 221–224° (1–2 mm.). Crystallization from dry methyl alcohol gave fine silky needles melting at 79° to a cloudy liquid which cleared at 90°. Analysis identified this as tri-*m*-tolylgermanium chloride with a trace of a bromine-containing impurity.

Anal. Calcd. for $C_{21}H_{21}GeCl$: C, 66.10; H, 5.55; mol. wt., 381. Found: C, 66.4; H, 5.51; mol. wt. (Rast), 445.

This compound was made also by warming tri-*m*-tolylgermanium oxide (see below) with concd. hydrochloric acid and alcohol on the water-bath. Evaporation of the alcohol and crystallization from methyl alcohol gave a product of m. p. 84–85° corr. A mixed melting point with the chloride obtained as by-product was 81.5–82.5° corr.

Tri-*m*-tolylgermanium chloride is a white solid crystallizing in fine optically active needles exhibiting parallel extinction. It is soluble in ligroin or benzene, and nearly insoluble in cold methyl alcohol.

Tri-*m*-tolylgermanium Bromide.—Tetra-*m*-tolylgermanium (25 g.) dissolved in 400 cc. of carbon tetrachloride was treated with 9.2 g. of bromine in 50 cc. of carbon tetrachloride added over a period of two hours. On refluxing the color gradually disappeared. After filtering with charcoal, the straw-yellow solution was distilled under slightly reduced pressure. *m*-Bromotoluene distilled at 128–129° at 135 mm.; b. p. 181–184° at 763 mm.; yield, 4.5 g. (46%).

The oily residue (25.0 g.) was crystallized from 400 cc. of hot methyl alcohol; yield, 15.8 g.; 65%. Two more crystallizations raised the melting point to 78.0–78.9° corr. The boiling point was 222–223° at 1 mm.

Anal. Calcd. for $C_{21}H_{21}GeBr$: C, 59.20; H, 4.97. Found: C, 59.1; H, 4.90.

Tri-*m*-tolylgermanium bromide is finely crystalline and white, but acquires a slight brown tinge on standing. It crystallizes in small, imperfectly formed, anisotropic needles. It is soluble in carbon tetrachloride, benzene and ether.

Tri-*m*-tolylgermanium Oxide.—The impure bromide (3.4 g.) from the mother liquors of the above preparation was shaken and then warmed with 150 cc. of a 1% alcoholic silver nitrate solution. The filtered solution was evaporated, the residue washed with water, taken up in benzene, dried with calcium chloride, and the solvent evaporated (yield, the theoretical). The product, crystallized three times from ligroin, melted at 125.0–125.2° corr.

Anal. Calcd. for $C_{42}H_{42}Ge_2O$: C, 71.23; H, 5.98; mol. wt., 708. Found: C, 71.0; H, 5.93; mol. wt. (cryoscopic in benzene), 686.

Tri-*m*-tolylgermanium oxide crystallizes in thick ill-formed crystals. It reacts with concd. hydrochloric acid in alcoholic solution to form tri-*m*-tolylgermanium chloride as described above. It is soluble in alcohol and benzene, and is insoluble in water.

Triphenyl-*m*-tolylgermanium.—Triphenylgermanium bromide (5 g.) and *m*-tolylmagnesium bromide reacted in the usual manner[18] and gave a product melting at 132–133° corr. Its analysis is reported below. A further crystallization from methyl alcohol raised its melting point to 136–138° corr. Attempts to repeat this experiment using twice the quantity of bromide were unsuccessful due to the large amount of triphenylgermanium oxide which was formed from unreacted bromide. The following procedure was better.

The zinc aryl compound from 20 g. of *m*-bromotoluene reacted in benzene solution with 6.0 g. of triphenylgermanium bromide. The mixture was refluxed for fourteen hours and then decomposed with ammonium chloride. The residue from distillation of the benzene layer deposited crystals which were washed with alcohol and dried; yield, 5.3 g.; 86%; m. p. 144–147° corr. After two crystallizations from alcohol and ligroin the substance was extracted eleven times with small quantities of methyl alcohol. This served to separate a high melting insoluble impurity and yielded a specimen of triphenyl *m*-tolylgermanium, resembling the above product under the microscope, and melting at 136.5–138.5° corr. A mixed melting point test gave the value 136–138° corr.

Anal. Calcd. for $C_{25}H_{22}Ge$: C, 75.99; H, 5.62; mol. wt., 395. Found: C, 75.9; H, 5.97; mol wt. (cryoscopic in benzene), 379.

Triphenyl *m*-tolylgermanium crystallizes from hot methyl alcohol in small strongly anisotropic needles which exhibit parallel extinction. It is soluble in benzene and hot ligroin; insoluble in cold ligroin, methyl and ethyl alcohols. Small amounts are best crystallized from methyl alcohol; larger amounts from a mixture of alcohol and ligroin.

o-Tolyl Derivatives

Tetra-*o*-tolylgermanium.—This compound was prepared according to the general procedure. The quantities were the same as for the *m*-tolyl compound; xylene was used as solvent in place of toluene. The oily residue was diluted with 20 cc. of 58–70° ligroin, and on standing yielded a solid product which was filtered off and washed with 58–70° ligroin. The melting point was 162–165° corr.; yield, 7.8 g.; 30%. The product was crystallized by boiling with 150 cc. of alcohol and enough benzene to clear the solution, which was filtered hot and chilled, yielding 4.9 g. of white, dense crystals of m. p. 173–174.5° corr. A specimen purified by repeated crystallization from 90–120° ligroin and then from a mixture of alcohol and benzene had a sharp melting point of 175–176° corr.

Anal. Calcd. for $C_{28}H_{28}Ge$: C, 76.92; H, 6.46; mol. wt., 437. Found: C, 76.9; H, 6.48; mol. wt. (cryoscopic in benzene), 392.

When crystallized from alcohol and benzene, crystals of the tetra-*o*-tolyl compound appear slowly and are usually badly developed, although their hexagonal character is easily observed under the microscope. The compound is insoluble in water, cold alcohol and light ligroin; slightly soluble in hot alcohol; and soluble in carbon tetrachloride, benzene, xylene or hot ligroin.

Tri-*o*-tolylgermanium Bromide.—A solution of tetra-*o*-tolylgermanium (4.0 g.) when refluxed with an equivalent quantity of bromine in 50 cc. of pure carbon tetrachloride was rapidly decolorized with the evolution of hydrogen bromide. Distillation

---

(18) Orndorff, Tabern and Dennis, THIS JOURNAL, 49, 2513 (1927).

of the solution yielded at 205–210° (1 mm.) a colorless oil with a bluish fluorescence. The product contained bromine. The molecular weight in benzene was 409; calcd. for $C_{21}H_{21}GeBr$, 426.

Tri-*o*-tolylgermanium Chloride.—The ligroin extract from the preparation of tetra-*o*-tolylgermanium was distilled *in vacuo*. After removal of some di-*o*-tolyl (b. p. (760 mm.) 272–282°), three fractionations at 1–2 mm. yielded finally a yellowish resinous oil with a bluish fluorescence which boiled at 229–235° at less than 1 mm. Its analysis indicated it to be probably a mixture of tri-*o*-tolylgermanium chloride and tetra-*o*-tolylgermanium.

Anal. Calcd. for $C_{21}H_{21}GeCl$: C, 66.10; H, 5.55; for $C_{28}H_{28}Ge$: C, 76.92; H, 6.46. Found: C, 74.0; H, 6.19.

Slow evaporation of an alcohol solution of this product deposited a solid which after crystallization from alcohol melted at 157–161°; it had the characteristic crystal form of tetra-*o*-tolylgermane under the microscope. The mother liquor from the first separation of the product was freed from alcohol and the residue distilled. It boiled at 216–222° at 1 mm. and treated with alcoholic silver nitrate yielded tri-*o*-tolylgermanium hydroxide, indicating it to be probably tri-*o*-tolylgermanium chloride.

Tri-*o*-tolylgermanium Hydroxide.—Tri-*o*-tolylgermanium chloride (4.0 g.) obtained as just described (b. p. (1 mm.) 215–219°) was treated with an excess of alcoholic silver nitrate. The filtrate, worked up as outlined under tri-*m*-tolylgermanium oxide, yielded an oily residue which would not crystallize but which distilled at 212–214° (1 mm.) as a resinous oil. On standing it became crystalline. From hot methyl alcohol it deposited as an amorphous powder. Qualitative tests showed the absence of halogen.

Anal. Calcd. for $C_{21}H_{22}GeO$: C, 69.46; H, 6.11; mol. wt., 363. Found: C, 69.6; H, 6.12; mol. wt. (cryoscopic in benzene), 344.

The Controlled Action of Hydrogen Bromide on Tetraarylgermanium Compounds

Tetraphenylgermanium.—An excess of hydrogen bromide was passed at room temperature through a solution of tetraphenylgermane (3.0 g.) in 100 cc. of chloroform. The solution was distilled to a residue which was crystallized twice from 90–120° ligroin. The crystals of triphenylgermanium bromide melted at 138.2° corr.

Tetra-*p*-tolylgermanium.—A 30% excess of hydrogen bromide reacted at room temperature with the germane (3.0 g.) in 100 cc. of chloroform. The solution was fractionally distilled and 3.2 cc. collected between 66 and 110°. Refractionation of this product yielded toluene, identified as 2,4-dinitrotoluene, m. p. 70–71° corr.[19]

The residue of 3.1 g. (2.9 g. calcd.) was crystallized from 58–70° ligroin. It melted at 124–128.5° obs.; mixed with tri-*p*-tolylgermanium bromide (m. p. 128–129.5° obs.) the melting point was 127–129.5° obs.

Summary

1. The following new tolyl compounds of germanium have been prepared and characterized: tetra-*o*-tolylgermanium, tetra-*m*-tolylgermanium, tri-*o*-tolylgermanium bromide, tri-*m*-tolylgermanium bromide and chloride, tri *o*-tolylgermanium hydroxide, tri-*m*-tolylgermanium oxide, tri-*p*-tolylgermanium oxide, triphenyl-*m*-tolylgermanium.

2. The zinc aryl procedure of Kraus and Foster has been used successfully in the preparation of tetratolylgermanes, including tetra-*p*-tolylgermanium, and the mixed compound triphenyl-*m*-tolylgermanium.

---

[19] Mulliken, "Identification of Pure Organic Compounds," John Wiley and Sons, New York, Vol. I, 1904, p. 202.

3. Interaction of germanium tetrachloride and *p*-tolylmagnesium bromide yielded principally tri-*p*-tolylgermanium bromide, indicating the probable cause of low yields of tetraarylgermanes hitherto obtained by this method.

4. Controlled action of hydrogen bromide on tetraphenyl- and tetra-*p*-tolylgermanium yielded the corresponding triarvlgermanium bromide and aromatic hydrocarbon.

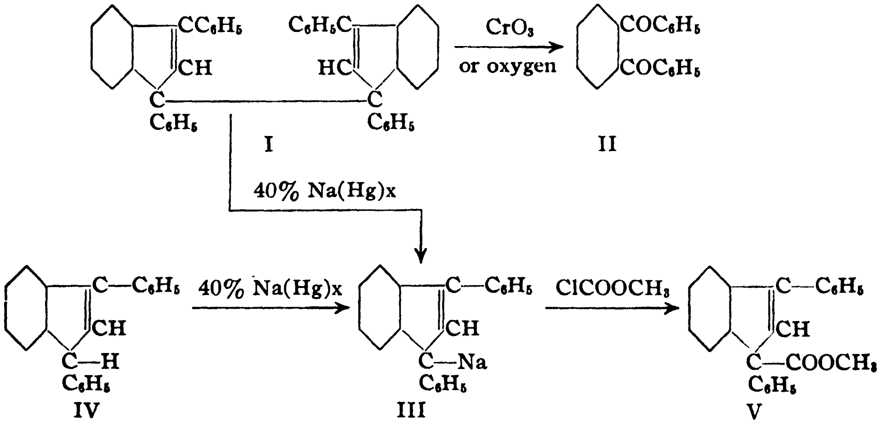
Rearrangements of the Polyines. V. Reactions of Bis-1,1'-(1,3-diphenylindenyl)

BY M. T. GOEBEL AND C. S. MARVEL

Bis-1,1'-(1,3-diphenylindenyl) (I) has recently been prepared[1] for the purpose of comparing it with the isomeric hydrocarbon $C_{42}H_{30}$, which is formed by the rearrangement of tetraphenyldiphenylethinylethane.[2] A comparison of the physical properties of these two hydrocarbons showed that they were not identical. The present study of the chemical reactions of bis-1,1'-(1,3-diphenylindenyl) has shown that it resembles the hexaarylethanes rather than the hydrocarbons produced when tetraaryldiethinylethanes undergo rearrangement.



Bis-1,1'-(1,3-diphenylindenyl) (I) was oxidized readily by chromic acid to give almost quantitative yields of *o*-dibenzoylbenzene (II) and no *o*-benzoylbenzoic acid was obtained. Under the same conditions Moureu's hydrocarbon[2] yielded no *o*-dibenzoylbenzene but did give *o*-benzoylbenzoic

acid. The bisindenyl was rapidly oxidized to *o*-dibenzoylbenzene by oxygen at the temperature of boiling xylene. Some oxygen was absorbed by a cold solution of the bisindenyl but no definite oxidation products were isolated.

The bisindenyl gave a faintly yellow colored solution in xylene at room temperature. Heating this solution out of contact with air caused the color to deepen and subsequent cooling caused this color to fade. However, the color change was not strictly reversible and continued heating and cooling changed the bisindenyl into a gummy solid.

The bisindenyl was slowly cleaved by 1% sodium amalgam but readily by 40% amalgam or sodium–potassium alloy to give a metal derivative (III) which was identical with the one prepared from 1,3-diphenylindene (IV). The identity of the two metal derivatives was shown by converting them to the same methyl ester of 1,3-diphenylindene-1-carboxylic acid (V).

These reactions of bis-1,1'-(1,3-diphenylindenyl) show that it contains a weak central carbon–carbon linkage and apparently dissociates to an unstable free radical at elevated temperatures. It is related in structure to the diarylvinyldiarylmethyl radicals of Ziegler[3] and to the triphenylindenyl of Kohler.[4]

Experimental

Bis-1,1'-(1,3-diphenylindenyl).—The procedure of Halley and Marvel[2] was followed but somewhat larger runs were made. The product was obtained in yields of 65% of the theoretical amount, m. p. 195–196°. It was also readily prepared by treating 1,3-diphenylindene with 40% sodium amalgam and treating the resulting metal alkyl with tetramethylethylene bromide.

Oxidation. 1. With Potassium Dichromate.—A solution of 1 g. of the hydrocarbon and 5 g. of potassium dichromate in 50 cc. of glacial acetic acid was boiled under a reflux condenser for about ten hours. The solution was poured into water, the precipitate was collected on a suction filter and then recrystallized from alcohol. The yield was 0.8 g. of *o*-dibenzoylbenzene, m. p. 145–146°. The identification was made by taking a mixed melting point of this material with *o*-dibenzoylbenzene prepared according to the method of Guyot and Catel.[5]

2. With Oxygen.—A solution of the bisindenyl in xylene did not absorb a measurable amount of oxygen at 30°. However, at the temperature of boiling xylene, the solution did absorb oxygen and the bisindenyl was oxidized to *o*-dibenzoylbenzene.

A solution of 0.5 g. of the bisindenyl in 30 cc. of xylene was placed in a flask attached to a gas buret filled with oxygen. The solution was heated to boiling and shaken vigorously for about thirty minutes. The solution was maintained at the boiling point of xylene by heating the flask occasionally with a small flame. The mixture was cooled, and the oxygen absorption (92 cc., 0°, 760 mm.) measured. The treatment was repeated but no further oxygen was absorbed. During the first treatment with oxygen there was a series of color changes which seemed of interest since they occurred in every trial. The solution was pale yellow at the beginning. During the first three minutes of the reaction, this color faded until the solution was entirely colorless. Then during the next five minutes a deep red color developed. At the end of thirty minutes this color had faded and the solution was again yellow in color. From the reaction mixture 0.3 g. of *o*-dibenzoylbenzene was obtained.

---

[3] Ziegler, *Ann.*, **434**, 34 (1923).

[4] Kohler, *Am. Chem. J.*, **40**, 217 (1908).

[5] Guyot and Catel, *Bull. soc. chim.*, [3] **35**, 1135 (1906).

A solution of 1 g. of the bisindenyl in 200 cc. of chloroform was shaken in an atmosphere of dry oxygen for three days. A deep red color developed in the solution and about 20 cc. of oxygen (0°, 760 mm.) was absorbed. Evaporation of the solution gave a red gum from which no crystalline material could be separated.

Effect of Heat.—A solution of the bisindenyl in xylene became deeper yellow in color on heating and the color faded on cooling. After two or three times the deeper color no longer faded. Evaporation of the solution gave a very impure sample of the bisindenyl. Prolonged heating in xylene changed the bisindenyl to gummy products which could not be identified.

Reduction.—Reduction of the bisindenyl by boiling 1 g. with 1.5 g. of phosphorus in 5 cc. of constant boiling hydriodic acid and 50 cc. of glacial acetic acid gave 0.8 g. of 1,3-diphenylhydrindene (m. p. 156–157°) which was identical with a sample of this material which was prepared by the method of Ziegler, Grabbe and Ulrich.[6]

Cleavage with Alkali Metals. With 1% Sodium Amalgam.—A solution of 1 g. of the bisindenyl in 250 cc. of dry ether gave a distinctly yellow colored solution when shaken with 10 cc. of 1% sodium amalgam for thirty minutes.

With 40% Sodium Amalgam.—A solution of 1.5 g. of the bisindenyl in 250 cc. of dry ether was shaken with 10 cc. of 40% sodium amalgam. The characteristic yellow color developed in ten minutes. The mixture was shaken overnight, the sodium derivative was treated with methyl chloroformate and a 20% yield of 1-carbomethoxy-1,3-diphenylindene was obtained. The ester was characterized by comparing it with the material described below.

With Liquid Sodium–Potassium Alloy.—A solution of 1 g. of the bisindenyl in 250 cc. of ether was shaken with 5 g. of liquid sodium–potassium alloy. A yellow color developed at once. After about thirty minutes the metal derivative was converted to the carbomethoxy derivative. The yield was 0.6 g. If the alloy was allowed to react for a longer period a secondary reaction occurred and no ester could be obtained.

1-Carbomethoxyl-1,3-diphenylindene.—A solution of 2 g. of 1,3-diphenylindene in 250 cc. of dry ether was shaken with 10 cc. of 40% sodium amalgam. The reaction seemed to be complete in about an hour, as little hydrogen was evolved after that time. At the end of about twenty-four hours, the excess amalgam was frozen and the yellow solution of the sodium derivative was decanted. An atmosphere of dry nitrogen was maintained over the solution during these operations. A slight excess of methyl chloroformate was added to the solution and then the solution was washed with water, dried over magnesium sulfate and the solvent evaporated. The residue was recrystallized from a mixture of ethyl acetate and methanol. The yield was 1.5 g. of a product melting at 99–100°.

Anal. Calcd. for $C_{23}H_{18}O_2$: C, 84.62; H, 5.56; mol. wt., 326. Found: C, 84.66, 84.58; H, 5.62, 5.51; mol. wt. (Rast), 334, 317.

The corresponding acid could not be obtained by treating the metallic derivative with dry carbon dioxide. When these experiments were performed the carbon dioxide discharged the color of the metal alkyl solution but on working up the reaction mixture only the original 1,3-diphenylindene was recovered. Attempts to hydrolyze the methyl ester with alcoholic potassium hydroxide and subsequent liberation of the acid by addition of mineral acid gave a gum which could not be purified.

Summary

Bis-1,1′-(1,3-diphenylindenyl) has been found to have many properties

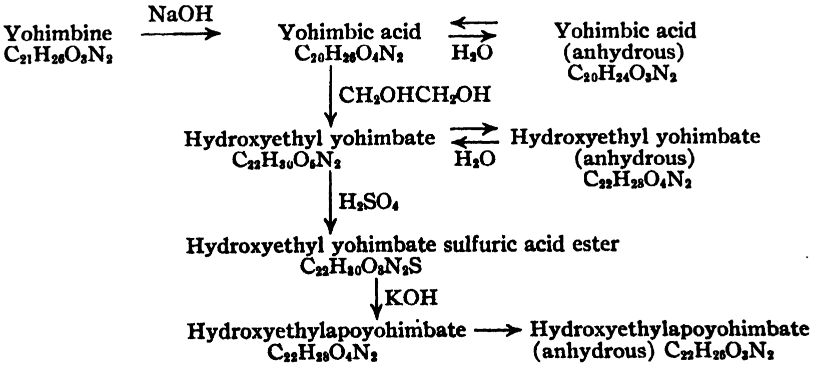
Some Hydroxy and Amino Esters of Yohimbic Acid

BY DAVID E. WORRALL

Yohimbine is an optically active alkaloid occurring in the bark of the African yohimbus tree. The present investigation is concerned with an attempt to increase the anesthetic action by the introduction of certain groups. Yohimbic acid exists in two forms differing one from the other by a molecule of water. Yohimbine is the methyl ester of anhydrous yohimbic acid and results whether one starts with hydrated or anhydrous yohimbic acid. Similarly ethyl alcohol forms an ester with yohimbic acid corresponding to the anhydrous form. On the contrary, propyl and butyl alcohols form esters that retain the additional molecule of water.[1]

It has been found in the present investigation that yohimbic acid forms esters with the polyhydric alcohols, ethylene glycol, trimethyleneglycol and glycerol, as well as with ethylene chlorohydrin, reacting with one equivalent of each. The resulting esters are derivatives of the hydrated form of yohimbic acid. The additional molecule of water is easily eliminated by drying in a vacuum over phosphorus pentoxide, a process that is reversed by exposing the product to air. The new esters turn yellow on exposure to light, form water-soluble salts with acids, etc. Esters are formed with sulfuric acid that on hydrolysis with alkali regenerate sulfuric acid, thereby producing an unsaturated group in the alkaloid. This reaction results in a base containing one molecule less of water than the

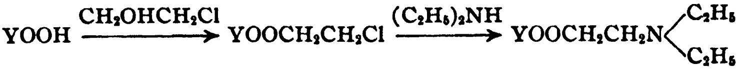


---

(1) Barger and Field, *J. Chem. Soc.*, **123**, 3003 (1923).

original substance. The new substance is still capable of losing a molecule of water, changing from the hydrated to anhydrous form. Therefore, the term *apo* introduced by Barger and Field,[2] who discovered this reaction with sulfuric acid, has been used to designate the unsaturated base. The scheme shown, using ethylene glycol with yohimbic acid, illustrates the changes and relationships involved.

The ester obtained from ethylene chlorohydrin is capable of condensing with secondary amines, thereby producing groups found in local anesthetics of the novacaine type.



$$\text{YOOH} \xrightarrow{\text{CH}_2\text{OHCH}_2\text{Cl}} \text{YOOCH}_2\text{CH}_2\text{Cl} \xrightarrow{(\text{C}_2\text{H}_5)_2\text{NH}} \text{YOOCH}_2\text{CH}_2\text{N}\begin{matrix}\diagup \text{C}_2\text{H}_5 \\ \diagdown \text{C}_2\text{H}_5\end{matrix}$$

Experimental

Yohimbic acid was prepared by the alkaline hydrolysis of yohimbine hydrochloride:[3] 5-g. samples were weighed out, mixed with 20–25 cc. of the appropriate alcohol and saturated with hydrogen chloride gas. The crude ester solutions after a week's standing were added slowly to a moderately large volume of water containing an excess of ammonia and recrystallized from dilute alcohol; yield of purified material 3–3.5 g.

TABLE I

ESTERS OF YOHIMBIC ACID

Substance	Formula	M. p., °C.	Cryst. form	Analyses, % Calcd. C	Calcd. H	Found C	Found H
α-Chloroethyl	$C_{22}H_{29}O_4N_2Cl$	119–120	Stout flat needles	Cl,	8.4	Cl,	8.4
α-Hydroxyethyl	$C_{22}H_{30}O_5N_2$	132–135	Prismatic needles	65.7	7.5	65.2	7.6
α-Hydroxypropyl	$C_{23}H_{32}O_5N_2$	135–138	Flat needles	66.4	7.7	66.0	7.8
α,β-Dihydroxypropyl	$C_{23}H_{32}O_6N_2$	111–112	Microscopic	63.9	7.4	63.5	7.5

The new esters, if dried in a vacuum over sulfuric acid, gain weight on exposure to the atmosphere until one molar equivalent of water has been absorbed.

α-Hydroxyethyl Yohimbate Sulfuric Acid Ester.—One gram of hydroxyethyl yohimbate was dissolved in 10 cc. of cold concd. sulfuric acid, warmed to room temperature and poured on cracked ice. The product was recrystallized from water, separating in the form of microscopic crystals melting at 288–289°.

Anal. Calcd. for $C_{22}H_{30}O_8N_2S$: S, 6.6. Found: S, 6.7.

α-Hydroxyethyl Apoyohimbate.—The sulfuric acid ester was heated for a few minutes with dilute alkali. Extraction with ether removed the apo compound, which was recrystallized from alcohol, separating in glistening irregular plates melting at 117–118°, and darkening rapidly on exposure to light or heat.

Anal. Calcd. for $C_{22}H_{28}O_4N_2$: C, 68.7, H, 7.3. Found: C, 68.2, H, 7.4.

The hydrochloric acid salt, prepared by adding a few drops of the acid to a hot alcoholic solution of the ester, separates from solution in clusters of flat needles melting with decomposition at 292–294°.

Anal. Calcd. for $C_{22}H_{28}O_4N_2 \cdot HCl$: Cl, 8.4. Found: Cl, 8.2.

The amine derivatives were prepared by dissolving chloroethyl yohimbate in an excess of the appropriate amine and heating the mixture in a sealed tube. The contents were then dissolved in acid and precipitated in the customary manner with ammonia. The anhydrous form in each case was used for analysis.

TABLE II

AMINO ESTERS OF YOHIMBIC ACID

Substance	Formula	M. p., °C.	Analyses, % Calcd. C	H	Found C	H	Time required for formation
α-Diethylaminoethyl	$C_{26}H_{37}O_3N_3$	76– 78	71.1	8.4	70.8	8.9	3 hours
α-Allylaminoethyl	$C_{25}H_{33}O_3N_3$	124–126	70.9	7.8	70.4	7.9	8 hours
α-Piperidinoethyl	$C_{27}H_{39}O_4N_3$	129–131	69.1	8.3	69.4	8.6	10 minutes

α-Diethylaminoethyl Apoyohimbate.—The diethylamino compound (5 g.) was dissolved in 50 cc. of cold concd. sulfuric acid. After standing for ten minutes the mixture was added to cracked ice, thereby producing a sticky gelatinous precipitate. This product was converted into the apo compound by heating with 2% alcoholic potash; yield approximately 1 g. The analytical sample was dried over sulfuric acid immediately before use. It separates from alcohol in lustrous microscopic crystals melting at 80–82°.

Anal. Calcd. for $C_{26}H_{35}O_2N_3$: C, 74.1; H, 8.3. Found: C, 73.6; H, 8.5.

These yohimbine compounds react smoothly with methyl iodide, forming addition products which were obtained as follows. To approximately 0.5 g. of the yohimbine derivative dissolved in 5 cc. of acetone was added an excess of methyl iodide. The resulting oil was separated, washed with acetone and dried at 105–110°.

TABLE III

METHYL IODIDES OF YOHIMBATES

Substance, yohimbate	Formula	Iodine, % Calcd.	Found	M. p., °C.
α-Hydroxypropyl	$C_{23}H_{32}O_5N_2 \cdot CH_3I$	22.6	22.7	Indefinite
α,β-Dihydroxypropyl	$C_{23}H_{32}O_6N_2 \cdot CH_3I$	22.1	22.2	Indefinite
α-Allylaminoethyl	$C_{25}H_{35}O_4N_3 \cdot CH_3I$	21.8	21.6	Indefinite
α-Piperidinoethyl	$C_{27}H_{39}O_4N_3 \cdot 2CH_3I$	33.1	32.9	218–219
α-Diethylaminoethyl	$C_{26}H_{39}O_4N_3 \cdot 2CH_3I$	34.3	34.6	217–218
α-Diethylaminoethyl apo-	$C_{26}H_{37}O_3N_3 \cdot 2CH_3I$	35.1	35.3	179–180

The hydrochloric acid salts were prepared by bubbling hydrogen chloride gas through an acetone solution of the yohimbate and drying in the oven at 105°.

TABLE IV

HYDROCHLORIDES OF YOHIMBATES

Substance, yohimbate	Formula	Chlorine, % Calcd.	Found	M. p., °C.
α-Allylaminoethyl	$C_{25}H_{35}O_4N_5 \cdot 2HCl$	13.8	14.0	263–264° + foaming
α-Piperidinoethyl	$C_{27}H_{39}O_4N_3 \cdot 2HCl$	13.1	13.0	212–214° + dec.
α-Diethylaminoethyl	$C_{26}H_{39}O_4N_3 \cdot 2HCl$	13.4	13.2	198–200° + foaming

Anal. Calcd. for $C_{26}H_{39}O_4N_3 \cdot 2HCl$: C, 58.9; H, 7.7. Found: C, 58.6; H, 7.8.

Several of these substances have been sent for physiological investigation to Dr. Albert G. Young of Boston for whose assistance in securing the gift of a generous quantity of this alkaloid from Hoffmann-Laroche of Nutley, New Jersey, I am very grateful.

Summary

Esters of yohimbic acid with ethylene glycol, trimethylene glycol, glycerol and ethylene chlorohydrin have been synthesized.

The ester with ethylene chlorohydrin has been found to react with allylamine, piperidine and diethylamine.

Certain salts and derivatives of the resulting hydroxy and amino esters were prepared.

Studies in the Rearrangements of Phenyl Ethers. The Action of Aluminum Chloride on Butyl Phenyl Ethers

BY RICHARD A. SMITH

The action of aluminum chloride on phenyl ethers has been studied extensively; this reaction is now reasonably clear and is known as the Fries migration.[1]

The isomerization of phenyl ethers to substituted phenols has received but little study; the two rearrangements appear, at the present time, to have many characteristics in common. There are undoubtedly many recorded instances of reactions in which phenyl ether isomerization took place due to the presence of an aluminum chloride catalyst. The transitory nature of the ether in most cases prevented the observation of the rearrangement as such. In 1892 Hartmann and Gattermann[2] in utilizing the action of aluminum chloride at elevated temperatures to hydrolyze phenyl ethers to phenols and alkyl halides noticed, in one case, the formation of a small quantity of a substituted phenol. This will be referred to in greater detail later. Ether rearrangements with the aid of aluminum chloride have been reported by Huston.[3] The author has reported the synthesis of thymol and an isomer by the catalytic isomerization of isopropyl *m*-cresyl ether with aluminum chloride.[4]

In this communication it is desired to show extensions of the method to rearrangements of different types of alkyl phenyl ethers. Ethers in which the carbon atom of the alkyl group attached to the ether oxygen was, respectively, primary, secondary and tertiary were studied. The three butyl ethers, iso, secondary and tertiary, were selected. A second purpose is to attempt to clarify contradictory evidence in the literature pertaining to para iso and tertiary butyl phenols.

The first purpose of the report was fulfilled by synthesizing the three designated butyl phenyl ethers in a conventional manner. The isobutyl phenyl ether has been prepared previously.[2,5]

(5) Riess, *Ber.*, **3**, 780 (1870); Bamberger, *ibid.*, **19**, 1820 (1886); Perkin, *J. Chem. Soc.*, **69**, 1250 (1896); Senkowski, *Ber.*, **24**, 2974 (1891).

The three ethers were treated in the cold with anhydrous aluminum chloride and the reaction products isolated and identified as substituted phenols.

Hartmann and Gattermann in reporting the small quantity of substituted phenol they obtained from isobutyl phenyl ether state it to be *p*-isobutylphenol. The melting point they cite is in agreement with that in the literature for *p*-isobutylphenol. Kraenzlein[1] in commenting on their work states that the action is a splitting off of isobutylene and readdition of this compound and phenol to yield *p*-tertiary-butylphenol. The compound prepared by Hartmann and Gattermann is reported as the tertiary product in Beilstein's "Handbuch." The situation is complicated by the data appearing in the literature concerning the two phenols in dispute. The methods of synthesis of *p*-tertiary-butylphenol leave but little doubt as to its structure.[6]

Senkowski and earlier workers[7] have reported the synthesis of *p*-isobutylphenol from the action of zinc chloride on isobutyl alcohol and phenol. The product so prepared has physical constants almost identical with those of the tertiary derivative. Senkowski notes this. Evidence of this communication, and earlier ones, indicates that the isobutylphenol has never been prepared, the product being tertiary-butylphenol.

The experimental evidence of the present communication indicates that both tertiary and isobutyl phenyl ether isomerize to the same product, *p*-tertiary-butylphenol. This is an agreement with the experimental results of the previous workers but not with their conclusions. The present findings support the mechanism of Kraenzlein. The fact that isobutyl phenyl ether leads to a tertiary-butylphenol strongly indicates the need of a mechanism involving scission of the ether with readdition of the subsequent products. The apparent necessity for such a mechanism in this one case does not prove that all such reactions are not intramolecular, as it is conceivable that a compound may change to an isomer, with a decrease in free energy, by more than one path. The mechanism of these isomerizations is at present under further study.

Secondary-butyl phenyl ether was found to rearrange to *p*-secondary-butylphenol, which has been previously prepared.[8]

The behavior of tertiary-butyl phenyl ether is worthy of note. This compound isomerizes very readily to *p*-tertiary-butylphenol by the application of heat alone. It cannot be distilled at atmospheric pressure without rearrangement taking place. The pyrolysis of this ether is described.

Experimental

Preparation of the Ethers.—The phenyl ethers were prepared by the action of the alkyl bromides on a solution of sodium phenolate in alcohol. An equivalent of sodium

---

(6) Studer, *Ber.*, **14**, 1474 (1881); *Ann.*, **211**, 242 (1882); Senkowski, *Ber.*, **23**, 2418 (1890); Gurewitsch, *ibid.*, **28**, 2428 (1895); Lewis, *J. Chem. Soc.*, **83**, 329 (1903).

(8) Estreicher, *ibid.*, **33**, 442 (1900).

was added to excess alcohol; an equivalent of phenol was added to the clear solution so obtained. An excess of the alkyl halide was then added and the whole refluxed for six to eight hours. In the case of the tertiary butyl derivative the time of refluxing was shortened to twenty minutes to minimize isomerization. The excess alcohol and alkyl halide were removed by evaporation, the sodium bromide was washed out with water, the phenolic compounds were removed with 15% sodium hydroxide solution, and the remaining organic material was water-washed, dried and distilled. The yields of the isobutyl and secondary butyl ethers ranged from 80–90%. The yields of the tertiary-butyl phenyl ether were poor. The analytical data and physical properties of these compounds appear in Table I. The tertiary-butyl product was obtained as long white needles insoluble in 15% potassium hydroxide, and with no action on aqueous or alcoholic ferric chloride. The product was recrystallized from benzene. The pure recrystallized product melted under water. Due to rearrangement to the phenol, no accurate melting point could be determined. Prolonged heating in the melting point tube gave the melting point of the *p*-tertiary-butylphenol.

Catalytic Rearrangement of the Ethers.—Each ether was rearranged to the phenol by allowing it to stand a few days at room temperature with an equal weight of aluminum chloride. The catalyst was always added to the ether in small portions with external cooling. The aluminum chloride in each case dissolved in the ether with the formation of a viscous dark red mass. After standing, the products were decomposed with ice, water and hydrochloric acid. The organic products were separated, water-washed and extracted with 15% potassium hydroxide. The quantity of unrearranged ether was always very small. The alkaline solutions were neutralized with hydrochloric acid. The product from secondary-butyl phenyl ether was a liquid which was purified by distillation. The other two ethers yielded solid products which were purified by recrystallizations from water. Long white needles of the same melting point and the same mixed melting point were obtained. Yields were always in excess of 50%.

Pyrolytic Rearrangement.—The secondary and isobutyl phenyl ethers did not rearrange on ten hours of refluxing. Tertiary-butyl phenyl ether isomerized entirely to an alkali-soluble product on a few hours of refluxing. The boiling point rose from 192 to 230° in three hours. The product was recrystallized from water. The mixed melting points with the products obtained by catalytic ether rearrangement were identical.

TABLE I

BUTYL PHENYL ETHERS AND BUTYLPHENOLS

Sec-butyl phenyl ether has been rearranged to the phenol by means of a sulfuric–acetic acid rearranging mixture by Natelson (Ph.D. Thesis, N. Y. U., 1931) and Siegel (M.Sc. Thesis, N. Y. U., 1933). The product they obtained is the same as that reported here.

Studies on the Rearrangement of Tertiary-butylmethylcarbinol (Pinacolyl Alcohol). II.[1] Dehydration

BY FRANK C. WHITMORE AND P. L. MEUNIER[2]

A primary alcohol containing the grouping R_3CCH_2OH can be dehydrated only with rearrangement.[3] On the other hand, a related tertiary alcohol, $R_3CC(OH)R_2$, is dehydrated mainly without rearrangement.[4] Conceivably a secondary alcohol, $R_3CCHOHR$, could be dehydrated either with or without rearrangement.[5] Until the present study, only rearranged products had been reported from the dehydration of such secondary alcohols.[1,6] The simplest of these alcohols, tertiaryl-butylmethylcarbinol, has been dehydrated by many workers.[7] The products obtained have been rearranged olefins, tetramethylethylene (b. p. 72°), and *unsym*-methylisopropylethylene (b. p. 54°). Previous work in this Laboratory has shown that the intermediate fraction, b. p. 65–67°, observed by some workers, is a mixture of the same two olefins.[1] The only preparations of the normal dehydration product, *tert*-butylethylene, have been made indirectly by the thermal decomposition of the xanthate of pinacolyl alcohol[8] and of the acetate.[1]

In the present work the pinacolyl alcohol was purified by repeated distillation and fractional crystallization and a large quantity was dehydrated at high pressure and temperature over a catalyst of phosphoric acid on silica gel. The usual rearranged olefins, tetramethylethylene and *unsym*-methylisopropylethylene, were obtained but, in addition, a small

amount (3%) of the unrearranged olefin, *tert*-butylethylene, was isolated and identified.

Experimental

Preparation and Purification of Tert-butylmethylcarbinol.—The alcohol, b. p. 118.7–119.7 (741 mm.), 120.4° (760 mm.), n^{20}_{D} 1.4148, was prepared by the action of acetaldehyde on *tert*-butylmagnesium chloride.[1] The yield for a 20-mole run, based on the chloride used, was 52.1%. The alcohol was distilled in an efficient laboratory column, 125 × 2.3 cm.,[9] after which it was further purified by fractional crystallization. In this way the freezing point was raised from 1.5 to 5.3°.

Dehydration of Tert-butylmethylcarbinol.—Ordinary laboratory methods for dehydrating the alcohol, using sulfuric acid, orthophosphoric acid, phosphoric anhydride, and oxalic acid, proved unsatisfactory for dehydrating large quantities. Finally, the alcohol was dehydrated in a high pressure flow system containing an electrically heated high pressure reactor made of Shelby seamless tubing, 91 cm. by 1.6 cm. (inside), partly filled with a catalyst of phosphoric acid on silica gel. A pump, adapted for handling small quantities of liquid, was used to pump the alcohol through the system. In a typical run 500 g. of the alcohol was dehydrated at 300° and 2500 lb. pressure. The loss was only 2%. The yield of olefins was 337 g. or 80%. These were repeatedly fractionated in a partial condensation column, 90 × 1.2 cm., using a reflux ratio of 200:1.[9] This gave three fractions of boiling range (740 mm.), wt., yield and n^{20}_{D} as follows: 38–43°, 10.5 g., 3%, 1.3775; 54–58°, 107 g., 31%, 1.3904; 69–72°, 208 g., 61%, 1.4121. The last two fractions were *unsym*-methylisopropylethylene and tetramethylethylene, respectively. The low-boiling fraction was identified as *tert*-butylethylene by ozonolysis.[10] In the aqueous layer of the decomposition products of the ozonide, qualitative tests for formaldehyde were obtained with fuchsin reagent and with aqueous resorcinol. The oily product oxidized in air to trimethylacetic acid, which was identified by conversion to the amide, m. p. 145–148°. Mixed with pure trimethylacetamide (m. p. 153–154°), it melted at 149–151°.

Summary

The catalytic dehydration of *tert*-butylmethylcarbinol at high temperature and pressure gave the rearranged olefins, tetramethylethylene and *unsym*-methylisopropylethylene, in the ratio 2:1 and, in addition, a small amount of the normal dehydration product, tertiary-butylethylene.

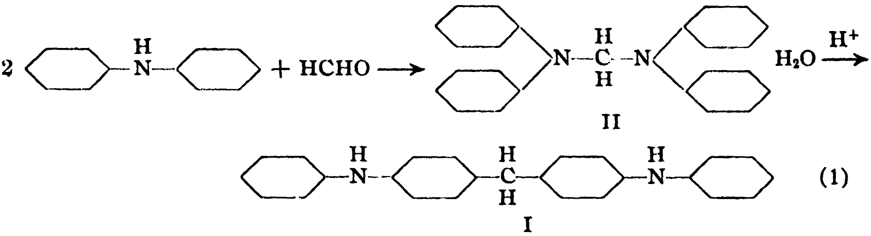
The Reaction of Formaldehyde with Diphenylamine

BY DAVID CRAIG

The formation of dianilinodiphenylmethane as a product of the reaction of formaldehyde with diphenylamine[1,2] has long been claimed. However, the isolation of pure compounds from the products of the reaction has not been recorded up to this time. This is true notwithstanding the fact that Straus and Bormann[3] succeeded in preparing *p,p'*-dianilinodiphenylmethane in a series of reactions starting with *p,p'*-diaminodiphenylmethane. A study of the reaction of formaldehyde with diphenylamine[4] under a variety of conditions was therefore undertaken, the results of which are described in this communication.



The course of the reaction of formaldehyde with diphenylamine in the presence of acids is dependent on the relative amounts of the reactants used. An excess of diphenylamine favors the formation of *p,p'*-dianilinodiphenylmethane. On the other hand, if an excess of formaldehyde or even equimolecular amounts of the reactants are employed, resins are formed which hinder or prevent the isolation of a pure product. Possibly these resins result from subsequent condensation with formaldehyde to form long chain molecules of the Staudinger type. This condensation occurs readily in the absence or presence of acid catalysts. Resins may also be obtained directly from *p,p'*-dianilinodiphenylmethane by heating with strong acids, diphenylamine being formed as one of the products.[5] Indeed, it appears that resins of this type are the ultimate condensation products of formaldehyde with amines rather than the simple diphenylmethanes as suggested by Wagner.[6]

(6) Wagner, THIS JOURNAL, **55**, 724 (1933).

The structure of the *p,p'*-dianilinodiphenylmethane is established by reference to the properties reported by Straus and Bormann[3] and also by synthesizing the compound by the method of Ullmann[7] from *o*-chlorobenzoic acid and *p,p'*-diaminodiphenylmethane.

The formation of *p,p'*-dianilinodiphenylmethane from diphenylamine and formaldehyde probably takes place in more than one step. If no acid catalyst is used and the reaction is carried out in benzene solution, there may be isolated as the chief product a compound (Compound II) having the empirical formula and molecular weight of tetraphenylmethylenediamine.

Compound II is rapidly hydrolyzed by warm, dilute mineral acids to formaldehyde and diphenylamine. It rearranges in the presence of diphenylamine and hydrochloric acid to *p,p'*-dianilinodiphenylmethane in a manner characteristic of other arylmethylenediamines.[8] In the absence of added diphenylamine and in the presence of dry hydrogen chloride, resinification occurs with the splitting out of diphenylamine but without the formation of *p,p'*-dianilinodiphenylmethane. The hydrogenolysis of Compound II in the presence of the Adkins copper chromite catalyst occurs with the formation of diphenylamine and methyldiphenylamine. No phenyl-*p*-tolylamine is formed. However, a side reaction taking place during this reduction is the rearrangement to form *p,p'*-dianilinodiphenylmethane. This, together with the fact that greater amounts of diphenylamine are formed during the reduction than can be accounted for by simple hydrogenolysis, indicates that Compound II has a tendency to dissociate with the formation of free methylene $\mathrm{H}\overset{|}{\underset{|}{\mathrm{C}}}\mathrm{H}$. It should be pointed out that methyldiphenylamine does not undergo reduction under the conditions found suitable for rapidly reducing Compound II.

The mode of formation and the reactions of Compound II indicate that it is tetraphenylmethylenediamine. It is interesting that Houben and Arnold[9] reported the formation of this substance as a product of the reaction of chloromethyl sulfate with diphenylamine. The product which they obtained readily hydrolyzed to formaldehyde and diphenylamine; however, it melted at 82–85°, while the tetraphenylmethylenediamine here reported melts at 104–105°. It is, therefore, believed that Houben and Arnold's compound was impure and probably contaminated with *p,p'*-dianilinodiphenylmethane. Houben and Arnold did not mention the previous crude preparation of tetraphenylmethylenediamine from the reaction of formaldehyde with diphenylamine.[10]

In searches for precursors of tetraphenylmethylenediamine it has not thus far been possible to isolate an amino alcohol,[8,11] an anhydroamino

alcohol, or a polymer thereof from mixtures secured from the reactions of formaldehyde with diphenylamine.

Experimental

The Reaction of Formaldehyde with Diphenylamine to Form *p,p'*-Dianilinodiphenylmethane, I.—This reaction was carried out by adding 1 cc. of concentrated hydrochloric acid to a mixture of 254 g. (1.5 moles) of diphenylamine and 16 g. (0.19 mole) of 36% formaldehyde dissolved in 250 cc. of alcohol at 40°. Reaction set in immediately and was complete after refluxing for thirty minutes on the steam-bath. Four grams of potassium carbonate was added and the product isolated by distillation in a 500-cc. Anders flask. The diphenylamine distilled off had a setting point of 53° and amounted to 192 g. The intermediate fraction amounting to 2.5 g. came over below 270° at 1.5 mm. of mercury and consisted mainly of *p,p*-dianilinodiphenylmethane. The main fraction distilled with considerable superheating between 270 and 290° at the same pressure. The yield of this fraction amounted to 41.5 g. or to a yield of 63% of crude product calculated on the formaldehyde used. When recrystallized from 250 cc. of alcohol, 35 g. of *p,p'*-dianilinodiphenylmethane was obtained having a melting point of 114–115°. After melting, the compound resolidified and melted at 120°. On recrystallization the second melting point was raised to 122–123°, the initial melting point being at 118–120°. The residue from the distillation weighed 23 g.

Anal. Calcd. for $C_{25}H_{22}N_2$: C, 85.7; H, 6.32; N, 7.98. Found: C, 85.7; H, 6.13; N, 8.06.

Solvents such as benzene, acetone, gasoline, and acetic acid were used for this reaction and found suitable. If acetic acid was used as the solvent, hydrochloric acid was not necessary as the catalyst. The reaction may be carried out in the absence of a solvent if an efficient agitator is used.

Difficulties encountered by previous workers who may have tried to isolate this compound are partly due to the fact that they did not use sufficient diphenylamine in the reaction. Using the amounts of the reactants called for by Equation (1) drops the yield to about 40%.

Under the proper conditions formaldehyde may be replaced by other methylene compounds. Anhydroformaldehyde aniline, hexamethylenetetramine, and diaminodiphenylmethane reacted above 150° with an excess of diphenylamine to form *p,p'*-dianilinodiphenylmethane. Chloromethyl ether in benzene solution reacted as vigorously as formaldehyde with diphenylamine, *p,p'*-dianilinodiphenylmethane being the main product. In order to carry out the reaction with paraformaldehyde, water was added and the mixture refluxed for several hours.

A double melting point for *p,p'*-dianilinodiphenylmethane was also observed by Straus and Bormann.[3] It was frequently found, however, that only the high melting form was obtained.

The Synthesis of *p,p'*-Dianilinodiphenylmethane by the Ullmann Method.—Fifteen grams of *o*-chlorobenzoic acid, 15 g. of potassium carbonate, and 10 g. of *p,p'*-diaminodiphenylmethane were intimately mixed in a 500-cc. flask and heated to 150° with stirring in an oil-bath. A trace of cuprous iodide was added, whereupon a vigorous reaction set in. The mixture turned black and considerable foaming occurred. After a few minutes the product was cooled and dissolved in 500 cc. of water. The solution was acidified with acetic acid, which precipitated an oily solid. This oily solid, which was a mixture of *o*-chlorobenzoic acid with anthranilic acids, was separated and heated to 250° for a few minutes with stirring. Carbon dioxide was evolved. The resulting product was then extracted with 100 cc. of 10% sodium hydroxide and the insoluble part was distilled. Two grams of a fraction boiling at about 280° at 1.5 mm.

was obtained, which on being recrystallized from alcohol melted at 121° and did not depress the melting point of the material melting at 122–123° secured from formaldehyde and diphenylamine.

The Preparation of Tetraphenylmethylenediamine, II.—One hundred and sixty-eight grams (2 moles) of 36% formaldehyde was added during two hours to a refluxing solution of 338 g. (2 moles) of diphenylamine in 250 cc. of benzene. Refluxing was continued for forty-five minutes. When the product was distilled, 87 g. of impure diphenylamine came over first. The next fraction boiling between 200 and 240° at 2.5 mm. pressure of mercury weighed 244 g. This represents a conversion of 70% based on the diphenylamine used. By redistillation and crystallization about two-thirds of this material was isolated as the pure compound melting at 104–105°. On dissolving the crude product in an equal volume of benzene and then stirring in two volumes of petroleum ether, thick transparent crystals were obtained. The compound was difficultly soluble in hot alcohol, from which it crystallized readily.

Anal. Calcd. for $C_{25}H_{22}N_2$: C, 85.7; H, 6.32; N, 7.98. Found: C, 85.1; H, 6.32; N, 7.98. *Mol. wt.* (in freezing benzene). Calcd. for $C_{25}H_{22}N_2$: 350. Found: 326, 329.

When warmed with very dilute hydrochloric acid or with 10% sulfuric acid, formaldehyde and diphenylamine were obtained. It also reacted with potassium bisulfite[10] solution, although the products of this reaction were not isolated.

The Rearrangement of Tetraphenylmethylenediamine into *p,p'*-Dianilinodiphenylmethane.—When 35 g. (0.1 mole) of the compound prepared by the above described method and melting at 103–105° was mixed with 33.8 g. (0.2 mole) of diphenylamine dissolved in 130 cc. of alcohol no reaction took place, but when 0.9 cc. of concentrated hydrochloric acid was added the temperature rose from 45 to 55° and an oil separated out which on standing overnight gave a small amount of crystals which was filtered off and washed with alcohol. After recrystallizing from alcohol the crystals melted at 148–152°. These crystals were not identified. The same material was secured from high boiling fractions of formaldehyde-diphenylamine reaction products. The alcoholic washings were united with the main solution and two volumes of water and 5 g. of sodium carbonate was added. The oil obtained was distilled in the usual way and gave as the main product *p,p'*-dianilinodiphenylmethane. After recrystallizing from alcohol the product melted at 122–123° when alone or when mixed with the *p,p'*-dianilinodiphenylmethane prepared directly from formaldehyde and diphenylamine.

The Hydrogenolysis of Tetraphenylmethylenediamine.—This reaction did not occur with sodium and alcohol but was successfully carried out by the method of Adkins. One hundred and seventeen grams (0.33 mole) of tetraphenylmethylenediamine, 250 cc. of benzene, and 4 g. of the copper chromite catalyst were placed in the reducer. Hydrogen at about 110 atmospheres pressure was admitted and the temperature raised to 225° gradually during four hours. The mixture was filtered and distilled at reduced pressure. Diphenylamine amounting to 63 g. or 0.37 mole, about 5 g. of methyldiphenylamine, and a trace of *p,p'*-dianilinodiphenylmethane were isolated from the product, besides about 30 g. of resinous material. The diphenylamine and methyldiphenylamine were separated from each other by the method described by Gibson and Vining.[12] The *p,p'*-dianilinodiphenylamine was isolated as described above. This compound and the diphenylamine were identified by melting points and mixed melting points with authentic specimens. The methyldiphenylamine was identified by the melting point and mixed melting point of its zinci-hydrochloride with an authentic specimen of this derivative, the preparation of which is described in the next section.

Under the conditions just described for the hydrogenolysis of tetraphenylmethylene-

---

(12) Gibson and Vining, *J. Chem. Soc.*, **123**, 834 (1923).

diamine no reaction with 38 g. of methyldiphenylamine, 2 g. of copper chromite and 100 cc. of benzene could be detected.

The Zinci-hydrochloride of Methyldiphenylamine.—Five grams (0.027 mole) of redistilled methyldiphenylamine obtained from the Eastman Kodak Company was dissolved in 40 cc. of glacial acetic acid. A solution of 5 g. of zinc chloride dissolved in a mixture of 5 cc. of concd. hydrochloric acid and 10 cc. of glacial acetic acid was added. A precipitate came down immediately. After cooling to 15° for fifteen minutes the precipitate was filtered off and washed consecutively with 20 and 10 cc. portions of glacial acetic acid. After standing in a vacuum desiccator to constant weight over potassium hydroxide a yield of 7.5 g. (95%) of a white powder was obtained, m. p. 186–188°, with evolution of hydrochloric acid. The compound can also be prepared in concentrated hydrochloric acid, in which it is difficultly soluble.

Anal. Calcd. for $[(C_6H_5)_2NCH_3\cdot HCl]_2\cdot ZnCl_2$: Zn, 11.4. Found: Zn, 11.4, 11.8. Calcd. for $[(C_6H_5)_2NCH_3\cdot HCl]_2\cdot ZnCl_2$, equiv. wt.: 143.5 according to the equation $[(C_6H_5)_2NCH_3\cdot HCl]_2\cdot ZnCl_2 + 4NaOH\ 2(C_6H_5)_2NCH_3 + Zn(OH)_2 + 4NaCl + 2H_2O$. Found by titrating with 0.01 N NaOH using phenolphthalein as the indicator: 140, 141.

This compound is hydrolyzed to methyldiphenylamine, zinc chloride and hydrochloric acid when mixed with water but is not particularly hygroscopic. Mixtures with water were titrated with standard potassium ferrocyanide solution for the zinc analysis and with standard sodium hydroxide solution for the equivalent weight determination without removing the precipitated methyldiphenylamine. During the titration with sodium hydroxide a precipitate of zinc hydroxide came down.

The author is grateful to Dr. W. L. Semon, under whose direction this work was conducted.

Summary

The main reaction product of formaldehyde with an excess of diphenylamine in the presence of hydrochloric acid has been found to be *p,p'*-dianilinodiphenylmethane. A possible intermediate product has been identified as tetraphenylmethylenediamine.

Mono and Disubstituted Organo-Mercury Derivatives of Acetylene

By R. J. Spahr, R. R. Vogt and J. A. Nieuwland

We have recently reported[1] the preparation and properties of a series of aryl and normal alkyl mercury acetylides formed by the replacement of both atoms of hydrogen from acetylene by organo-mercury groups. The present paper describes the similar preparation and some variations in the behavior of analogous compounds containing branched alkyl and a few substituted alkyl and aryl groups linked to mercury.

In the preparation of acetylides containing secondary organo-mercury radicals and also of bis-amylmercury acetylide it was noticed after these compounds had been precipitated from alcoholic potassium hydroxide solution, that they could be redissolved by excess acetylene. When the excess acetylene was allowed to escape or was removed by suction, a precipitate separated from solution. In each case comparison of the melting points of purified samples of the two precipitates proved them to be identical, and analysis showed that both hydrogens of acetylene had been replaced by organo-mercury groups.

These acetylides were all very soluble in the common organic solvents, and greater solubility was found to be associated with a more rapid reaction with excess acetylene. It was also found that the more soluble of the normal alkyl mercury acetylides were very slowly redissolved. So it appears that this phenomenon is not due to the presence of any one type of group, but depends solely on the solubility of the bis-organomercury acetylide.

It was found that the presence of alkali in solution catalyzed the formation of the acetylides and their solution in excess acetylene. Thus four minutes elapsed before a precipitate began to appear when acetylene was passed into an alkali-free alcoholic solution of ethylmercury hydroxide prepared by the action of silver hydroxide on ethylmercury chloride in alcohol.[2] An alcoholic potassium hydroxide solution, having the same concentration of ethylmercury chloride, gave the acetylide precipitate immediately. Likewise when the purified acetylides were suspended in alcohol they were slowly attacked by acetylene, while the addition of sodium or potassium hydroxide or even ammonia to these solutions caused the acetylene to dissolve the precipitates much more rapidly.

In order to explain these facts it was assumed that an equilibrium exists between the mono and the bis-organo-mercury acetylides $C_2H_2 + R—Hg—C\equiv C—Hg—R \rightleftarrows 2\ R—Hg—C\equiv C—H$.

---

[1] Spahr, Vogt and Nieuwland, This Journal, 55, 2465 (1933).

[2] Dunhaupt, *J. prakt. Chem.*, [1] 61, 415 (1854).

The catalytic effect of the alkali may possibly be explained as being due to the existence of more acetylide ions in alkaline solution. It has not as yet been found possible to isolate compounds of the type R—Hg—C≡C—H, but their mode of formation and certain reactions indicate their presence in solution. A reaction of this type is the preparation of isopropylmercury *n*-amyl acetylide formed by the action of *n*-amylacetylene on bis-isopropylmercury acetylide in the presence of excess acetylene.

Marvel and Gould have pointed out[3] that the carbon–mercury linkage R_2CH—Hg— is more easily broken than that in R—CH_2—Hg— by heat and acids. We have found that the same relationship holds with regard to stability toward aqueous alkaline solution. When a secondary organomercury acetylide was prepared in aqueous alkaline solution, it decomposed, splitting out metallic mercury and leaving a black gummy mass from which no crystalline precipitate could be obtained. In an alcoholic alkaline solution prepared from absolute alcohol, the acetylide is stable.

Schoeller and Schrauth[4] have called attention to the fact that α-acetoxymercuri-β-methoxyethane is a powerful vesicant, producing irritating blisters when in contact with the skin. The acetylide of this compound when applied to the skin in undiluted form produced no skin irritation. When heated above its melting point it decomposed, metallic mercury splitting out, leaving behind an oil with a carnation-like odor which solidified on cooling to room temperature. The products of this reaction are at present being investigated.

Experimental Part

Preparation of Organomercury Bromides.—The secondary alkyl mercury, isoamylmercury, and cyclohexylmercury bromides were prepared by converting the organobromide into its Grignard compound, and treating this with an excess of mercuric bromide.[5]

Preparation of *p*-Aminophenylmercury Chloride.—Freshly distilled aniline was treated with mercuric acetate and the *p*-aminophenylmercury acetate which formed was finely powdered and boiled with a large volume of water containing an excess of sodium chloride. Shiny leaflets of *p*-aminophenylmercury chloride separated from solution on cooling.[6]

Preparation of *o*-Nitrophenylmercury Chloride.—Mercuric acetate was heated with five times its weight of nitrobenzene until the solution no longer gave a test with sodium hydroxide. It was allowed to cool and filtered. The filtrate was treated with an excess of sodium chloride solution and steam distilled to remove any unreacted nitrobenzene. The residue was dried and extracted with ligroin, and recrystallized from glacial acetic acid. It was soluble in ether and high boiling ligroin and insoluble in water, m. p. 180–182.°[6]

Preparation of *o*-Hydroxyphenylmercury Chloride.—This was prepared from phenol, mercuric acetate and sodium chloride according to the method of Whitmore and Hanson.[7]

---

[3] Marvel and Gould, THIS JOURNAL, **45**, 820–823 (1923).

[4] Schoeller and Schrauth, *Ber.*, **46**, 2869 (1913).

[5] Marvel and Calvery, THIS JOURNAL, **45**, 820–823 (1923); Hill, *ibid.*, **50**, 167 (1928); Grüttner, *Ber.*, **47**, 1651–1656 (1914).

[6] Dimroth, *ibid.*, **35**, 2032–2045 (1902).

Preparation of Allylmercury Iodide.—This was prepared by the method of Zinin from allyl iodide and metallic mercury.[8]

Preparation of α-Acetoxymercuri-β-methoxyethane.—It was prepared according to the method of Schoeller and Schrauth,[4] as modified by Manchot,[9] and further modified by Ford in this Laboratory.[10]

Ethylene was passed into a solution of one-half mol of mercuric acetate in excess alcohol and one-half mol of mercuric oxide was added at a rate which kept the reaction mixture a faint pink. A Benning gas absorption stirrer[11] was used and the reaction was conducted in a three-necked water-cooled flask, ethylene being supplied by the constant pressure, alarm, gas feeding device described by Vaughn.[12] The reaction was complete in one-quarter hour. After removing the alcohol *in vacuo*, the residue was recrystallized from ether. The melting point was 42°. The yield based on total mercury used was 92.8%.

Preparation of Mercury Acetylides. General Procedure.—They were prepared according to the method outlined in a previous communication,[1] except that a 10% alcoholic solution of potassium hydroxide was used instead of an aqueous solution. The secondary alkyl mercury and the isoamylmercury acetylides were very soluble in the common organic solvents, and were crystallized from ethyl alcohol, giving in each case fine needles. Their melting points are recorded in Table I. The *o*-nitrophenylmercury acetylide is practically insoluble in all organic solvents, and we were unable to purify it by crystallization. Its melting point could not be determined for on heating it above 300°, it decomposed with explosive violence. The *p*-aminophenylmercury acetylide is but slightly soluble in organic solvents. It crystallized in long needles from ethyl alcohol, and turned brown when exposed to the air. Allylmercury iodide, when dissolved in alcoholic ammonia and treated with acetylene, gave a white precipitate which immediately decomposed on exposure to air liberating black metallic mercury.

TABLE I

MERCURIC ACETYLIDES, GENERAL FORMULA $R—Hg—C\equiv C—Hg—R$

Nature of R	M. p., °C.	Mercury, %	
		Calcd.	Found
Isopropyl	110.5–111.5	78.46	78.18
Sec-butyl	105.5–106	74.38	74.25
Isoamyl	106 –107	70.70	70.72
Cyclohexyl	172 –173	67.84	67.51
β-Methoxyethyl	129.5–130.5 (with dec.)	73.85	73.41
p-Aminophenyl	188 –190 (with dec.)	65.65	66.34
o-Nitrophenyl	Explodes above 300°	59.94	60.99

Method of Analysis.—Mercury was determined according to the method outlined in a previous communication.[1]

Attempted Preparation of *o*-Hydroxyphenylmercury Acetylide.—No acetylide was obtained on passing acetylene into either *o*-hydroxyphenylmercury chloride in alcoholic potash or *o*-hydroxyphenylmercury hydroxide in alcohol. In the latter solution the final products appeared to be free mercury and phenol which was identified by conversion into picric acid. It is possible that these were formed by the decomposition of an intermediate acetylide.

Preparation of Isopropylmercury Amyl Acetylide.—12.5 g. of isopropylmercury bromide was dissolved in a 10% alcoholic potassium hydroxide solution. Four grams of amylacetylene was added slowly to the isopropylmercury hydroxide which was mechanically stirred. During the addition, the solution assumed a pale yellow color. On the addition of 300 ml. of water to the stirred solution an oil separated and settled to the bottom of the flask. The oil was separated and dried over anhydrous sodium sulfate. It contained a trace of amylacetylene which was removed by distillation under reduced pressure. The crude product weighed 9.2 g. (70% yield). It is an oil with a pale yellow color and of very penetrating odor. It is insoluble in water, but miscible with organic solvents. This material could not be distilled even under 3 cm. pressure on account of decomposition with the formation of free mercury, d_4^{20} 1.628.

Anal. Calcd.: Hg, 59.22. Found: Hg, 58.59.

Acknowledgment.—The authors wish to thank Mr. Joseph Pozzi, who kindly prepared the secondary organo-mercury halides.

Summary

1. The acetylene derivatives of isopropyl, *sec*-butyl, isoamyl, cyclohexyl, *o*-nitrophenyl, *p*-aminophenylmercury halides and α-acetoxymercuri-β-methoxyethane have been prepared and their properties recorded.

2. Isopropylmercury amyl acetylide has been prepared and its properties are recorded.

3. It has been shown that alkalies act as catalyst in the formation of organo-mercury acetylides.

4. Evidence of the existence of mono-mercury acetylides in solution has been given, and it has been shown that the formation of such compounds from the di-mercury acetylides when treated with excess acetylene depends primarily upon the solubility of the di-mercury derivative.

5. Secondary organo-mercury acetylides are unstable in aqueous potassium hydroxide solution, undergoing decomposition with the liberation of mercury.

The Dehydration of Tertiary Alcohols Containing a Neopentyl System. II.[1] Methylisopropyl-*tert*-butylcarbinol, Methyldi-*tert*-butylcarbinol, and Methylethylneopentylcarbinol

BY FRANK C. WHITMORE AND KENNETH C. LAUGHLIN[2]

The three alcohols, methylisopropyl-*tert*-butylcarbinol, methyldi-*tert*-butylcarbinol, and methylethylneopentylcarbinol, were selected as representing various types of tertiary alcohols containing a neopentyl group. The study of the dehydration of methylethyl-*tert*-butylcarbinol and dimethyl-*tert*-amylcarbinol has been continued.[1]

Dehydration of methylethyl-*tert*-butylcarbinol with β-naphthalenesulfonic acid gave the same mixture of olefins as with iodine.[1] Ozonolysis of intermediate fractions failed to give positive evidence for any olefin formed by dehydration from the methyl group. Dehydration of dimethyl-*tert*-amylcarbinol gave less than 6% of 2,2,3-trimethylpentene-3 formed by rearrangement of a methyl group.[1] The rearrangement of the ethyl group would give the same olefin as would the normal dehydration.[1,3]

Methylisopropyl-*tert*-butylcarbinol gave 3,3-dimethyl-2-isopropylbutene-1 (by normal dehydration involving the methyl group) and the rearrangement product 2,3,3,4-tetramethylpentene-1 in the ratio 3 : 1, with only traces of 2,3,4,4-tetramethylpentene-2 (by normal dehydration involving the isopropyl group). The sluggishness of the isopropyl group in losing a proton is noteworthy and is being further studied.[4] Methyldi-*tert*-butylcarbinol gave over 90% of 2-*tert*-butyl-3,3-dimethylbutene-1 (by dehydration involving the methyl group), and some low-boiling material which has not been identified. Methylethylneopentylcarbinol was dehydrated without rearrangement, giving mainly 2,2,4-trimethylhexene-4 (from the ethyl group), with less than 5% of 2,2,4-trimethylhexene-3 (from the neopentyl group) and only traces of 4,4-dimethyl-2-ethylpentene-1 (from the methyl group).

These results show the tendency of tertiary alcohols to dehydrate without rearrangement, in contrast to related primary and secondary alcohols containing a neopentyl group, which dehydrate mainly with rearrangement.[5]

With the hydroxyl group directly attached to the neopentyl system, the amount of rearrangement varied from less than 6% in the case of dimethyl-*tert*-amylcarbinol and methyldi-*tert*-butylcarbinol to 25% in the

case of methylisopropyl-*tert*-butylcarbinol. No rearrangement was found when the hydroxyl group, as in methylethylneopentylcarbinol, was not attached to the neopentyl system.

Experimental Part

Distillation Equipment.—The Johnston column has been described.[6] Column N[7] was of the same partial condensation type, but with a thermometer at the top of the packing so as to obtain significant temperature readings. The packed section, 130 × 1.4 cm., filled with 4-mm. glass helixes,[8] was equivalent to 16.5 theoretical plates.

Columns K, 44 × 1.4 cm., 9.6 theoretical plates, and L, 40 × 0.8 cm., 7.7 theoretical plates, were also packed with glass helixes. They were of the total condensation, variable take-off type previously described.[6] The 65 × 2.3 cm. column, and column A, 38 × 1.5 cm., were of the same type, but were packed with glass tubes (5 × 5 mm.). Column B, 25 × 0.8 cm., of the partial condensation indented type with no packing, was fitted with a 50-cc. pear-shaped flask by a ground-glass joint.

Preparation and Dehydration of Methylethyl-*tert*-butylcarbinol.—Methyl *tert*-butyl ketone (2 moles)[9] with 2.5 moles of ethylmagnesium bromide gave a 64% yield of methylethyl-*tert*-butylcarbinol, b. p. 76.1–76.6° (50 mm.), n^{20}_D 1.4354, d^{20}_4 0.849. The alcohol was dehydrated by distilling from 0.1 g. of β-naphthalene sulfonic acid through column K. The yield of olefin after drying and redistilling was 138 g. (95%). This was distilled through column N, the resulting curve showing the presence of 2,2,3-trimethylpentene-3 and 2,3,3-trimethylpentene-1 in the ratio 4:1 the same as with iodine as the dehydrating agent.[1] The following physical properties were determined:

	Cottrell b. p. °C., 760 mm.	n^{20}_D	d^{20}_4
2,2,3-Trimethylpentene-3	111.9	1.4232	0.739
2,3,3-Trimethylpentene-1	108.2	1.4178	0.736

In the search for some dehydration involving the methyl group, the intermediate fractions from two distillations (88 g.) were redistilled through column N without any indication of material with either a constant b. p. or refractive index. Since no third olefin could be separated by distillation, the intermediate fractions were again combined (73 g.) and ozonized as usual.[10] Formaldehyde was formed. The oily products were fractionated through column L, and the material of b. p. 116–126° (740 mm.) was treated with 2,4-dinitrophenylhydrazine. The main product was the derivative of methyl *tert*-amyl ketone (m. p. 111–111.5°). Careful fractional crystallization yielded no higher melting derivative. Thus no ethyl *tert*-butyl ketone (2,4-dinitrophenylhydrazone m. p. 145°[11]) was present, and consequently there was no dehydration from the methyl group.

Preparation and Dehydration of Dimethyl-*tert*-amylcarbinol.—Ethyl dimethylethylacetate, b. p. 140–140.8° (730 mm.), n^{20}_D 1.4040, was prepared in 37% yield from *tert*-amylmagnesium chloride and ethyl chlorocarbonate.[12] The ester, 0.75 mole, was dissolved in an equal volume of dry ether and added to 2 moles of methylmagnesium chloride. The yield of dimethyl-*tert*-amylcarbinol was 78%. The material from two runs (145 g.) was distilled through column K under reduced pressure to give 135 g. of

carbinol, b. p. 86.5° (60 mm.), n^{20}_{D} 1.4420, d^{20}_{4} 0.861. The carbinol was dehydrated by twice distilling from 0.1 g. of β-naphthalene sulfonic acid through a steam-jacketed condenser. After drying with 5 g. of potassium carbonate and 0.5 g. of sodium, the olefin was distilled rapidly through column K and again dried over 0.1 g. of sodium. The yield was 112 g. (96.5%).

Isolation and Identification of the Rearrangement Product.—The olefin mixture (112 g.) was distilled through column N with a reflux ratio of more than 50:1. Fourteen fractions (90 cc.) were collected, b. p. 106.0–107.4° (732 mm.), n^{20}_{D} 1.4178–1.4183. The middle fractions were used to determine the physical properties of 2,3,3-trimethylpentene-1. The residue, 27 cc., was distilled through column K to give six fractions b. p. 107.5–108.7° (743 mm.), n^{20}_{D} 1.4187–1.4198, and a residue of 4.5 cc. This was distilled from a small flask to give a liquid of n^{20}_{D} 1.4260. The six fractions and residue were combined (17 g.) and ozonized as usual,[10] using an ether wash bottle to collect the acetaldehyde. The acetaldehyde-ammonia formed, m. p. 90.5–91°, did not lower the m. p. of a known sample. The oily layer was distilled through column L and the fraction (1 cc.) b. p. 100–110° (732 mm.), n^{20}_{D} 1.3983, was identified as methyl *tert*-butyl ketone by conversion to the 2,4-dinitrophenylhydrazone, m. p. 123–124°, which did not lower the m. p. (125°) of a known sample. The formation of acetaldehyde and methyl *tert*-butyl ketone by ozonolysis proves the presence of 2,2,3-trimethylpentene-3. The refractive index of the original mixture of olefins (1.4182) shows that this olefin was less than 6% of the total.

Preparation of Pentamethylacetone.— (1) *Tert*-butylisopropylcarbinol was prepared in 35% yield from isobutyraldehyde, b. p. 62.3–62.9° (735 mm.), and *tert*-butylmagnesium chloride.[13] The crude carbinol of n^{20}_{D} 1.428 was oxidized with chromic acid at 40° giving a 67% yield of pentamethylacetone,[14] b. p. 133–135° (738 mm.), n^{20}_{D} 1.4057, oxime m. p. 139–140°.[15]

(2) Methyl *tert*-butyl ketone, dimethylated in one operation by the sodamide method,[16] gave a 33% yield of pentamethylacetone. One mole of methyl *tert*-butyl ketone, b. p. 104–106° (739 mm.),[9] was dissolved in 1 liter of dry ether and 200 cc. of dry benzene. One mole (50 g. of 80%) of finely ground sodamide was added and the mixture was refluxed vigorously with good stirring for two hours. The mixture was cooled and one mole of methyl iodide was added over a period of two hours. After refluxing for fifteen minutes, the mixture was cooled, 1.4 moles (70 g.) of sodamide was added and the refluxing was continued until no more ammonia was evolved. The mixture was cooled and 1.75 moles of methyl sulfate dissolved in an equal volume of dry ether was added slowly, then refluxed for half an hour. The excess methyl sulfate was decomposed by vigorously stirring overnight with 200 cc. of water and 100 cc. of ammonium hydroxide. The upper layer was washed with 100 cc. of 5% sulfuric acid, 100 cc. of 5% sodium carbonate, and dried over 25 g. of potassium carbonate. After removal of the ether and benzene the residue was treated with 50 cc. of phenylhydrazine to remove any ethyl *tert*-butyl ketone, and the mixture was distilled to a residue of 50 cc. The distillate was washed with four 100-cc. portions of dilute hydrochloric acid, 100 cc. of water, and dried over 10 g. of potassium carbonate, giving 76 g. of material which was distilled through the 65 × 2.3 cm. column, collecting 42 g. of pentamethylacetone, b. p. 132–134° (730 mm.), n^{20}_{D} 1.4082, yield 33%. On account of the toxicity of methyl sulfate and phenylhydrazine, all the above operations were carried out in a good hood.

(3) Pentamethylacetone was prepared in 54% yield by treating diisopropyl

ketone[17] in toluene solution with sodamide and methyl sulfate as above. The combined product from three runs was 227 g., b. p. 133–134° (739 mm.), n^{20}_{D} 1.4071.

Preparation and Dehydration of Methylisopropyl-*tert*-butylcarbinol.—Pentamethylacetone, 2.1 moles, with 2.25 moles of methylmagnesium chloride gave a 67% yield of the carbinol, b. p. 62° (12 mm.), n^{20}_{D} 1.4440, d^{20}_{4} 0.856. A second run gave a 68% yield.

(A) The carbinol, 90 g., was dehydrated with a crystal of iodine under a 90 × 2 cm. column provided with a water separator at its top. The dried olefin mixture (82% yield) was distilled through the Johnston column to give fourteen fractions (total 49 g.) and a residue of 19 g., n^{20}_{D} 1.4302: fractions 1–2, 7 g., n^{20}_{D} 1.4149; fractions 3–14, 42 g., n^{20}_{D} 1.4159–1.4163, Cottrell b. p. 120.1° (734 mm.).

(B) The carbinol, 130 g., was dehydrated by distilling from 0.1 g. of β-naphthalene sulfonic acid through a steam-jacketed condenser, giving a 92.5% yield of dried olefin. This was distilled through the Johnston column to give 27 fractions (total 87 g.) and a residue of 11 g., n^{20}_{D} 1.4357, having a strong odor of the carbinol. Fraction 1, 1.8 g., n^{20}_{D} 1.4152, was not identified. Fractions 2–13, 62 g. 3,3-dimethyl-2-isopropylbutene-1, n^{20}_{D} 1.4174–1.4176, Cottrell b. p. 121.6° (760 mm.), d^{20}_{4} 0.737, and fractions 23–27, 8 g., 2,3,3,4-tetramethylpentene-1, n^{20}_{D} 1.4305, b. p. 132.6° (743 mm.), d^{20}_{4} 0.761, were identified by ozonolysis. The intermediate fractions 14–22, n^{20}_{D} 1.4184–1.4298, totaled 14 g. The olefins 3,3-dimethyl-2-isopropylbutene-1 and 2,3,3,4-tetramethylpentene-1 were present in the ratio 3:1 as calculated from the refractive indices.

Identification of 3,3-Dimethyl-2-isopropylbutene-1.—(1) Ozonolysis of fractions 1–14 from (A) 49 g. according to the technique of Church[10] yielded 18 g. of ozonide (33%) which on decomposition gave a strong test[18] for formaldehyde and an oil which was dried and distilled through column B at 739 mm.: fraction 1, 0.5 cc., b. p. 85–123°, n^{20}_{D} 1.3943, fractions 2–4, 7.5 cc., 123–131°, 1.3997, and a residue of 5 cc., 1.4123, were obtained. Fraction 4 was identified as pentamethylacetone by the oxime, m. p. and mixed m. p. 139–140°.

(2) Because of the low yield of ozonide, the process was repeated. The low-boiling olefin (44 g.) from (B) was ozonized and the ozonides were decomposed in the presence of the hydrocarbon solvent.[10] Careful fractionation through Column L showed that only about two-thirds of the olefin had reacted with ozone. The unchanged olefin was again ozonized and again only about two-thirds of it reacted. The ozonolysis products were the same in both cases. The possibility of an equilibrium in ozonization is being further investigated in this Laboratory.

Identification of 2,3,3,4-Tetramethylpentene-1.—Fractions 23–27 from (B) and similar fractions from another preparation (14 g.) were ozonized to give formaldehyde and an oil which was fractionated through Column L to give about 4 cc. of material of b. p. 135–150° (743 mm.), n^{20}_{D} 1.4300, which proved to contain 3,3,4-trimethylpentanone-2. The 2,4-dinitrophenylhydrazone, after five crystallizations from absolute alcohol, melted at 145.5–146.5°. The semicarbazone, crystallized twice from 50% ethanol and once from 50% methanol, melted at 146.5–148.5°. The known semicarbazone kindly supplied by Professor Locquin[19] melted at 147–150° and a mixture melted at 147–149.5°. The structure of the ketone was further proved by oxidation with sodium hypobromite according to the method of Sandborn and Bousquet[20] to give an acid, m. p. 45–47°, and an amide of m. p. 128° which did not lower the melting point of a known sample of dimethylisopropylacetamide prepared from the acid obtained by the action of carbon dioxide on dimethylisopropylcarbinylmagnesium chloride.

Identification of 2,3,4,4-Tetramethylpentene-2.—One fraction from the above ozonolysis, 0.5 g., b. p. 95–118° (742 mm.), n^{20}_{D} 1.4090, gave a 2,4-dinitrophenylhydrazone, m. p. 128–129°, which was shown by mixed melting point determinations to be identical with the crystalline modification, m. p. 131°, obtained by melting the known derivative (m. p. 125°) of methyl *tert*-butyl ketone. Thus a small amount of 2,3,4,4-tetramethylpentene-2 occurred in the higher boiling fractions.

Preparation and Dehydration of Methyldi-*tert*-butylcarbinol.—Hexamethylacetone was prepared from diisopropyl ketone by the sodamide synthesis.[16] Three moles, 342 g., of diisopropyl ketone[17] was dissolved in xylene and treated with sodamide and methyl iodide for the first step, sodamide and methyl sulfate for the second. The reaction was carried out without isolating the intermediate product. Because of the difficulty of separating hexamethylacetone from pentamethylacetone and xylene by distillation, the mixture of products was treated with methylmagnesium chloride until a positive test was obtained with Gilman's reagent.[21] The product was worked up as usual and distilled through column A under reduced pressure. The carbinol (135 g.), collected at 122.5–123° (100 mm.), m. p. 42°,[22] represented a yield of 29% from the diisopropyl ketone.

The carbinol, 112 g., was dehydrated by distilling from 0.1 g. of β-naphthalene sulfonic acid through a steam-jacketed reflux condenser. No gas was formed. After drying with 5 g. of potassium carbonate and 1 g. of sodium, the olefin (90 g., 90% yield) was distilled at 731 mm. through the Johnston column to give twenty-five fractions totaling 95.5 cc. and a residue of 11 cc.: fractions 1–2, 3 cc., b. p. 78°, n^{20}_{D} 1.4129–1.4130, rapidly decolorized a solution of bromine in carbon tetrachloride; fractions 3–8, 13.5 cc., n^{20}_{D} 1.4275–1.4362, could not be further separated by redistillation through column L; fractions 9–15, 45 cc., n^{20}_{D} 1.4364, d^{20}_{4} 0.770, Cottrell b. p. 149.5° (760 mm.), were identified as 2-*tert*-butyl-3,3-dimethylbutene-1; fractions 16–25, 34 cc., 1.4365–1.4388, yielded on redistillation through the same column 13 cc. with n^{20}_{D} 1.4364. The residue, 11 cc., n^{20}_{D} 1.4457, distilled from a small distillation flask at 156–185°. The last portion of the distillate solidified in the condenser and was proved by mixed melting point to be unchanged carbinol.

Identification of 2-*Tert*-butyl-3,3-dimethylbutene-1.—A 32-g. portion of fractions 9–15 was ozonized as usual. After fifteen hours the tube plugged due to formation of a solid ozonide. The solution was decanted to another tube and ozonization was completed in less than an hour. The hydrocarbon solution was decomposed as usual, and the solid ozonide was washed into the reaction flask with 300 cc. of acetic acid and likewise decomposed. A positive test for formaldehyde[18] was obtained. The oil layer was dried with 3 g. of potassium carbonate and distilled through column L at 737 mm. to give the principal fractions with b. p. and n^{20}_{D} as follows: 6 cc., 140–149°, 1.4164; 9 cc., 149.0–149.5°, 1.4198; residue, 7 cc., 1.4222. The middle fraction was identified as hexamethylacetone by reaction of 5 cc. with methylmagnesium iodide prepared from 2.4 g. of magnesium and 14 g. of methyl iodide. After decomposing and drying as usual the product distilled from a small distillation flask at 100–117° (100 mm.). The solid carbinol thus obtained, m. p. 41.5°, did not lower the melting point of pure methyldi-*tert*-butylcarbinol. From a consideration of the distillation and ozonolysis results it was concluded that 2-*tert*-butyl-3,3-dimethylbutene-1 constituted over 90% of the dehydration products.

Preparation and Dehydration of Methylethylneopentylcarbinol.—The carbinol was prepared in 67% yield from 2.3 moles of methyl neopentyl ketone, b. p. 123–123.2° (736 mm.), n^{20}_{D} 1.4027, and 2.5 moles ethylmagnesium bromide. The carbinol, 144 g. collected from 62–62.5° (14 mm.), n^{20}_{D} 1.4340, was dehydrated with 3 g. of β-naphthalene sulfonic acid by distilling through a steam-jacketed condenser. The olefin, obtained in 95% yield, was dried over 1 g. of sodium and distilled through the Johnston

---

(21) Gilman and Schulze, THIS JOURNAL, 47, 2002 (1925).

(22) Conant and Blatt, *ibid.*, 51, 1236 (1929).

column to give 18 fractions amounting to 120 cc. and a residue of 9 cc., n^{20}_{D} 1.4292. Cottrell boiling points at 734 mm., n^{20}_{D} and volumes of the constant refractive index materials were as follows: fractions 5-6, 128.0°, 1.4220, 8 cc.; fractions 12-13, 129.4°, 1.4230, 11 cc.; fractions 17-18, 130.2°, 1.4237, 14 cc.

Identification of the Dehydration Products.—Fractions 2-6, 18 g., gave 20 g. of ozonide which on decomposition gave formaldehyde[18] and 12 g. of an oil layer which was dried and distilled through column B at 725 mm. to give fractions of wts., boiling ranges, and n^{20}_{D} as follows: No. 1, 2 g., 75-100°, 1.3915; No. 2, 3 g., 100-121°, 1.4035; No. 3, 5 g., 121-126°, 1.4049; No. 4, 1 g., 126-131°, 1.4051; residue, 1 g., 1.4158. Fraction 3 gave a 2,4-dinitrophenylhydrazone m. p. 99° which did not lower the melting point of the derivative prepared from pure methyl neopentyl ketone. From fraction 1, two 2,4-dinitrophenylhydrazones were isolated: one of m. p. 207° which did not lower the melting point of the derivative prepared from known trimethylacetaldehyde, and one m. p. 109-110° which melted at 112° when mixed with the derivative (m. p. 115°) prepared from methyl ethyl ketone. These products proved the presence of 2,2,4-trimethylhexene-4 and 2,2,4-trimethylhexene-3. The presence of 4,4-dimethyl-2-ethylpentene-1 was indicated by the formation of formaldehyde and by the high refractive index of the residue, but attempts to isolate a derivative of ethyl neopentyl ketone were unsuccessful. Since no physical constants for this compound could be found in the literature, it was synthesized from *tert*-butylacetyl chloride and ethylzinc iodide. The following constants for ethyl neopentyl ketone were determined: b. p. 143° (736 mm.), n^{20}_{D} 1.4110, d^{20}_{4} 0.812, 2,4-dinitrophenylhydrazone m. p. 135.5°, semicarbazone m. p. 160-161°.

The original olefin fractions 10-14, 23 g., and 15-18, 23 g., gave practically identical results on ozonolysis. The water layers gave no test for formaldehyde,[18] and the oil layers, 15 g. each, gave very similar results when distilled through column B at 727 mm. One of these distillations gave fractions as follows: No. 1, 0.5 g., b. p. 74-100°, n^{20}_{D} 1.3920; No. 2, 1 g., 100-121°, 1.4014; No. 3, 4 g., 121-123°, 1.4029; No. 4, 3.5 g., 123-124°, 1.4029; No. 5, 1.5 g., 124-126°, 1.4031; No. 6, 1 g., 126-129°, 1.4037; res., 2.5 g., 1.4199. Fraction 3 was identified as methyl neopentyl ketone as before. The distillation and ozonolysis results show that methylethylneopentylcarbinol dehydrates mainly to the ethyl group, with less than 5% dehydrating from the neopentyl group, and only traces due to dehydration from the methyl group. No evidence of rearrangement during the dehydration of methylethylneopentylcarbinol was detected. The expected rearrangement products would yield, on ozonolysis, formaldehyde and 3,4-dimethylhexanone-2, and acetone and methyl *sec*-butyl ketone, respectively. These ketones were not formed. 3,4-Dimethylhexanone-2 has been variously reported with b. p. 152-154°, semicarbazone, m. p. 119°,[23] and b. p. 158°, semicarbazone m. p. 124-126°.[24] The semicarbazone prepared from the residue, n^{20}_{D} 1.4199, melted at 160-165°, and no material melting lower than 135° could be obtained from the mother liquor, hence no 3,4-dimethylhexanone-2 was present. The other residues proved equally barren of this material.

Methyl *sec*-butyl ketone[25] has b. p. 118°, n^{18}_{D} 1.4002, semicarbazone m. p. 95.6°. In the search for this material all ozonolysis products were combined and distilled through column L. The semicarbazone prepared from the fraction b. p. 110-120° (736 mm.), n^{20}_{D} 1.4039, melted at 175° after one crystallization from alcohol (methyl neopentyl ketone semicarbazone m. p. 176°). No material melting lower than 135° could be obtained by fractional crystallization of the mother liquor, so no methyl *sec*-butyl ketone was present. These results prove the absence of rearrangement in the dehydration of methylethylneopentylcarbinol.

Summary

1. The dehydration of tertiary alcohols containing a neopentyl system has been studied with relation to rearrangement.

2. In no case was the rearrangement greater than 25%.

3. No rearrangement took place during the dehydration of methylethylneopentylcarbinol.

4. In the case of methyldi-*tert*-butylcarbinol no rearrangement products were found. Over 90% of the normal dehydration product was isolated.

The Isoelectric Point of Orange Seed Globulin

BY D. C. CARPENTER AND F. E. LOVELACE

A crystalline protein was first isolated from California orange seed in 1931 by Saunders.[1] He obtained the protein in a crystalline form by dialysis of ammonium sulfate solutions of the protein and named it pomelin. The writers have been unable to obtain a crystalline product from Florida or California orange seed by Saunders' method, the product being in all cases in our experience an amorphous mass instead of definite crystals. However, the writers have been successful in preparing a crystalline globulin from orange seed by an adaptation of the method used by Vickery, Wakeman, and Leavenworth[2] for the extraction of the globulin from tobacco seed and its preparation in crystalline form.

Csonka, Murphy and Jones[3] record the isoelectric point of a number of proteins as deduced from data on minimum solubility. A large amount of their data deals with various plant globulins for which the various individual isoelectric points range between *P*H's 5.0 and 5.5.

The point of electrical neutrality of a colloid may be determined in either of two ways, *i. e.*, by the moving boundary method described by Tiselius[4] in which the movement of a column of colloidal particles under a known potential is measured, or the somewhat different method[5] in which the rate of movement of the individual colloidal particle or an aggregate is observed under the microscope. In many cases a substance such as powdered quartz has been added to a sol on which the colloid was supposedly adsorbed and which powder then behaved as the colloid itself.[6]

From the Helmholtz–Lamb equation $V = \zeta HD/4\pi h$, where V is velocity

of particle, ζ is electrokinetic potential, H is potential gradient per cm., D is dielectric constant of the dispersion medium, and h is viscosity of the medium. In the present paper the values for D and h have been assumed to be those for water, namely, 81 and 0.009, respectively, at 25°. All quantities in the above equation are expressed in c. g. s. electrostatic units.

Preparation of Material.—Whole seeds of the California orange were coarsely ground in a Wiley mill and extracted repeatedly with cold benzene to remove oil, then air dried and ground to pass a one-millimeter sieve. The protein was extracted from the fat-free meal by warm (55°) molar sodium chloride solution in the proportion of one liter of solvent per 100 g. of meal. The mixture was stirred occasionally and, after two hours standing, the liquid was removed from the undissolved matter in a centrifuge. The somewhat turbid centrifugate was filtered through an asbestos and paper pulp filter, after which treatment it was sparkling clear and amber in color. The filtrate was diluted with five volumes of water at 55° and again filtered through asbestos and paper pulp. Toluene was then added as a preservative and the filtrate allowed to stand twenty-four to forty-eight hours at 0°. The protein crystallized out under this procedure in microscopic octahedral crystals which were separated from the mother liquor by centrifuging.

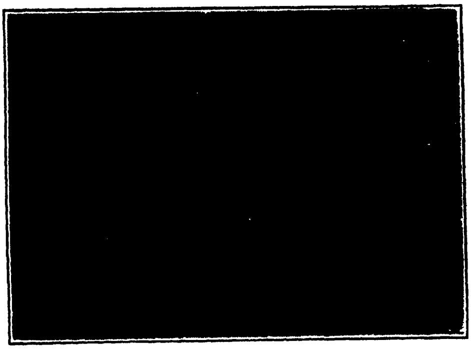

Fig. 1.—Crystalline globulin of orange seed (× 480).

The crystalline protein was redissolved in the least quantity of warm molar sodium chloride solution required, filtered as mentioned before, and again precipitated by dilution, this time adding ten volumes of water at 55° instead of five volumes to effect crystallization. The diluted mixture was allowed to stand overnight at 0° for crystallization of the protein. The crystalline precipitate was separated in a centrifuge, suspended in distilled water and electrodialyzed between parchment membranes to remove the last traces of sodium chloride. After the first crystallization, solutions of the protein in salt solution were colorless. Whether the writers' crystalline preparation is a single chemical entity or not and whether it is the same protein obtained from orange seed by Saunders cannot be judged at present. In Fig. 1 is shown a photomicrograph of one of our preparations.

A portion of the crystalline protein was removed before electrodialysis and washed with successive portions of ethyl alcohol of increasing concentrations, finally with ether and then dried in a desiccator. No change in structure could be observed in the crystals under this treatment. For the electrophoretic work to be described, however, electrodialyzed material which had not been alcohol treated or dried was used.

Electrophoresis Experiments.—The solutions of protein were prepared by dissolving about one gram of protein in 100 cc. of each of a series of buffer solutions ($M/30$ after Sörensen) containing the required amount of the proper citrate or phosphate, respectively, to give the desired P_H value over the range P_H 1.5 to 7.8. The actual P_H of each protein solution was determined potentiometrically with the quinhydrone electrode. After preparation the protein solutions were stored a few days at 0° with toluene until the electrophoresis measurements could be completed.

TABLE I

ELECTROPHORETIC VELOCITY AND CALCULATED ζ-POTENTIAL OF ORANGE SEED GLOBULIN

*P*H	Velocity μ/sec./v/cm.	Calcd. ζ-potential, millivolts	*P*H	Velocity μ/sec./v/cm.	Calcd. ζ-potential, millivolts
1.47	+8.2	+103.0	5.43	−2.2	−27.6
1.67	+7.6	+ 95.5	5.57	−2.2	−27.6
1.69	+8.0	+100.5	5.72	−3.7	−46.5
1.71	+7.8	+ 98.0	5.87	−4.8	−60.3
2.00	+7.8	+ 98.0	5.89	−4.9	−61.6
2.43	+7.3	+ 91.7	5.90	−5.2	−65.3
2.84	+6.3	+ 79.2	6.18	−5.1	−64.1
3.36	+6.1	+ 77.6	6.73	−5.4	−67.9
4.53	+5.2	+ 65.3	7.61	−5.7	−71.6
5.02	+1.8	+ 22.6	7.70	−6.3	−79.2
5.32	−0.7	− 8.8	7.76	−6.7	−84.2

The cell used for the electrophoresis work has been described by Northrup.[5] Velocity observations were always made at the same place in the cell, using a micrometer eyepiece. All measurements recorded for a given *P*H are the mean of ten or twelve closely agreeing observations in which the current direction was repeatedly reversed.

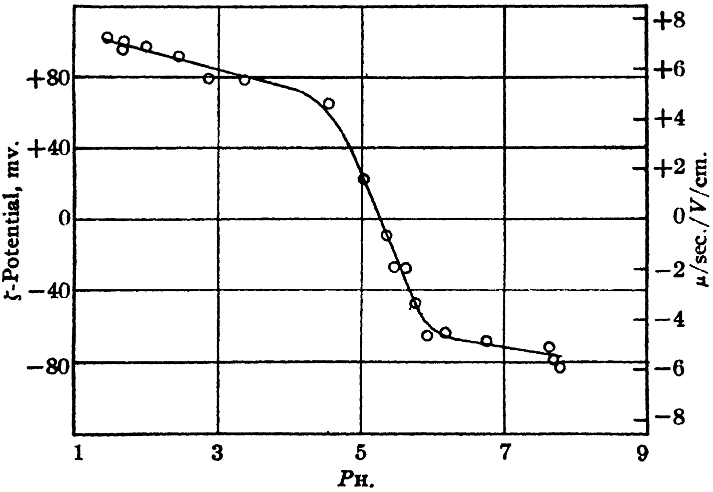

Fig. 2.—ζ-Potential and migration velocity of orange seed globulin.

The data are given in Table I and are presented graphically in Fig. 2. Interpolated from the graph, the isoelectric point of the protein is at *P*H 5.23 or C_H 5.9 × 10^{-6}.

Summary

1. The electrophoretic velocity of orange seed globulin has been measured in citrate and phosphate buffer solutions in the *P*H range 1.5 to 7.8 and the electrical charge on the particle calculated.

2. The isoelectric point of orange seed globulin was found to be at *P*H 5.23 or C_H 5.9 × 10^{-6}.

The Formation of Cyclic Acetals from Aldehydes or Ketones and Alkylene Oxides

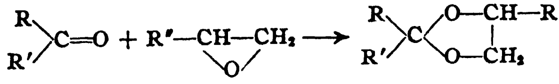
BY MARSTON TAYLOR BOGERT AND RICHARD O. ROBLIN, JR.[1]

Introduction

Cyclic acetals have been the subject of numerous investigations,[2] and in every case their formation has involved the use of a polyhydroxy compound. Wurtz,[3] in preparing ethylidene glycol, , attempted a direct condensation of ethylene oxide and acetaldehyde, but reported only negative results. Later, Lochert[4] confirmed this observation of Wurtz. He was unable to obtain a reaction between propylene oxide and acetaldehyde. More recently[5] negative results have also been reported in the case of benzyl ethylene oxide, when 40% sulfuric acid was used as a catalyst.

When dioxane is prepared from ethylene oxide in the presence of a catalyst, some cyclic acetal is formed.[6] It has been suggested that the acetal formation involved a rearrangement of ethylene oxide to acetaldehyde, which then reacted with more ethylene oxide to form ethylidene glycol. While up to the present time there has been no direct experimental basis for the second step in this hypothesis, it has been generally accepted, and has even crept into textbooks as a reaction of ethylene oxide.[7]

During a study of the properties of ethylene oxides in this Laboratory, it was discovered that these compounds react with aldehydes and ketones in the presence of metallic chlorides. The resulting compounds are cyclic acetals, the formation of which may be typified as follows



In so far as we have been able to determine, this is the first time that the reaction of ethylene oxides with aldehydes or ketones has been carried out successfully.

Since the reaction does not take place in the absence of a catalyst, any hypothetical mechanism must take cognizance of this fact. It is well established that stannic chloride forms addition compounds with ethers and carbonyl compounds.[8] The addition of stannic chloride to benzaldehyde, for example, causes the precipitation of a solid complex, which gradually dissolves as ethylene oxide is introduced. This may be due to the formation of a soluble addition compound between ethylene oxide and stannic chloride, which, in turn, interacts either with free benzaldehyde, or the benzaldehyde–stannic chloride complex, I, as follows

As will be seen in II, this involves the simultaneous opening of the three membered oxide ring and the two membered carbonyl ring. If these two unstable systems combine, the cyclic acetal III will be formed. The benzaldehyde is written in the form of its stannic chloride complex rather than in the free form, because this solid complex does not disappear until the reaction is practically complete.

The course of the reaction, in the case of benzaldehyde, may be followed by observing the color changes which take place. As ethylene oxide is added the liquid becomes red in color. The red color gradually deepens until, near the end of the reaction, a green fluorescence appears. When the reaction is complete the solution is a clear green. If this green solution is allowed to stand in the presence of sunlight, it fades to a pale yellow, but it persists indefinitely in the absence of light. The red color was shown to be due to the benzaldehyde–stannic chloride complex in solution, while the green color could be produced by the addition of stannic chloride to the pure cyclic acetal. The low yield may be accounted for, in part, by this cyclic acetal complex, which removes stannic chloride from the reaction. When acetophenone or methyl hexyl ketone is used, the solution becomes orange, and this color persists during the reaction. Here, too, the color is sensitive to sunlight. No color appears when heptaldehyde is used.

Experimental

Since a trace of water is detrimental to the reaction, the starting materials were thoroughly dried. In the case of ethylene oxide this was accomplished by passing the gas over soda lime, as recommended in "Organic Syntheses."[9] The propylene oxide and other starting materials were purified by two fractional distillations.

Preparation of Cyclic Acetals

After a number of experiments, the following conditions were selected as giving the best results: 0.2 mole of the aldehyde or ketone was cooled in an ice-bath to 5°, and 0.01 mole of anhydrous stannic chloride added slowly from a graduated pipet. A complex formed which in the case of benzaldehyde and acetophenone was a white solid; 0.25 mole of the oxide was then added gradually with occasional shaking. The temperature was maintained between 40–50° throughout the addition, which generally required about eighty minutes. The clear solution[10] was allowed to cool to room temperature, and an equal volume of benzene added, the mixture washed with three 10-cc. portions of 10% sodium hydroxide to remove the stannic chloride, and then with three 10-cc. portions of water. The resulting benzene solution was dried over anhydrous sodium sulfate, the benzene removed on a steam-bath, and the product fractionated; yield, 25-35%.

Attempts to increase the yields were unsuccessful because of two opposing factors. The amount of cyclic acetal formed was shown to be directly proportional to the amount of stannic chloride used, and also to the temperature of the reaction. However, these factors bore a similar relation to the formation of a high boiling material, probably a polymer. Thus, the use of larger relative amounts of stannic chloride resulted in the recovery of less of the original carbonyl compound, but a larger amount of the "polymer" was formed; so that the yield of cyclic acetal had not been increased and may even have been decreased. The same was true of the temperature; high temperatures favored the reaction, but also favored "polymerization." The procedure described above represents the optimum conditions possible in the face of these opposing factors. The use of solvents such as ether, benzene or carbon tetrachloride did not give an appreciable increase in the yield. Benzene was found to be the best solvent, while ether actually inhibited the reaction.

Under the same experimental conditions the following catalysts produced only a trace of the desired product: $SnCl_4 \cdot 4H_2O$, $ZnCl_2$, $FeCl_3$, $SbCl_3$, $AlCl_3$.[11] $CaCl_2$, NH_4Cl, HCl, H_2SO_4 and $POCl_3$ gave no appreciable reaction.

Formation of the "Polymer" and Reversibility of the Reaction.—The formation of the high boiling material seriously decreased the yield, and an attempt was made to determine its constitution. If the residue consists of polymerized acetal it should be possible to obtain a quantitative hydrolysis to the original aldehyde or ketone and the corresponding glycol. The residue resulting from the reaction of benzaldehyde and ethylene oxide was, therefore, heated at 150° and 20 mm. for three hours to remove as much of the lower boiling material as possible. Ten grams of the resulting residue was refluxed with dilute hydrochloric acid for one-half hour. This treatment resulted in the formation of only a trace of benzaldehyde. The remainder of the material was recovered unchanged. Since, under the same conditions, benzylidene glycol is hydrolyzed quantitatively to benzaldehyde and ethylene glycol, it would appear that the high boiling residue is not a polymer of the cyclic acetal. An attempt to distil the high boiling "polymer" at 20 mm. pressure produced a slow decomposition. Benzaldehyde was the only definite compound which could be isolated from the resulting distillate.

The reaction was shown to be non-reversible by the following experiment: 10 g. of pure benzylidene glycol was heated in a distilling flask with 0.7 g. of anhydrous stannic chloride at 50° for one hour. The receiver was immersed in solid carbon dioxide, but no ethylene oxide was liberated, and the original material was recovered unchanged.

---

(10) In the case of acetophenone and ethylene oxide, the ketal separated as a crystalline solid. By cooling to −5° practically all of the material separated from the reaction mixture. It was dissolved in ether, washed and dried in the usual manner, and purified by fractional distillation *in vacuo*.

(11) Because of the tendency of this salt to resinify the carbonyl compound only 0.003 mole could be used.

The following cyclic acetals and ketals were prepared by the procedure described above.

Compound (1,3-dioxolane)	B. p., (corr.), °C.	Yield, %	Analyses Calcd. C	H	Found C	H
2-Phenyl-[12a] (benzylidene glycol)	225	35	..	..	..	..
4-Methyl-2-phenyl-	118 (23 mm.)	30	73.1	7.3	72.9	7.5
2-Hexyl-[12b,13]	200	25	..	..	..	..
4-Methyl-2-hexyl-	102.5–103.5 (23 mm.)	22	69 7	11.6	69.6	11.7
2-Methyl-2-hexyl-	97 (23 mm.)	25	69.7	11 6	68 9	11.9
2,4-Dimethyl-2-hexyl-	102 (23 mm.)	30	70.9	12 0	70 5	12.2
2-Methyl-2-phenyl-[14]	103.5–104.5 (23 mm.)	28	73.1	7.3	73.1	7.3
2,4-Dimethyl-2-phenyl-	105 (23 mm.)	32	74.1	7.9	73.8	7.9

2-Phenyl-1,3-dioxolane and 2-hexyl-1,3-dioxolane were identified by their boiling points, and by comparison with the same compounds prepared from ethylene glycol. In every case the compounds were readily hydrolyzed by dilute acid to the corresponding aldehyde or ketone.

Hibbert[15] has shown that compounds of the type  $\begin{matrix}R\\H\end{matrix}\!>\!C\!<\!\begin{matrix}\text{—O—}\\\text{O—CH}_2\end{matrix}\!>\!C\!<\!\begin{matrix}R'\\H\end{matrix}$ are capable of existing in two isomeric forms. These isomers are accounted for by the different relative positions of the groups R and R′, and may be considered as *cis* and *trans* isomers. In this case the *trans* form would be represented by the formula  $\begin{matrix}R\\H\end{matrix}\!>\!C\!<\!\begin{matrix}\text{—O—}\\\text{O—CH}_2\end{matrix}\!>\!C\!<\!\begin{matrix}H\\R'\end{matrix}$. All of the compounds in this paper, which were prepared from propylene oxide, should show this type of isomerism, in addition to optical isomerism. Since none of these compounds were solids, no method could be devised for separating the isomers.

While the preparation of cyclic acetals from ethylene or substituted ethylene glycols is quite satisfactory in most cases, the cyclic ketals are prepared only with difficulty and in very small yields.[16] Thus, by the use of ethylene glycol in the presence of 40% sulfuric acid, the authors were unable to prepare even a trace of the cyclic ketal of acetophenone.[17] Although the method described in this paper is not entirely satisfactory, it furnishes a simple approach to cyclic ketals which are difficult or impossible to make by the usual method.

The polysubstituted ethylene oxides in which more than one hydrogen is replaced have not been studied. However, it may be anticipated that these compounds will react in an analogous manner, at least in the case of

the simpler derivatives. An investigation of the higher membered oxides such as trimethylene oxide and tetrahydrofuran was not undertaken, since the lesser reactivity of these compounds made it seem doubtful that an appreciable reaction would take place.

Summary

Ethylene oxides react with aldehydes and ketones in the presence of metallic chlorides to form cyclic acetals, in yields varying from 25 to 35%.

By this method six new acetals and ketals were prepared, some of which would be difficult or impossible to make by the use of a glycol.

The Measurement of Oxidation–Reduction Potentials in Glacial Acetic Acid Solutions

BY J. B. CONANT AND B. F. CHOW

It was shown eight years ago[1] that the ion of a halochromic salt and a free radical such as triphenylmethyl form a mobile oxidation–reduction system whose potential can be measured in a non-aqueous medium. The lack of adequate information about the properties of acids and bases in such non-aqueous media prevented a detailed quantitative study of the problem at that time. A study of glacial acetic acid solutions was undertaken therefore, and has now reached a point where it is possible to return to the study of oxidation–reduction potentials in this and similar non-aqueous media. In this paper we shall present the results of the study of certain dyes and quinones of the type which has been studied extensively in water; in a later paper we shall consider the rather unique system composed of a free radical and a halochromic salt.

The measurements were all made using glacial acetic acid as the solvent. The hydrogen-ion activity was kept constant in each experiment by means of suitable "buffers," which in most instances consisted of an organic base partially neutralized with sulfuric acid. The ionic strength was constant at 0.2 in all the buffers, and where necessary a neutral salt was added to bring the value of the ionic strength to 0.2. The exact composition of the buffers is given in Table I together with the $(P\mathrm{H})^{\mathrm{HAc}}$ values determined by means of a chloranil electrode as previously described in papers from this Laboratory.

The Acidity Scale in Acetic Acid

A few words are necessary in regard to the significance of the $(P\mathrm{H})^{\mathrm{HAc}}$ values. Since the first work from this Laboratory on glacial acetic acid,

---

[1] Conant, Small and Taylor, THIS JOURNAL, 47, 1959 (1925).

TABLE I

COMPOSITION OF BUFFERED GLACIAL ACETIC ACID SOLUTIONS

The glacial acetic acid employed melted at 16.5°. Solution 10 was not very stable. In two weeks time its P_H changed from −0.95 to +0.02. Only the freshly made solutions were used in the experiments. Unless otherwise noted the neutral salt added was trimethylammonium *p*-toluene sulfonate.

Soln.	Concn. of base in moles per liter	Neutralized with H_2SO_4, %	Moles of neutral salts per liter	$(P_H)^{HAc}$
1	1.0 Pyridine	0	0.200	+4.24
2	0.1 Pyridine	0	.200	+3.64 +3.52
3	.05 Acetoxime	0	.200	+2.47 +2.29
4	.05 Antipyrine	50	.175	+1.66
5	.05 Urea	0	.200	+1.86 +1.61
6	.05 Acetoxime	50	.175	+1.00
7	.05 Urea	15	.1925[a]	+0.34
8	.30 Acetoxime	65	.005	+ .25
9	.25 Acetoxime	80	.000	− .15
10	.05 Acetamide	70	.163	− .98
11	.1 Benzamide	9	.110	−2.10

[a] Indicates that the neutral salt was triethylammonium perchlorate. A partially neutralized urea buffer of $(P_H)^{HAc}$ value −0.63 with somewhat less ionic strength was also used in some experiments.

it has become evident that it is impossible to relate the fugacities of an individual ion from two solvents. It has further become evident[2] from a series of experimental results in acetic acid solutions of varying ionic strength that the relation of the base strength of two bases in acetic acid and in water depends on (a) the charge of the base, and (b) the ionic strength of the acetic acid. For practical purposes a very dilute solution of a base in acetic acid is of no value, but a solution containing enough neutral salt so that $\mu = 0.2$ is conveniently prepared. Slight changes in ionic strength at this point have little effect, although a change of the neutral salt may cause shifts in the apparent $(pK)^{HAc}$ value of as much as 0.5 of a unit (see Fig. 3, Conant and Werner, THIS JOURNAL, **52**, 4442 (1930)).

Hammett and Deyrup[3] have greatly clarified the subject of non-aqueous solutions by defining an acidity function of such solutions by the equation

$$H_0 = -\log a_{H^+}(f_B/f_{BH^+})$$

The acidity function will depend on the charge on the base and they propose the symbol H_0 for bases like urea, H_- for bases like the acetate ion, etc. To the extent that the ratio f_B/f_{BH^+} in a given solution is the same for all bases, this definition is exact and has real meaning. The pK'_B value of a base defined in terms of this scale of acidity function is independent of the solvent to the extent that the assumption just mentioned is exact. We may now redefine our $(P_H)^{HAc}$ scale in terms of Hammett and Deyrup's

---

(2) Guggenheim, *J. Phys. Chem.*, **33**, 842 (1929).

(3) Hammett and Deyrup, THIS JOURNAL, **54**, 2721 (1932).

acidity function referred to a base of the zero charge type (H_0) and defining our solvent as glacial acetic acid with neutral salt added to give $\mu = 0.2$.

The best comparison now available of the relative strengths of two bases in water and an acetic acid solution of high ionic strength is given in Fig. 4, of the paper by Conant and Werner. From the data there given the apparent pK values of urea and acetoxime are $+1.1$ and $+0.3$, the corresponding values in water are about $+1.75$ and $+0.1$; the uncertainties in the acetic acid values are at least ± 0.2 and the values in aqueous solution of such very weak bases may be in error to a considerable extent. The zero point of the $(P_{\text{H}})^{\text{HAc}}$ scale was originally chosen in part because the value of $(pK)^{\text{HAc}}$ for urea titrated in a 0.2 M solution ($\mu = 0.2$ at the midpoint) closely coincided with the pK value in water. It is evident that if urea is used for the comparison, $(P_{\text{H}})^{\text{HAc}} = H_0$ within the limits of experimental error; if acetoxime is used for the comparison, the old $(P_{\text{H}})^{\text{HAc}}$ scale should be corrected by about 0.6 of a unit. The discrepancy between these two bases of the same charge type may in part reflect experimental uncertainties but may also represent the limit of accuracy of the assumption that $f_{\text{B}}/f_{\text{BH}^+}$ for the two bases is the same. At all events, it seems best to continue the use of the old $(P_{\text{H}})^{\text{HAc}}$ scale for acetic acid solutions where $\mu = 0.2$, as any correction of it to make it coincide more closely with the H_0 scale is perhaps impossible.

It should be borne in mind that at low values of μ, the $(P_{\text{H}})^{\text{HAc}}$ scale must be corrected to make it correspond even approximately with the H_0 scale. For example, at $\mu = 0.025$ (the half-neutralized base contributing the salt), Hall[4] found a fairly consistent spread of about 2 units between $(pK)^{\text{HAc}}$ (defined on the old $(P_{\text{H}})^{\text{HAc}}$ scale) and $pK^{(\text{H}_2\text{O})}$ for a variety of bases of the zero type. Therefore at $\mu = 0.025$, $H_0 \cong (P_{\text{H}})^{\text{HAc}} + 2$. The irregularities may be certainly as much as 0.5 of a unit, however. The impossibility of making any of these definitions exact must be emphasized; the assumption of the constant ratio of the activity coefficients is certainly inexact and in solutions of high ionic strength experiment has shown that the nature of the neutral salt may affect the apparent pK values by several tenths of a unit.

The Measurement of Oxidation–Reduction Potentials

We shall define our oxidation–reduction potentials (E_{h}) in glacial acetic acid solutions with reference to a hypothetical hydrogen electrode (1 atm.) functioning in a buffered solution of ionic strength 0.2 and $(P_{\text{H}})^{\text{HAc}} = 0$. Actually the oxidation–reduction half-cell was measured against a saturated aqueous calomel electrode through a lithium chloride bridge. Since the same arrangement was used in measuring the $(P_{\text{H}})^{\text{HAc}}$ values of the buffer with the chloranil electrode, the aqueous electrode and the salt bridge cancel in the final calculations. By the definition of our original

---

(4) Hall, This Journal, 52, 5115 (Fig. 2) (1930).

$(P\text{H})^{\text{HAc}}$ scale, the saturated chloranil electrode at $(P\text{H})^{\text{HAc}} = 0$ was given the value of +0.566 referred to aqueous calomel through the lithium chloride bridge.[1a] The value of the saturated chloranil electrode against the hydrogen electrode is independent of the solvent and has the value +0.664. From this it follows that the potential of a hypothetical hydrogen electrode in acetic acid $(P\text{H})^{\text{HAc}} = 0$, against aqueous calomel is $0.566 - 0.664 = -0.098$ volt (European convention in regard to sign). The value of E_h of the oxidation-reduction potential is thus 98 millivolts greater than the observed potentials measured against the aqueous calomel electrode.

The apparatus used was very similar to that employed in the measurement of $(P\text{H})^{\text{HAc}}$ values (see Fig. 6, Ref. 1). The stirrer was omitted and an inlet tube for oxygen-free nitrogen dipped well beneath the liquid. The air-tight rubber stopper carried two bright platinum electrodes, a buret tip and an exit tube. A slow stream of nitrogen supplied sufficient agitation. The temperature was 25 ± 2°. Two methods of varying the ratio of oxidant and reductant were employed. One was the well-known method of mixtures, the other was by titration of the oxidant with chromous acetate. The reductant in most cases was prepared by reducing the oxidant with hydrogen and platinized asbestos; the solution was kept in a reservoir connected to a buret in an atmosphere of oxygen-free nitrogen. Five cc. of buffer solution was placed in the cell in each experiment and 0.25 to 1.00 cc. of a 0.0060 M solution of the oxidant or reductant added; the total concentration of oxidant and reductant at the midpoint was therefore about 0.0017 molar.

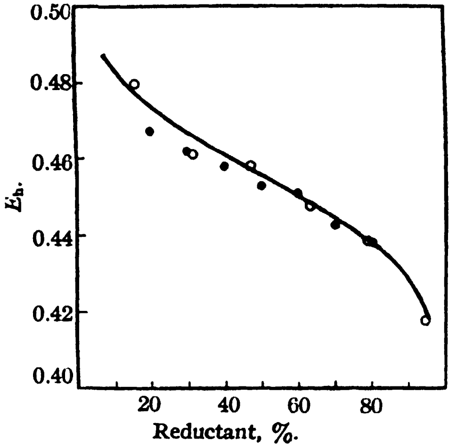

Fig. 1.—Showing the relation between the potential and the varying ratios of oxidized and reduced o-cresol-indophenol in $P\text{H}$ +2.32: ●, method of mixtures; ○, method of titration. The curves were drawn with the theoretical slope through the average $E_h^{0\prime}$.

The accuracy of the results is, of course, much less than that obtained using aqueous solutions. Figures 1 and 2 illustrate typical results. In Fig. 1 are plotted results obtained by the method of mixtures and by titration (using $Cr(Ac)_2$); the usual sigmoid curve was drawn to correspond to the equation

$$E_h = E_h^0 + \frac{RT}{2F} \ln \frac{[\text{Oxid.}]}{[\text{Red.}]}$$

The value of E_h^0 obtained by considering the titration results alone was 0.455 and that obtained from the method of mixtures 0.453. In Fig. 2 a logarithmic plot presents the results obtained with indothymol in four different buffers by the method of mixtures. The straight lines are drawn with a slope corresponding to the equation given above. The value of E_h^0 calculated from all the points in an experiment usually deviated not more than ±2 millivolts from the average value. In the case of benzoquinone at $(PH)^{HAc} = +3.52$, both the titration method and the method of mixtures gave a value of E_h^0 identical within half a millivolt.

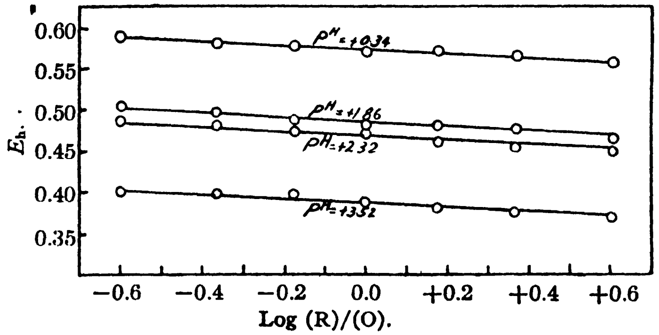

Fig. 2.—Potentials of indothymol in different PH. Lines are drawn with the theoretical slope.

The values of E_h^0 are plotted against $(P\text{H})^{HAc}$ for five compounds in Fig. 3. The values for chloranil and benzoquinone were obtained simply

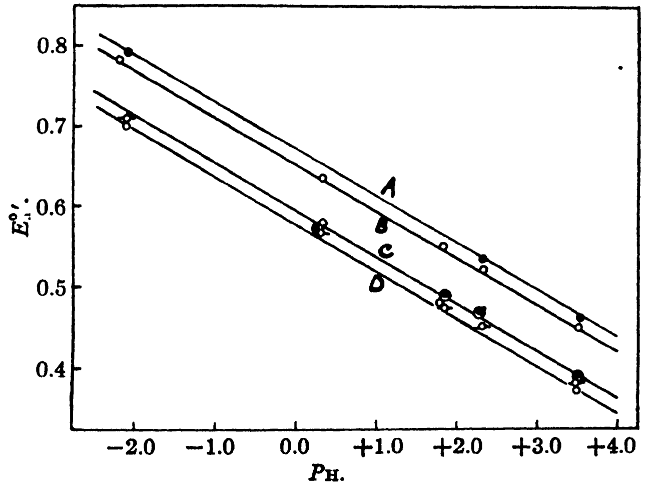

Fig. 3.—Showing the relationship between PH and $E_h^{0\prime}$. The lines were drawn with the theoretical slope: A, chloranil; B, benzoquinone; C (●), indothymol; D, -O- indo-o-cresol; ⊙ o-cresol-indophenol.

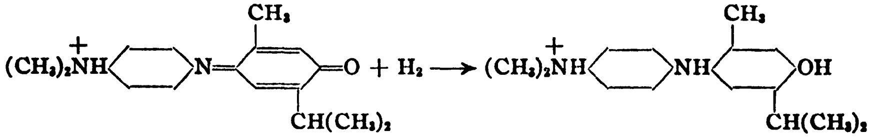
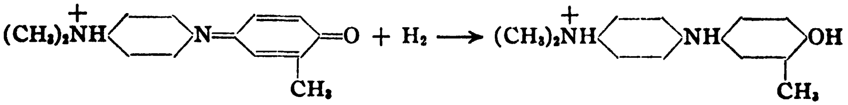
by using an equimolecular mixture of the reductant and oxidant in each buffer (except $(P\text{H})^{HAc} = 3.52$ where the titration method was also employed with benzoquinone). The values for the three dyes are the average of a number of points obtained by the method of mixtures or in a few cases by titration with chromous acetate as explained above. To save space we are omitting the several hundred individual determinations of E_h from which the average values of E_h^0 were calculated for each buffer. The slope of the lines in Fig. 3 corresponds to $\Delta E_h^0/\Delta(P_H) = -0.060$. A close agreement of the experimental points to this line is, of course, to be expected in the case of quinone and tetrachloroquinone (chloranil) since the dissociation of the phenolic groups lies far beyond the most alkaline end of this range of $(P_H)^{HAc}$ values (much more alkaline than can be reached in glacial acetic acid, in fact). The value of E_h^0 at $(P_H)^{HAc} = 0$ corresponds to the free energy of the reduction of the quinone by hydrogen; we shall designate it as E_0'. The values from Fig. 3 are 0.675 for chloranil and 0.650 for benzoquinone. These values differ from those in alcoholic solution which are 0.703 and 0.711, respectively, as might be expected. The fact that chloranil in acetic acid is a stronger oxidizing agent than benzoquinone is of interest as the free energies referred to the gaseous state are in the same order with even a greater difference between the two compounds.[5]

The equations for the reduction of the three dyestuffs in the range of acidity we are here concerned with, are as follows

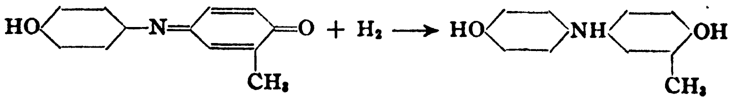
(1) Indothymol: $E_0' = 0.600$



(2) Indo-*o*-cresol: $E_0' = 0.575$



(3) *o*-Cresol-indophenol: $E_0' = 0.575$



The free energy of each of the reactions written above is equal to $-2FE_0'$ where E_0' is the value of E_h^0 at $(P_H)^{HAc} = 0$. The values of E_0' given above were obtained by graphical interpolation of the lines of Fig. 3. Any differences between E_0' for (2) and (3) are within our experimental error, which is probably as much as ±7 millivolts because of the difficulties attending the preparation and measurement of $(P_H)^{HAc}$ of the buffer solutions. The small difference between even (1) and (3) is not surprising

[5] This Journal, 49, 293 (1927).

since in all three cases the group undergoing reduction is very nearly the same  . The linear relationship between $(P\text{H})^{\text{HAc}}$ values and E_h^0 is surprising since it might be expected that the diphenylamine grouping of the reductant would unite with a proton at about $(P\text{H})^{\text{HAc}} = 0$. (The value of pK_B for diphenylamine is about 0.) This should result in a bend of the curve as many examples studied in aqueous solution have shown. Evidently the hydroxyl group in the para position has made the base still weaker than diphenylamine.

In all the experiments recorded in this paper, the ionic strength of the glacial acetic acid solutions has been kept constant at $\mu = 0.2$. In such a solvent $(P\text{H})^{\text{HAc}} = H_0$ as explained early in this paper. H_0, therefore, might replace $(P\text{H})^{\text{HAc}}$ in the plot in Fig. 3 without change It is interesting to note that if the oxidation-reduction potential of one of the substances is determined in a buffer solution of different ionic strength, the result will also fall on the straight line of Fig. 3, but the position of the point will then depend on whether $(P\text{H})^{\text{HAc}}$ (as defined in all our work) or H_0 is plotted horizontally.

Summary

It has been shown that the oxidation-reduction potential of quinones and certain dyes may be measured in glacial acetic acid by the method of mixtures or by titration of the oxidant with chromous acetate. The results obtained in a series of buffers with constant ionic strength lie on a straight line with the theoretical slope when E_h^0 is plotted against $(P\text{H})^{\text{HAc}}$. The relation of the $(P\text{H})^{\text{HAc}}$ scale to Hammett and Deyrup's acidity function is discussed briefly.

The Potential of Free Radicals of the Triphenylmethyl Type in Glacial Acetic Acid Solutions

BY J. B. CONANT AND B. F. CHOW

In a preceding paper[1] it was shown that the oxidation-reduction potentials of quinones and certain dyes could be measured in a series of glacial acetic acid buffer solutions by the usual procedure. In this paper we shall consider the application of these methods to the problem of the potential between a free carbon radical and a halochromic salt—a problem stated and partially solved in an earlier paper from this Laboratory.[2] The buffer solutions employed were the same as those used in the preceding paper and their $(P_H)^{HAc}$ values were measured with the chloranil electrode as previously described.

The electrode reaction involved in all the cases studied may be written in the general form

$$\underset{\text{(halochromic ion)}}{R_3C^+} + e \rightleftharpoons \underset{\text{(free radical)}}{R_3C}$$

At constant hydrogen-ion activity the potential will depend on the relative amounts of the halochromic ion and free radical according to the usual electrochemical equation (1).

$$E_h = E_0 + \frac{RT}{F}\ln\frac{[R_3C^+]}{[R_3C]}$$

As usual, the potential is referred to a hypothetical hydrogen electrode operating in a buffer solution in glacial acetic acid of $(P_H)^{HAc} = 0$. The relation of this scale to Hammett and Deyrup's acidity function has been discussed in the preceding paper.[1] The relation between the concentration of free radical and the total reductant expressed as moles of ethane (associated form) is as follows $[R_3C] = 2\alpha[\text{Ethane}]_T$. At a given dilution and temperature we may consider that α, the degree of dissociation of the ethane, is essentially constant and therefore substitute in equation 1 the term $2\alpha(\text{Ethane})_T$ for the term $[R_3C]$. The halochromic salt is formed from the carbinol by the action of a proton

$$R_3COH + H^+ = R_3C^+ + H_2O \qquad (2)$$

The equilibrium constant for this reaction may be expressed by equation 3

$$K = \frac{[R_3COH]\,[H^+]}{[R_3C^+]\,[H_2O]} \qquad (3)$$

The concentration of total carbinol $[\text{Carb.}]_T$ is equal to $[R_3COH] + [R_3C^+]$ therefore substituting for $[R_3COH]$ in equation 3, the terms $[\text{Carb.}]_T - [R_3C^+]$ we obtain equation 3a

$$[R_3C^+] = \frac{[\text{Carb.}]_T\,[H^+]}{[H^+] + K[H_2O]} \qquad (3a)$$

---

(1) THIS JOURNAL, 55, 3745 (1933).

(2) Conant, Small and Taylor, *ibid.*, 47, 1959 (1925).

Now making the appropriate substitutions in equation 1, we therefore arrive at the general equation 4

$$E_h = E_0 - \frac{RT}{F}\ln\alpha + \frac{RT}{F}\ln\frac{[\text{Carb.}]_T}{2[\text{Ethane}]_T} - \frac{RT}{F}\ln\frac{[H^+] + K[H_2O]}{[H^+]} \qquad (4)$$

At constant volume we may consider that α is constant and set E_0' equal to $E_0 - RT \ln \alpha/F$. At constant hydrogen-ion activity and constant water content the potential of a solution in which $(\text{Carb.})_T = 2(\text{Ethane})_T$ may be called E_0''. It will be noted if the concentration of the reductant is expressed in terms of the dissociated compound that this would be an equimolecular mixture of oxidant and reductant. Inspection of the last term of equation 4 which contains the hydrogen-ion activity makes it evident that when the value of $K[H_2O]$ is much greater than (H^+) the value of E_0'' will be a linear function of the hydrogen-ion activity and $E_0'' = E_0' - (RT/F) \ln K(H_2O)$. At the point where $K[H_2O]$ is less than (H^+) the potential will be independent of the hydrogen-ion activity and $E_0'' = E_0'$. There should thus be a sharp bend in the $E_0'':(P_H)^{HAc}$ curve at a point corresponding to the change of the oxidant from being almost exclusively in the carbinol form to being almost exclusively in the halochromic ion form. Such breaks do occur as will be shown below.

The apparatus employed in measuring the oxidation–reduction potentials of the free radicals was identical with that used in the study of quinones and certain dyes. The potential was actually measured in every instance against a saturated aqueous calomel electrode and these readings were converted to the hydrogen electrode scale by adding 98 mv., which we have calculated in the previous paper to be the potential of the hypothetical hydrogen electrode against saturated calomel at $(P_H)^{HAc} = 0$. It is, of course, necessary that all the measurements be carried out in the complete absence of oxygen, as the free radicals react very rapidly with this gas. Three different methods were employed of varying the ratio of oxidant and reductant. In the method of mixtures a solution of the free radical in dry bromobenzene was placed in an atmosphere of oxygen-free nitrogen. Varying quantities of such a solution were then added to the glacial acetic acid buffer which contained a solution of the halochromic ion. The latter was usually formed by dissolving the corresponding carbinol directly in the buffer solution. Varying quantities of the reductant (the free radical) were added and the potential measured. Bright platinum electrodes were used in all of the work. Two titration methods were also employed. In one of these the halochromic salt solution was titrated with a chromous acetate. The other procedure depended on the fact that the indophenols in glacial acetic acid are much more powerful oxidizing agents than the halochromic salts. As a result it is possible to titrate the free radical with a solution of the oxidized form of indophenol dye. A very satisfactory end-point can be determined electrometrically, since there is a change of potential of some 200 mv. at the end-point. The end-point could also be estimated visually by the color change and these results always agreed satisfactorily with the electrometric end-point. In each experiment 5 cc. of buffer solution was employed; the concentration of carbinol and total reductant at the midpoint was usually about 0.001 molar.

To save space the three methods are illustrated by the three diagrams shown in Figs. 1, 2 and 3, illustrating, respectively, the method of mixtures (with a logarithmic plot of the ratio of oxidant to reductant), the titration of triphenylcarbinol with chromous acetate, and the titration of diphenyldixanthyl with indothymol. In each case the values plotted are E_0''.

The agreement between the method of mixtures and the titration methods was within the experimental error (10 millivolts). For example, with the triphenylmethyl system at $(P_H)^{HAc} = -0.98$, the method of mixtures yielded a value for E_0'' of 0.277 while the chromous acetate titration gave 0.277; with phenylxanthyl at $(P_H)^{HAc} = +0.24$, E_0'' by mixtures was 0.098, by titration with indothymol +0.084. In the more acid solutions the potentials were not stable for any long period as there is, of course, a decomposition of the free radicals by the action of the acids present. The temperature was kept at 25 ± 1° by means of a jacket around the electrochemical cell through which water at a constant temperature was allowed to flow. In one experiment with the triphenylmethyl system at $(P_H)^{HAc} = -0.98$ it was found that an increase in temperature of 10° changed the potential less than 2 mv. It is therefore clear that the temperature coefficient of such a system is so small that the control of temperature is not a significant factor.

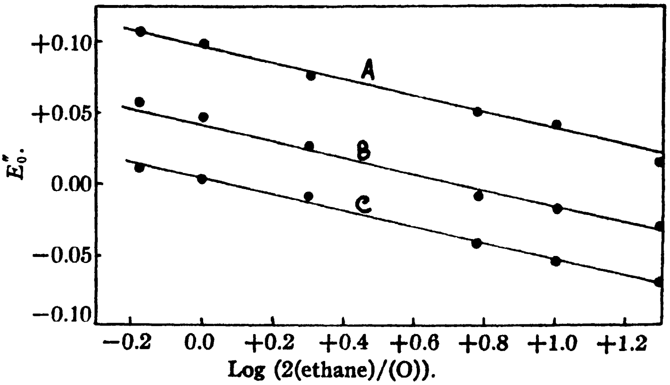

Fig. 1.—Potentials of diphenyldixanthyl by the method of mixtures: A at P_H +1.00, B at P_H +2.47, C at P_H +3.68. Lines were drawn with the theoretical slope.

In Fig. 4 are plotted all the final results with the three free radical systems which have been studied, namely, triphenylmethyl, phenylxanthyl and benzylxanthyl. The values plotted are those of E_0'' *vs.* $(P_H)^{HAc}$ the ionic strength of all the buffers was 0.2. The various symbols show whether the results were obtained by the method of titration or the method of mixtures. It will be seen that the agreement between the two methods is all that could be expected considering the difficulties of handling the free radicals and non-aqueous solutions.

The concentration of water in our solutions we estimate to be about 0.006 molar, due primarily to the water formed in the neutralization of the added carbinol. This is essentially the water concentration in previous work of Conant and Werner[3] on the basic strength of the carbinols and therefore their values of (pK) are directly comparable with those in this paper. We have measured the value of pK' of benzylxanthydrol by

(3) Conant and Werner, THIS JOURNAL, 52, 4436 (1930).

titration at $\mu = 0.2$ following the previous method and found a value of $+0.70$. The values of $pK' = -\log K(\mathrm{H_2O})$ for the three carbinols studied are therefore $(\mathrm{C_6H_5})_3\mathrm{COH}$, -1.47, $\mathrm{C_6H_5COH(C_6H_4)_2O}$, $+1.91$, $\mathrm{C_6H_5CH_2COH(C_6H_4)_2O}$, $+0.70$. The inflection of the E''_0 *vs.* $(P\mathrm{H})^{\mathrm{HAc}}$ curve of Fig. 4 should occur at the corresponding values of $(P\mathrm{H})^{\mathrm{HAc}}$. The points are indicated by the arrows. It is evident that in the case of the benzylxanthydrol system, the inflection occurs at exactly the right point; in the case of the phenylxanthydrol system there is a discrepancy of about 0.25 of a $P\mathrm{H}$ unit, which is about the experimental uncertainty. Unfortunately we were unable to obtain satisfactory potentials with the triphenylmethyl system in solutions sufficiently acid to give a fair test of the relation between theory and experiment in this instance. It may be that the E''_0 *vs.* $(P\mathrm{H})^{\mathrm{HAc}}$ curve becomes flat between $(P\mathrm{H})^{\mathrm{HAc}} = 0$ and -1, but we believe that it is more probable that the point at -1 is in error and the curve takes the course shown in Fig. 4.

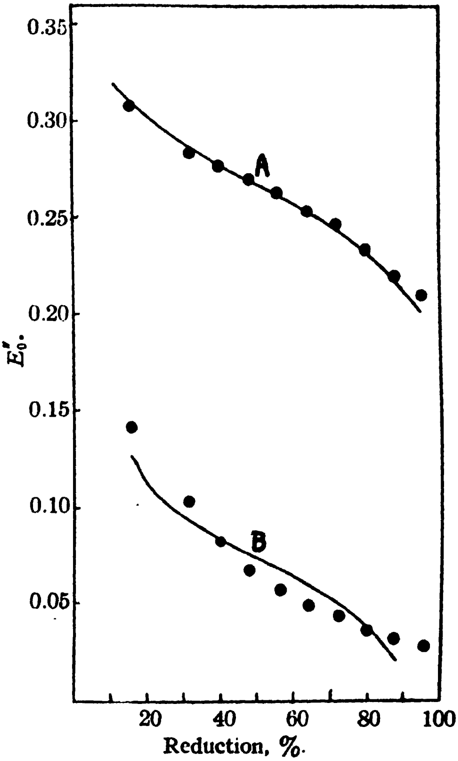

Fig. 2.—Reduction of triphenylcarbinol with chromous acetate. Theoretical curves were drawn through average E''_0: A at $P\mathrm{H} = 0.97$, B at $P\mathrm{H} = +3.64$.

The horizontal portions of the curves in Fig. 4 correspond to the value of E'_0; corrected for the value of α these give values of E_0 which is a measure of ΔF for the reduction of the halochromic ion to the free radical. The value of ΔF for the reduction of the carbinol to the free radical and water (in acetic acid at 0.006 M in water) can be calculated from this value and the term $-RT \ln K[\mathrm{H_2O}]$. (These values correspond to the intercept of the diagonal lines with the $(P\mathrm{H})^{\mathrm{HAc}} = 0$ axis when the correction for α is duly applied.) In Table I we have summarized the values of ΔF expressed in volt electrons and for comparison the values of ΔF of dissociation of the ethane (the associated free radical). The data necessary for estimating α are indicated in the footnote of the table. The change of volume during an experiment would affect α in the case of triphenylmethyl and benzylxanthyl but we have calculated that the maximum change is not more than 14 mv. over the whole range; the values used in calculating the data in Table I correspond to the midpoint. Probably some of the discrepancies illustrated by the data in Figs. 1–3 are due to the change of α during the experiment but it did not seem worth while to carry out the calculations to make the necessary corrections.

TABLE I

FREE ENERGY OF REDUCTION OF HALOCHROMIC CARBINOLS TO FREE RADICALS

Carbinol	E_0'	Estimated α at dilution of expt.	ΔF of reduction of halochromic ion, E_0	ΔF of reduction of carbinol, E_0	ΔF of dissociation of ethane
$(C_6H_5)_3COH$	+0.315	0.38	+0.290	+0.225	−0.26
$(C_6H_5COH(C_6H_4)_2O$	+0.095	.92	+ .095	+ .175	− .16
$C_6H_5CH_2COH(C_6H_4)_2O$	+ .150	5×10^{-3}	− .062	− .017	− .50

The value of α for hexaphenylethane was taken from Ziegler's data;[4] the value for phenylxanthyl and benzylxanthyl from calculations appearing in another paper from this Laboratory. In this paper the value of ΔF of dissociation of these compounds is also estimated. The values of ΔF in columns 3, 4 and 5 correspond, respectively, to the processes

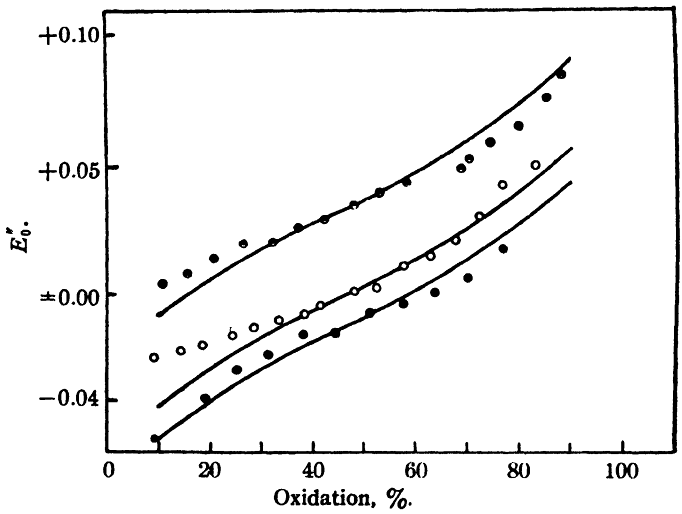

Fig. 3.—Oxidation of diphenyldixanthyl with indothymol. Theoretical curves were drawn through the average E_0'. A at P_H +2.47, B at P_H +3.68, C at P_H +4.24.

$$R_3C^+ + {}^1/_2H_2(\text{gas}) \longrightarrow R_3C + H^+ \ (\text{at } (P_H)^{HAc} = 0) \qquad (a)$$

$$R_3COH + {}^1/_2H_2(\text{gas}) \longrightarrow R_3C + H_2O \ (\text{in a } 0.006\ M \text{ soln. in HAc}) \qquad (b)$$

$$R_3C—CR_3 \longrightarrow 2R_3C \qquad (c)$$

An inspection of the results shows that the free energies of reactions (a) and (c) are influenced to a greater degree by changes in structure than are the

---

(4) Ziegler, *Ann.*, 473, 163 (1929).

values for reaction (b). In even this latter case, however, there is a difference of 0.242 volt (the corresponding extreme difference for reaction (a) is 0.350 volt). The orders of the three compounds for reactions (a) and (b) are the same but clearly bear no relation to the free energy of dissociation (reaction c). At first sight it is surprising that there should be greater differences in the free energy of reduction of the ion than the carbinol in a series of compounds, particularly in view of the work of Bent,[5] which has shown that the affinity of free radicals for an electron is relatively little influenced by changes in structure. It seems probable that the explanation is due to the fact that in the case of the xanthyl ions, the halochromic ion is in part in the oxonium form (A). This ion cannot be reduced to a free radical only as a result of an electronic rearrangement. The relatively extreme basicity of the xanthyl compounds is, of course, merely another reflection of this same tendency. The few results obtained in our preliminary paper with the free radical from the very basic $C_6H_5COH(C_6H_3OCH_3)_2O$ indicate that the value for ΔF of reduction of the ion would here be even much more divergent from the value for the reduction of the carbinol. This compound is too basic to measure in glacial acetic acid. It would be a matter of considerable interest to measure the potentials of the free radicals from this compound and other very basic carbinols such as trianisylcarbinol in a series of non-aqueous buffers in such a solvent as butyl carbitol, and it is hoped that this may be soon accomplished. Such results would provide a drastic test of the hypothesis offered above.

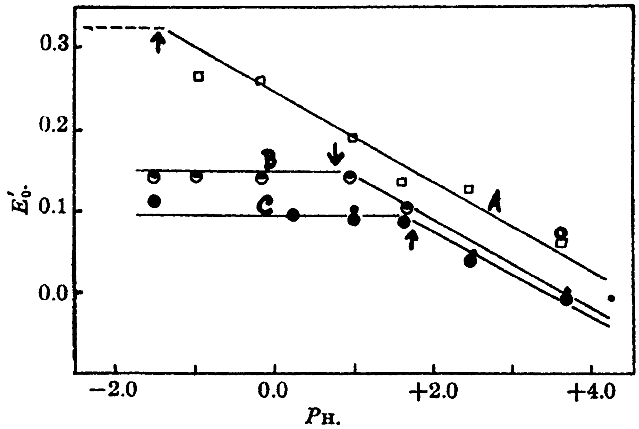

Fig. 4.—Change of $E_h^{0\prime}$ with the change of *Ph.* A for triphenylmethyl, B for benzylxanthyl, C for phenylxanthyl. Curves were drawn with the theoretical slope. Points in circles were obtained by titration.

(5) Bent, THIS JOURNAL, 52, 1498 (1930); 53, 1786 (1931).

In conclusion we may point out an interesting consequence of the low oxidation–reduction potential of the free radical and the relatively high oxidation–reduction potential of the indophenol dyes. The free radical is oxidized by the dye to the corresponding halochromic ion (or, at the proper acidities, to the corresponding carbinol). As a result it is possible to titrate a free radical with indothymol. An excess of the dye is employed in a solution of acetic acid and bromobenzene. The excess of dye is then titrated with an aqueous solution of sodium thiosulfate. It was proved conclusively that these dyestuffs are quantitatively reduced by sodium thiosulfate according to the equation

$$\underset{\text{(indophenol)}}{A} + 2R_3C + 2H^+ \longrightarrow \underset{\text{(reduced indophenol)}}{AH_2} + 2R_3C^+ \text{ (or } R_3COH)$$

The titration of the dye with sodium thiosulfate was shown to correspond to the reaction

$$A + Na_2S_2O_3 + H_2O \longrightarrow AH_2 + Na_2SO_4 + S$$

A typical experiment was as follows: 2 cc. of a 0.006 M indothymol solution in acetic acid (glacial) was placed in a 50-cc. flask containing 1 cc. of bromobenzene. A weighed sample of free radical was introduced into the flask in a carbon dioxide atmosphere. After a few moments' agitation, 3 cc. of water was added and the excess of dye with thiosulfate; 2.329 mg. of diphenyldixanthyl required 0.834 cc. of 0.00926 N $Na_2S_2O_3$ for the back titration as compared with 1.318 cc. required by 2 cc. of the dye without addition of the free radical. Purity of diphenyldixanthyl 99%; by oxygen absorption in bromobenzene the purity was 98%.

The purity of the triphenylmethyl (hexaphenylethane) and the other free radicals used in this work were checked by oxygen absorption measurements in bromobenzene or by titration with indothymol. Since these free radicals have been prepared repeatedly in many laboratories, we will not take the space to detail their preparation in this paper. In all cases the purity was at least 98% as determined by one of the two methods.

Summary

The oxidation–reduction potentials of three free radicals and their halochromic salts have been measured in glacial acetic acid solutions. The changes of potential with changes in acidity of the buffer solutions are in accord with the theory developed in a preliminary paper.

Monoarylguanidines. IV. Benzoselenazoleguanidine[1,2]

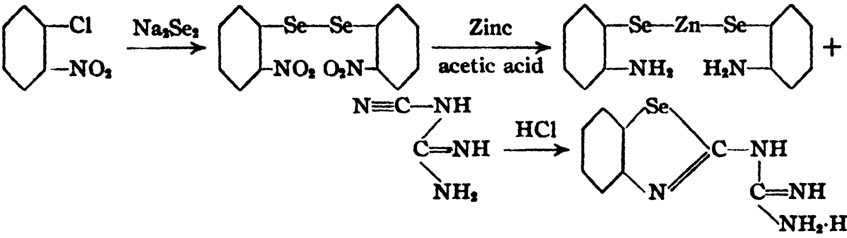
BY G. B. L. SMITH, J. P. MIALE AND C. W. MASON[3]

Introduction

In previous communications[1b,1c] it has been shown that dicyandiamide reacts with *o*-aminophenol and *o*-aminothiophenol to form benzoxazoleguanidine and benzothiazoleguanidine. Since the analogy existing in organic chemistry between selenium on the one hand, and oxygen and sulfur on the other, is well established for many types of compounds, the preparation of benzoselenazoleguanidine by the analogous reaction of dicyandiamide with *o*-aminoselenophenol should be possible.

This investigation was undertaken in order that the physical, chemical, and pharmacological properties of benzoselenazoleguanidine might be studied and compared with those of the oxy, thio and imide analogs. The present paper describes a further application of the nitrile property of dicyandiamide in its reaction with *o*-aminoselenophenol to form benzoselenazoleguanidine.

Properties of Benzoselenazoleguanidine.—The synthesis of benzoselenazoleguanidine was accomplished through the reaction series



Benzoselenazoleguanidine is a white crystalline solid resembling macroscopically the hydrated needles of benzothiazoleguanidine[1c] but it is not hydrated. It is only sparingly soluble in water and its aqueous solution is a weak base comparable in strength with the other analogs. This is shown by the potentiometric titration and the fact that the salts of benzoselenazoleguanidine and strong acids may be titrated with a standard solution of sodium hydroxide, using phenolphthalein as indicator.[4]

In another respect the salts are like those of the thio and oxy compounds, the picrate being the least soluble and the hydrochloride the most soluble.

(1) For earlier articles of the series see (a) Smith, THIS JOURNAL, 51, 476 (1929); (b) Smith, Kane, and Mason, *ibid.*, 51, 2522 (1929); (c) Smith, Mason, and Carroll, *ibid.*, 53, 4103 (1931).

(2) The substances described were prepared by Mr. Miale and this paper is an abstract of part of the thesis submitted by him in partial fulfilment of the requirements for the degree of Bachelor of Science in Chemistry at the Polytechnic Institute of Brooklyn in June, 1932.

(3) Assistant Professor of Chemical Microscopy at Cornell University.

(4) The titration curve will be given in an article on base strength of some arylbiguanidines and related compounds soon to be published from this Laboratory.

For the series, the order of solubility of their salts in aqueous solution from most soluble to least soluble is as follows: hydrochloride—thio, seleno, oxy; sulfate—seleno, oxy, thio; nitrate—oxy, thio, seleno; picrate—oxy, seleno, thio; and of the base—thio, oxy, seleno. A comparison of the melting points of the several compounds[1b,1c] likewise fails to show any strict periodic relationships among them.

Experimental

Materials.—*The zinc salt of o-aminoselenophenol* was prepared by reducing *o*-dinitrodiphenyl diselenide with zinc in a solution of glacial acetic acid.[5] *o*-Dinitrodiphenyl diselenide was prepared by the method of Bogert and Anderson[5] as modified by Bogert and Stull,[6] which consisted of the interaction of sodium diselenide[7] with *o*-nitrochlorobenzene.[8]

Benzoselenazoleguanidine Hydrochloride.—Dicyandiamide (approx. 2 g.) and zinc *o*-aminoselenophenol (approx. 2 g.) were dissolved in 200 ml. of water and heated to boiling under a reflux. A dilute solution of hydrochloric acid was added slowly in very slight excess and the heating was continued for about three hours. There was a slight odor of hydrogen selenide and a small amount of elementary selenium separated. The solution was then filtered and decolorized with Norit, and after making strongly acid with hydrochloric acid (50 ml. of solution and 5 ml. of concd. hydrochloric acid), was allowed to stand for twelve hours. The hydrochloride separated as a white microcrystalline precipitate, which was filtered, washed with alcohol and dried.

Benzoselenazoleguanidine (Base).—One gram of benzoselenazoleguanidine hydrochloride was dissolved in 20 ml. of hot water and a slight excess of a 20% solution of sodium hydroxide was added. The base separated immediately and was filtered, washed with cold water and dried.

Benzoselenazoleguanidine Sulfate, Nitrate and Picrate.—The sulfate, nitrate and picrate were obtained by adding a solution of the respective acid to a solution of benzoselenazoleguanidine hydrochloride obtained as described above and in each case an immediate precipitation of the salt resulted. The substances were filtered, washed with cold water and dried. The nitrate and sulfate were white microcrystalline solids and the picrate was yellow. Analytical and other data concerning benzoselenazoleguanidine and its salts are given in Table I.

Microscopical Studies

Benzoselenazoleguanidine.—As prepared macroscopically there is no evidence of decomposition and coarse prisms, roughened by transverse striations, but otherwise transparent, are observed. When recrystallized from aqueous alcohol either thin plates and skeletal leaflets, or, if cooled very slowly, tabular crystals, rectangular or with terminal angles of about 140°, are formed. These crystals are biaxial and have their axial plane lengthwise, with the acute bisectrix inclined to the principal pinacoidal faces; they are in all probability monoclinic. Double refraction is strong, positive (+), with $2\ V$ about 30° and $r > v$ very strong. Refractive indices of the pinacoidal views are: vibrations crosswise, 1.780 (±0.005);

(7) Sodium selenide was purchased from Eimer and Amend.

(8) Purchased from the Eastman Kodak Company.

TABLE I

ANALYTICAL AND OTHER DATA OF BENZOSELENAZOLEGUANIDINE AND ITS SALTS

Compound	M. p., °C.	Analyses, %				Soly. at 20° g./100 g. of H_2O	Solubility in non-aqueous solvents
			Calcd.	Found			
Base	198–200	C	40.13	40.08	39.94	0.0134	Insol. CS_2, $CHCl_3$, Bz; sol. EtOH, Et_2O, acetone
		H	3.34	3.38	3.68		
Nitrate	193–198	C	31.77	31.89		0.0388	Insol. Et_2O, Bz, CS_2, $CHCl_3$; sl. sol. EtOH; sol. acetone
		H	3.00	3.26			
		HNO_3	20.84	20.74			
Hydrochloride	247–249	C	34.81	34.83		1.9114	Insol. $CHCl_3$, Bz; sl. sol. CS_2, EtOH, Et_2O; sol. acetone
		H	3.29	3.26			
		N	20.30	19.36			
Sulfate	287–289	C	33.29	32.89		0.3891	Insol. Et_2O, Bz, CS_2, $CHCl_3$; sl. sol. EtOH, acetone
		H	2.95	3.42			
		Se	27.47	27.63	27.50		
Picrate	267–270	C	35.88	35.86		0.0316	Insol. Et_2O, CS_2, $CHCl_3$; sl. sol. EtOH, Bz, acetone
		H	2.36	2.59			
		N	20.90	20.99			

lengthwise, 1.640 (±0.005); crystals on edge exhibit another value for vibrations crosswise, 1.9 (est.). From the melt spherulites of fine leaflets are obtained and there is no evidence of decomposition before melting.

Benzoselenazoleguanidine Hydrochloride.—Prisms with numerous lengthwise striations and inclusions are observed in the original sample of the material. On recrystallization from water well-formed prisms (110), of orthorhombic symmetry, with basal (001) and macro (100), pinacoidal faces also prominent are observed. All views give parallel extinction; $Bx_a = C$; axial plane $\perp$ b; $2V$ is large, $r > v$, and double refraction negative (−). Refractive indices are $\alpha = 1.580$ (±0.005); $\beta = 1.785$ (±0.005); $\gamma = 2.0 +$ (est.). $X = c$, $Y = b$, $Z = a$. From a fused melt there are obtained monoclinic prisms with clinopinacoid, analogous in form to those similarly obtained from benzothiazoleguanidine hydrochloride. They show an extinction angle of about 15°, strong positive (+) double refraction, and Bx_a nearly $\perp$ to (001).

Benzoselenazoleguanidine Sulfate.—The substance appears as thin rectangular plates, usually nearly square, and as platy rosets. The crystals are uniaxial, optically positive (+) and belong to the tetragonal system. Refractive indices are, ω 1.615 (±0.005), ϵ 1.83 ± 0.1.

Benzoselenazoleguanidine Nitrate.—Either as originally prepared or as recrystallized from water, thin prisms are observed. The crystals are of monoclinic symmetry, elongated // c with clinopinacoidal faces prominent; the angle β is about 75°. Views showing parallel extinction have refractive indices of 1.480 (±0.005) for vibrations lengthwise and 1.87 (±0.1) for vibrations crosswise. Views showing oblique extinction have refractive indices of 1.460 (±0.005) for vibrations 18° to their elongation and 1.81 (±0.01) for vibrations ⊥ to this direction. 2 *V* is about 60°, and double refraction is negative (−). The axial plane is // *b*, with Bx_a visible in end views.

Benzoselenazoleguanidine Picrate.—Yellow needles with faint if any pleochroism appear in recrystallization from water. Extinction is either parallel or about 18°. Refractive indices are: vibration crosswise, *ca.* 1.9; vibrations lengthwise, 1.495 (±0.005). The crystals are probably monoclinic.

Summary

The benzazoleguanidine series has been extended by the preparation of benzoselenazoleguanidine through the reaction between dicyandiamide and *o*-aminoselenophenol. The base, nitrate, hydrochloride, sulfate and picrate have been isolated and certain physical, chemical and crystallographical properties of these substances have been observed.

Studies of Conjugated Systems. XIV. The Preparation and Properties of 1-Phenyl-4-aminobutadiene and 1-Phenyl-4-anilidobutadiene

BY IRVING E. MUSKAT AND LOREN B. GRIMSLEY

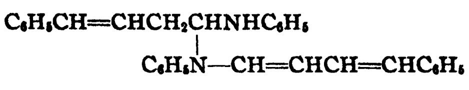
The characteristic properties and addition reactions of conjugated systems have been for some time the subject of an investigation in this Laboratory. One of the objects of this investigation was to throw some light on the mechanism of substitution and directive influence in the aromatic series. Some of the addition reactions of butadiene, phenylbutadiene, carboxybutadiene, chloro- and bromobutadiene have already been studied and a theory has been developed[1] which explains these addition reactions without recourse to any special hypothesis of conjugation. In this paper we shall present the results of an investigation on the preparation and properties of aminobutadiene derivatives.

The aminobutadiene derivatives are the aliphatic analogs of the aromatic amines, such as aniline, diphenylamine and α-naphthylamine. Since the aromatic amines are among the most reactive as well as among the most important of aromatic compounds, a study of the aminobutadiene derivatives may not only throw some light on the reactions of aromatic amines, but may also prove of considerable interest for synthetic work. For instance, the diazotization and subsequent coupling reactions of these aminobutadiene derivatives would lead to a most interesting group of compounds. The aminobutadiene derivatives selected for this study were 1-phenyl-4-anilidobutadiene and 1-phenyl-4-aminobutadiene.

---

[1] Muskat and Northrup, THIS JOURNAL, 52, 4043 (1930).

The 1-phenyl-4-anilidobutadiene was prepared by treating 1-phenyl-4-bromobutadiene with aniline. This reaction was carried out in various solvents in order to determine the conditions for optimum yield of the amine. It was found that the best yield was obtained when aniline was used as the solvent. The amine could not be distilled even under reduced pressure; there remained in the distilling flask a dimer of the amine which readily forms a monohydrochloride salt. No effort was made to prove the structure of this dimer but the formula given is suggested. This formula would account for the fact that only the monohydrochloride salt of the dimer is formed.



$$\begin{array}{l} C_6H_5CH{=}CHCH_2\overset{}{C}HNHC_6H_5 \\ \qquad\qquad\quad | \\ C_6H_5N{-}CH{=}CHCH{=}CHC_6H_5 \end{array}$$

The reactions of this amine were then studied. When dry hydrogen chloride is passed into an anhydrous ether solution of the amine, the hydrogen chloride salt of 1-phenyl-4-anilidobutadiene is precipitated. This salt hydrolyzes when exposed to the atmosphere. When dry benzene is used as the solvent in place of ether, the dihydrochloride of 1-phenyl-4-anilidobutadiene is formed. This compound is the hydrogen chloride salt of what is probably 1-phenyl-3-chloro-4-anilido-Δ^1-butene. This salt hydrolyzes only very slowly when exposed to the atmosphere. The 1-phenyl-3-chloro-4-anilido-Δ^1-butene was treated with an excess of chlorine in chloroform solution. 1-Phenyl-1,2,3-trichloro-4-trichloroanilidobutane hydrochloride was formed.

It was further found that the 1-phenyl-4-anilidobutadiene readily absorbs one mole of bromine to give 1-phenyl-3,4-dibromo-4-anilido-Δ^1-butene. The structure of this compound was determined by ozonolysis. This dibromide absorbs a second mole of bromine to give 1-phenyl-1,2,3,4-tetrabromo-4-anilidobutane. On further treatment with an excess of bromine, 1-phenyl-1,2,3,4-tetrabromo-4-tribromoanilidobutane hydrobromide was formed. The 1-phenyl-4-anilidobutadiene absorbs likewise a mole of chlorine to give 1-phenyl-3,4-dichloro-4-anilido-Δ^1-butene. The hydrogen chloride salt was precipitated when dry hydrogen chloride was passed into an ethereal solution of the dichloride.

The 1-phenyl-4-aminobutadiene was prepared by the interaction of alcoholic ammonia with 1-phenyl-4-bromobutadiene. An attempt to distil the amine under reduced pressure was not successful. When dry hydrogen chloride is passed into an ether solution of the amine, the hydrogen chloride salt is formed. This salt hydrolyzes when exposed to the atmosphere. If dry benzene is used as the solvent in place of the ether, the hydrochloride salt of what is probably 1-phenyl-3-chloro-4-amino-Δ^1-butene is formed. This salt is hydrolyzed only very slowly under similar conditions.

It was likewise found possible to prepare the 1-phenyl-4-aminobutadiene by the reaction of sodium or potassium amide in liquid ammonia solution upon 1-phenyl-4-bromobutadiene, and also by the reaction of potassium phthalimide upon 1-phenyl-4-bromobutadiene, followed by the hydrolysis of the resulting product. It was further found possible to bring about the rearrangement of the acid amide of styrylacrylic acid to 1-phenyl-4-aminobutadiene by heating it with an aqueous solution of sodium hypochlorite.[2]

It is interesting to note that both the 1-phenyl-4-aminobutadiene and 1-phenyl-4-anilidobutadiene are stable in the amino form rather than in the imino form. This seems to emphasize the rather close analogy between the aliphatic conjugated compounds and aromatic compounds. Every effort to prepare aliphatic amines in which the amino group is attached to an unsaturated carbon atom has always yielded the corresponding imino derivatives or cyclic derivatives.[3] In the case of vinylamine, there is some question as to its true structure. Gabriel,[4] who first synthesized it, gave its structure as $CH_2{=}CHNH_2$. This was later disproved by Marckwald[3] who favored the cyclic structure,  $\underset{\llcorner NH \lrcorner}{CH_2{-}CH_2}$. A number of the unsaturated amino derivatives have been given the imide structure, $RCH_2CH{=}NH$.[3] However, the 1-phenyl-4-aminobutadiene and 1-phenyl-4-anilidobutadiene are stable in the amino form just as is aniline. A number of attempts were made to hydrolyze both these amines but in no case were we able to detect ammonia or aniline in the hydrolytic products. The addition reactions of the 1-phenyl-4-anilidobutadiene and of 1-phenyl-4-aminobutadiene eliminate the possibility of the cyclic structure.

Experimental Part

1-Phenyl-4-anilidobutadiene.—1-Phenyl-4-bromobutadiene prepared according to the method of Muskat and Grimsley[5] was treated with a large excess of aniline and allowed to stand at room temperature for twenty-four hours. The excess aniline was removed by treating with cold dilute hydrochloric acid. The resulting mixture was extracted several times with ether, the ether extract dried over anhydrous sodium sulfate and then over sodium hydroxide. The ether solution was filtered from the sodium hydroxide and dry hydrogen chloride was passed into the filtrate. A slightly yellow, crystalline precipitate was formed. The crystals were collected on a filter by means of suction, washed with dry ether to remove the excess hydrogen chloride, and then dried in a vacuum desiccator over phosphorus pentoxide. These crystals melted at 104–106° and hydrolyzed when exposed to the atmosphere. Due to this hydrolysis, the melting point may be somewhat low. The maximum yield, based upon the amount of the 1-phenyl-4-bromobutadiene which reacted, was 57%.

---

Anal. Calcd. for $C_{16}H_{16}NCl$: Cl, 13.74. Found: Cl, 13.81, 13.91.

This chlorine analysis indicates that the compound is the hydrogen chloride salt of 1-phenyl-4-anilidobutadiene.

The hydrogen chloride salt of 1-phenyl-4-anilidobutadiene was hydrolyzed with dilute aqueous alkali and the resulting mixture was extracted with ether. The ether solution was washed free of chloride ion and then dried first over anhydrous sodium sulfate and finally over sodium hydroxide. The ether was removed by means of suction. The free base, a dark red viscous oil, remained.

Anal. Calcd. for $C_{16}H_{15}N$: N, 6.33. Found: N, 6.21, 6.26.

These analyses show that the compound is 1-phenyl-4-anilidobutadiene.

1-Phenyl-4-chlorobutadiene, prepared according to the method of Muskat and Huggins,[6] was treated with aniline in a manner exactly analogous to that described above for the corresponding bromo derivative. The hydrogen chloride salt of the anilide thus obtained was identical with the 1-phenyl-4-anilidobutadiene hydrochloride whose preparation from 1-phenyl-4-bromobutadiene was described above. Since the monochloride was definitely proved[6] to have the structure $C_6H_5CH{=}CHCH{=}CHCl$, this constitutes definite proof of the similar structure of the corresponding monobromide.

An attempt to distil, under reduced pressure, the 1-phenyl-4-anilidobutadiene was not successful but there remained in the distilling flask a red rosin-like solid which was easily pulverized into an orange powder. This powder melted at 105°.

Mol. wt. Calcd. for $(C_{16}H_{15}N)_2$: mol. wt., 442. Found: mol. wt. (freezing point method, benzene), 446.

The powder was dissolved in benzene and dry hydrogen chloride was passed into the solution; a crystalline precipitate was formed. The crystals were collected on a filter by means of suction and washed with dry ether to remove the excess hydrogen chloride. These crystals melted at 152°.

Anal. Calcd. for $(C_{16}H_{15}N)_2HCl$: Cl, 7.41. Found: Cl, 6.80, 6.89.

Reactions of 1-Phenyl-4-anilidobutadiene

Addition of Hydrogen Chloride.—The 1-phenyl-4-anilidobutadiene was dissolved in dry benzene and dry hydrogen chloride passed into the solution while the container was immersed in an ice-bath. The solution became dark red in color but no precipitate was formed. Dry, low boiling ligroin (30–60°) was added dropwise to the solution and a chocolate brown crystalline material was precipitated. These crystals were collected on a filter by means of suction and washed with a small amount of warm benzene. The crystals which remained were slightly pink in color.

Anal. Calcd. for $C_{16}H_{17}NCl_2$: Cl, 24.12. Found: Cl, 24.03, 23.93.

The compound is the dihydrochloride of 1-phenyl-4-anilidobutadiene.

In order to determine the ionizable chlorine, the compound was dissolved in alcohol. An equal volume of water was added to precipitate the organic residue, and immediately filtered to avoid the hydrolysis of any loosely bound organic chlorine. The chloride ion was determined in the filtrate.

Anal. Calcd. for one ionizable chlorine in $C_{16}H_{17}NCl_2$: Cl, 12.06. Found: Cl, 12.58.

The compound is then the hydrogen chloride salt of the monohydrochloride addition product of 1-phenyl-4-anilidobutadiene.

These crystals melted at 124° and were hydrolyzed in contact with the atmosphere, but not as readily as was the hydrogen chloride salt of 1-phenyl-4-anilidobutadiene. The crystals are soluble in alcohol, acetone, chloroform, and to quite an appreciable extent in hot benzene.

---

(6) Muskat and Huggins, THIS JOURNAL, 51, 2496 (1929).

This dihydrogen chloride derivative of 1-phenyl-4-anilidobutadiene was dissolved in chloroform and a current of ozonized oxygen passed into the solution for about twenty-four hours. The chloroform was removed by means of suction and the residual ozonide decomposed with water. It was possible to isolate benzoic acid from the ozonization products. The benzoic acid was identified by its melting point and by the melting point of a mixture with known benzoic acid. The hydrogen chloride has therefore been absorbed in the 3,4-positions of the 1-phenyl-4-anilidobutadiene. We did not determine the orientation of the hydrogen chloride in the 3,4-double bond but due to its reactions and also upon theoretical grounds we favor the formula 1-phenyl-3-chloro-4-anilido-Δ^1-butene. In what follows, we shall use this formula although its structure was not proved.

The 1-phenyl-3-chloro-4-anilido-Δ^1-butene hydrochloride was dissolved in chloroform, and a current of chlorine was passed into the solution until no more was absorbed. The chloroform was removed by means of suction. There remained a residue of slightly yellow crystals which were washed with ether to remove the color. The pure white crystals melted at 218°

Anal. Calcd. for $C_{16}H_{14}NCl_7$: Cl, 53.00 Found: Cl, 53.17, 53.08.

The compound is 1-phenyl-1,2,3-trichloro-4-trichloroanilidobutane hydrochloride.

Addition of Bromine.—The 1-phenyl-4-anilidobutadiene was dissolved in chloroform and exactly one mole of bromine, dissolved in chloroform, was added. After the reaction was complete, the chloroform was removed by means of suction. There remained a dark purple colored solid, which when pulverized was dark brown in color This compound melted at 103°.

Anal. Calcd. for $C_{16}H_{15}NBr_2$: Br, 42.22. Found: Br, 42.25, 42.41.

This analysis shows the compound to be the dibromide of 1-phenyl-4-anilidobutadiene.

The dibromide was dissolved in chloroform and a current of ozonized oxygen passed into the solution for about twenty-four hours. The chloroform was removed by means of suction and the residual ozonide decomposed with water. It was possible to isolate benzoic acid from the ozonization products. The benzoic acid was identified by its melting point and by the melting point of a mixture with known benzoic acid. The compound thus proves to be 1-phenyl-3,4-dibromo-4-anilido-Δ^1-butene.

The 1-phenyl-3,4-dibromo-4-anilido-Δ^1-butene was dissolved in chloroform and exactly one mole of bromine, dissolved in carbon tetrachloride was added. When the raction was complete, the chloroform and the carbon tetrachloride were removed by means of suction and a purple crystalline residue remained.[7]

Anal. Calcd. for $C_{16}H_{15}NBr_4$: Br, 59.14. Found: Br, 58.94, 58.92.

The compound is the tetrabromide of 1-phenyl-4-anilidobutadiene.

The tetrabromide of 1-phenyl-4-anilidobutadiene was dissolved in chloroform and quite an excess of bromine, dissolved in carbon tetrachloride, added. The reaction mixture was allowed to stand at room temperature for about forty-eight hours. Large volumes of hydrogen bromide were evolved and crystals separated out. The crystals were collected on a filter by means of suction and washed with small amounts of chloroform. The pure white crystals which remained melted at 182°.

Anal. Calcd. for $C_{16}H_{13}NBr_8$: Br, 74.50. Found: Br, 74.62, 74.70.

The compound is the hydrogen bromide salt of 1-phenyl-1,2,3,4-tetrabromo-4-tribromoanilidobutane.

Addition of Chlorine.—The 1-phenyl-4-anilidobutadiene was dissolved in chloroform and exactly one mole of chlorine, dissolved in chloroform, was added. The re-

---

(7) These crystals melted at 88–91°. Judging from the melting point of similar compounds described above, this melting point may be low.

action mixture was allowed to stand at room temperature for about twenty-four hours. The chloroform was removed by means of suction and the dark red viscous oil remaining was taken up in dry ether. The solution was filtered clear and the ether was removed from the filtrate by means of suction. The dark red viscous oil which remained was analyzed for chlorine.

Anal. Calcd. for $C_{16}H_{15}NCl_2$: Cl, 24.28. Found: Cl, 24.10, 24.12.

The compound is the dichloride of 1-phenyl-4-anilidobutadiene.

The dichloride of 1-phenyl-4-anilidobutadiene was dissolved in dry ether and dry hydrogen chloride was passed into the solution. The crystals which precipitated out were almost pure white. They were collected on a filter by means of suction, washed with dry ether to remove the excess hydrogen chloride and then dried in a vacuum desiccator over anhydrous calcium chloride. The crystals melted at 135°.

Anal. Calcd. for $C_{16}H_{16}NCl_3$: Cl, 32.39. Found: Cl, 32.55, 32.59.

The compound is the hydrogen chloride salt of the dichloride of 1-phenyl-4-anilidobutadiene.

These crystals were dissolved in chloroform and a current of ozonized oxygen passed into the solution. The chloroform was removed by means of suction and the residual ozonide decomposed with water. It was possible to isolate benzoic acid from the ozonization products. The benzoic acid was identified by its melting point and by the melting point of a mixture with known benzoic acid. The compound is therefore 1-phenyl-3,4-dichloro-4-anilido-Δ^1-butene hydrochloride.

1-Phenyl-4-aminobutadiene.—The 1-phenyl-4-bromobutadiene was dissolved in alcohol and gaseous ammonia passed into the solution for about three days. The reaction product was diluted with a large volume of water and then extracted with ether. The ether extract was washed free of bromide ion and of ammonia and dried, first over anhydrous sodium sulfate, and then over sodium hydroxide. Dry hydrogen chloride was passed into the solution; a slightly yellow crystalline precipitate was formed. The passage of the hydrogen chloride into the solution was not carried out too long lest the salt of any secondary amine be likewise precipitated. The crystals were collected on a filter by means of suction, washed with dry ether to remove the excess hydrogen chloride and then dried in a vacuum desiccator over phosphorus pentoxide. The crystals were slightly yellow and melted at 111°.

Anal. Calcd. for $C_{10}H_{12}NCl$: Cl, 19.53; N, 7.71. Found: Cl, 19.64, 19.70; N, 7.52, 7.61.

The compound is the hydrogen chloride salt of 1-phenyl-4-aminobutadiene.

The hydrogen chloride salt of 1-phenyl-4-aminobutadiene was dissolved in moist chloroform and a current of ozonized oxygen was passed into the solution. The chloroform was removed by means of suction and the residual ozonide decomposed with water. Benzoic acid was isolated from the ozonization products. The benzoic acid was identified by its melting point and by the melting point of a mixture with known benzoic acid.

Addition of Hydrogen Chloride.—The 1-phenyl-4-aminobutadiene was dissolved in dry benzene and dry hydrogen chloride was passed into the solution. A precipitate was not formed but the solution became dark red in color. Low boiling ligroin was added, drop by drop, to the solution and a chocolate brown crystalline mass was precipitated. The crystals were washed with small quantities of warm benzene and then dried on a porous plate. The crystals were slightly pink in color and melted at 138°.

Anal. Calcd. for $C_{10}H_{13}NCl_2$: Cl, 32.54. Found: Cl, 32.41, 32.38.

The structure of the compound is assumed to be 1-phenyl-3-chloro-4-amino-Δ^1-butene hydrochloride for the same reasons as given above for 1-phenyl-3-chloro-4-anilido-Δ^1-butene.

The 1-phenyl-4-aminobutadiene was prepared also by the following methods. (a) An ether solution of 1-phenyl-4-bromobutadiene was introduced into a bomb tube and liquid ammonia condensed upon it. The tube was sealed and allowed to stand at room temperature for two or three days. The reaction product was worked up in a manner analogous to that described above. It was found that if sufficient alcohol were added to the tube to ensure a homogenous solution, the time of the reaction was materially shortened. It was likewise found that if the 1-phenyl-4-bromobutadiene was dissolved in alcohol, concentrated ammonium hydroxide added almost to the point of precipitating out the monobromide and the solution allowed to stand for about forty-eight hours, the 1-phenyl-4-aminobutadiene was formed.

(b) 1-Phenyl-4-bromobutadiene was dissolved in ether, a suspension of finely ground sodium amide in dry ether added and the mixture stirred mechanically. The reaction mixture was allowed to stand for eight to ten hours and the excess of sodium amide destroyed with moist ether. The reaction product was then diluted with an equal volume of ether and the solution was washed free of bromide ion and dried, first over anhydrous sodium sulfate and then over sodium hydroxide. Dry hydrogen chloride was passed into the solution and the hydrogen chloride salt of 1-phenyl-4-aminobutadiene was precipitated. Dry xylene was used to replace the ether in order that the temperature might be raised. The only result apparent was an increase in the polymerization.

The 1-phenyl-4-bromobutadiene was treated with sodium amide, dissolved in liquid ammonia, and the reaction mixture worked up as before. The 1-phenyl-4-aminobutadiene hydrochloride was isolated. Potassium amide was used with similar results.

(c) 1-Phenyl-4-bromobutadiene, in alcoholic solution, was treated with an alcoholic solution of potassium phthalimide and the reaction mixture allowed to stand at room temperature for about twenty-four hours. The reaction mixture was diluted with a large quantity of water and then extracted with ether. The ether extract was washed free of bromide ion and the ether was removed by gentle warming. The resulting residue was hydrolyzed with aqueous hydrochloric acid. The solution was then made alkaline with sodium hydroxide and extracted with ether. The ether solution was washed free of chloride ion and dried, first over anhydrous sodium sulfate and then over sodium hydroxide. 1-Phenyl-4-aminobutadiene hydrochloride was isolated from this solution.

(d) Styrylacrylic acid, $C_6H_5CH{=}CH{-}CH{=}CHCOOH$, was prepared according to the method of Doebner[8] by heating for six hours a mixture of 90 g. of cinnamic aldehyde, 90 g. of malonic acid, and 70 g. of pyridine and then pouring the reaction mixture into cold dilute sulfuric acid. The acid thus formed was purified by crystallization from dilute alcohol. The acid melted at 165°. The acid chloride of styrylacrylic acid was prepared according to the method of Rupe[9] by heating, the acid for forty minutes with an excess of phosphorus trichloride in the presence of a small amount of dry benzene. However, it was not found necessary to isolate the acid chloride. The benzene solution of the acid chloride was poured off. Concentrated ammonium hydroxide was added to the benzene solution and then gaseous ammonia was passed into the solution for about thirty minutes. The reaction vessel was immersed in an ice-bath during the reaction. The solid that was formed was collected on a filter by means of suction and washed several times with concentrated ammonium hydroxide in order to remove any unchanged acid. The crystals which remained melted at 185°, the melting point of the acid amide of styrylacrylic acid. These crystals, in aqueous suspension, were treated with a freshly prepared 8% solution of sodium hypochlorite and the reaction mixture heated on the water-bath for six hours. The reaction mixture was then extracted with ether and the solution washed free of chloride ion. It was then dried, first over anhydrous sodium sulfate and then over sodium hydroxide. Dry hydrogen chloride was passed into the

---

(9) Rupe, *Ann.*, **369**, 340 (1909).

dry ether solution; the hydrogen chloride salt of 1-phenyl-4-aminobutadiene was precipitated from this solution. It is apparent that the acid amide of styrylacrylic acid has undergone a rearrangement to give 1-phenyl-4-aminobutadiene.

Summary

1. The method of preparation of 1-phenyl-4-aminobutadiene and of 1-phenyl-4-anilidobutadiene is described.

2. Both of these amines absorb hydrogen chloride in the 3,4-positions.

3. 1-Phenyl-4-anilidobutadiene absorbs both chlorine and bromine in the 3,4-positions.

4. The significance of these reactions of aliphatic amino conjugated compounds to the problem of substitution in the benzene ring is indicated.

The Effects of Glucose and Fructose on the Sucrose Content in Potato Slices

BY J. M. NELSON AND R. AUCHINCLOSS

The opinion seems to be held by many[1] that desiccation of starch containing plant tissues, such as leaves and potato slices, increases the sucrose content. Schroeder and Horn[2] studying the increase in sucrose on drying tropæolum leaves as well as the changes in the amount of reducing sugar present in the leaves, reached the conclusion that starch is converted into sucrose in the desiccation of the leaves in a more direct way than through the reducing sugars as an intermediate stage. Ahrns[3] more or less repeated the work of Schroeder and his co-workers using starch bearing leaves of several plants, and also reached the conclusion that the conversion of the starch to sucrose in the desiccation of leaves is independent of the reducing sugars present.

Waterman[4] studied the phenomenon of starch to sucrose by drying potato slices at temperatures from 30 to 50°, and like the above-mentioned investigators expressed the opinion that starch is changed to sucrose during the drying process, in some direct way, probably by the aid of enzymic action. Following Waterman, de Wolff[5] studied the starch to sucrose reaction when potato slices are subjected to desiccation. He too looked upon the reaction as one independent of the reducing sugars present.

Contrary to the conclusions reached by Schroeder and his co-workers and by Ahrns, in the case of leaves, and also contrary to the view held by Waterman and de Wolff that starch is changed directly into sucrose when these plant tissues are dried, the results obtained in this Laboratory show that reducing sugars, in the form of glucose and fructose, play a dominating role in the formation of sucrose in potato slices, and that desiccation is only incidental. By dipping the slices in aqueous glucose or fructose solutions and then permitting them to remain in the moist condition, without any desiccation or loss of moisture whatever, in contact with air, even a larger increase in sucrose content results than when the slices are dried without dipping them in the hexose solution. The formation of sucrose by simply drying leaves and potato slices is probably also due to reducing sugars present in the tissue or formed during the desiccation.

In connection with the effect of reducing sugars on the sucrose content of potato slices it was found that slices dipped in galactose, maltose or glycerin solutions instead of glucose or fructose solutions showed only a small increase in sucrose. Similarly freshly cut slices, dipped in distilled water, instead of in a glucose solution, or not dipped at all, when exposed in the wet condition to air gave only slight increases in sucrose. These small increases are very likely due to wounding. Hopkins[6] has shown that when potato tissues are wounded by cutting, the respiration is increased and along with it a slight increase in sucrose content occurs. This inability of galactose, maltose and glycerin to increase the sucrose content recalls the observations made by Meyer[7] who found leaves of several kinds of plants were able to form starch when floated on aqueous solutions of sucrose, glucose or fructose, but only in one or two instances did he observe any starch formation when the leaves were floated on galactose, or glycerin solutions. Similarly, Parkin[8] found in the case of narcissus and iris leaves that maltose, in contrast to sucrose, glucose and fructose, gave rise to only very little starch formation.

Another factor involved in the formation of sucrose noticed in the case of potato slices, which has not been mentioned by Waterman, or de Wolff, nor by Schroeder and Horn or Ahrns, in the case of leaves, is the effect of oxygen or air. When potato slices are dried in an atmosphere of nitrogen, no increase, or at least very little, in sucrose content occurs, and the same is true when the slices, dipped in a glucose solution, are stored wet in an atmosphere of nitrogen. This necessity of oxygen for the formation of sucrose seems to be like the dependence on oxygen noticed in the transformation of starch into sucrose in the ripening of fruit. Thus Bailey[9] found when green bananas were coated with paraffin or immersed in oil so

as to keep the fruit from being in contact with air, the decrease in starch as well as the increase in sucrose ceased. Miss Hemperly in this Laboratory (unpublished) since then has observed the same, and Thornton[10] finds that storing green bananas in an atmosphere of carbon dioxide prevents the starch from changing into sugar. The fact that oxygen is essential for changing reducing sugars in potato slices to sucrose shows that the reactions involved must be related in some way to aerobic respiration.

Experimental Procedure

1. **Variety of Potatoes Used.**—Mostly Irish Cobbler and Idaho Russets, all in the dormant condition.

2. **Slices.**—Tubers of fairly regular shape, about 10–15 cm. long and 5–7 cm. in diameter, were peeled and slices varying in thickness from 1 to 2 mm. cut from the middle portion of the tuber. Six slices weighing from 12 to 20 g. usually constituted an experimental sample.

3. **Slow Drying of Slices.**—Instead of drying the slices by warming them to about 30 to 40° over a low gas flame as was done by Waterman and de Wolff, the slices were usually dried at room temperature in a desiccator by means of anhydrous calcium chloride. For this purpose, the slices were distributed on a large perforated porcelain disk which constituted the shelf in the large 10-inch desiccator. Supported above the porcelain disk by means of three or four corks was a large watch glass containing the calcium chloride. By choosing the right amount of the drying agent it was possible to lower the weight of the sample from 15 to 75% in ten to twenty hours.

TABLE I

Treatment	Orig. wt. of sample, g.	After storage, g.	Change in wt. during storage, %	Time of storage, hrs.	Orig. non-reducing sugar content, %[a]	Non-reducing sugar content after storage, %	Increase in non-reducing sugar, %

4. Storing the Slices.—In order to show that no desiccation is necessary for the sucrose formation when the slices have been dipped in an aqueous glucose or fructose solution, it was necessary to keep the slices moist while being exposed to air. Instead of the watch-glass containing calcium chloride suspended over the slices on the porcelain disk, the bottom of the desiccator was covered with a layer of water. This kept the air sufficiently saturated with water vapor so that the slices suffered no appreciable change in weight on remaining in the desiccator for several hours.

5. Dipping Slices in Hexose Solutions.—The freshly cut slices were placed in 20% hexose solution, allowed to remain in the latter for two to three minutes, removed and either dried and stored as described in 3 or stored wet as indicated in 4.

6. Determination of Sugars.—The slices, after they had been stored in the desiccator for the desired length of time, or, in the case of the control samples, immediately after they were cut, were placed in 75 cc. of 95% ethyl alcohol and boiled on the water-bath for ten minutes. The slices were then removed from the alcohol, ground to a powder in a mortar and the ground material and alcohol used for washing the mortar returned to the original alcohol. The latter was then diluted by the addition of 25 cc. of water, placed in a flask and agitated in a shaking machine for two hours and filtered. The filtrate containing the dissolved sugars together with the alcohol washings was then distilled under reduced pressure at about 45° to remove the alcohol, the aqueous residue clarified by lead acetate and the reducing sugars determined, before and after inversion by yeast invertase, by means of copper reduction.[11]

The following table is given to show the degree of precision in the determinations of the sucrose content. Six samples of potato slices were cut from the same potato, three for determining the sucrose content immediately after cutting the slices, and three for the sucrose content after dipping in 20% glucose solution and being stored for twenty-two hours in a desiccator containing moist air.

Experiment number	1	2	3
Non-reducing sugar in fresh slices	0.13	0.12	0.12
Non-reducing sugar after dipped in glucose solution and stored wet for 22 hrs.	1.15	1.11	1.09

Summary

1. Contrary to the conclusions of earlier investigators, it has been shown that dehydration of potato slices is not necessary in order to effect marked increases in sucrose content.

2. Evidence has been given that sucrose in the potato is synthesized from glucose or fructose, rather than, as has been supposed, in some more direct way from starch.

3. It has been shown that the presence of oxygen is necessary for the formation of sucrose in the potato slices.

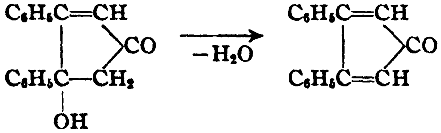
The Reactions of Anhydracetonebenzil. II[1]

BY C. F. H. ALLEN AND E. W. SPANAGEL

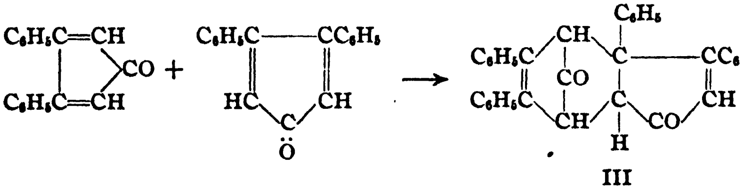
The most characteristic reaction of anhydracetonebenzil (I) is the ease with which it loses water and forms a "bimolecular product" when treated with acidic dehydrating agents. Japp[2] and Gray[3] observed that the homologs of (I) exhibited the same behavior, as long as there was one hydrogen left in the alpha position and adjacent to the hydroxyl group, but neither suggested a possible structure for the new type of substance. They also found that the latter lost quantitatively one molecule of carbon monoxide on pyrolysis, and that the resulting product formed a monophenylhydrazone. The problem has been investigated in this Laboratory and the results are described in this communication.

In a previous paper[4] it was suggested that a cyclopentadienone (II) was the primary product of dehydration, although it was never isolated.



I II

This substance contains two conjugated systems, one that of an α,β-unsaturated ketone and the other that of a diene, so should enter into a diene synthesis with itself. Assuming that it did so, it was possible to write the structure (III) for the bimolecular product; its correctness was then verified by a long series of reactions that ultimately gave *o*-diphenylbenzene.



III

This tricyclic ketone forms a dioxime; the carbonyl groups are not linked alike, one being removed readily as carbon monoxide on heating. *A priori*, it would be expected that the bridge would be more easily lost, leaving a bicyclic ketone (IV); the presence of a conjugated system in (IV) was shown by the addition of maleic anhydride to give (V)—the latter could be more conveniently prepared directly from the bimolecular product

---

(1) This paper is a more extended presentation of results originally embodied in a Communication to the Editor received November 25, 1932.

(2) Japp and co-workers. This long list of references is given in detail in the previous paper.[4]

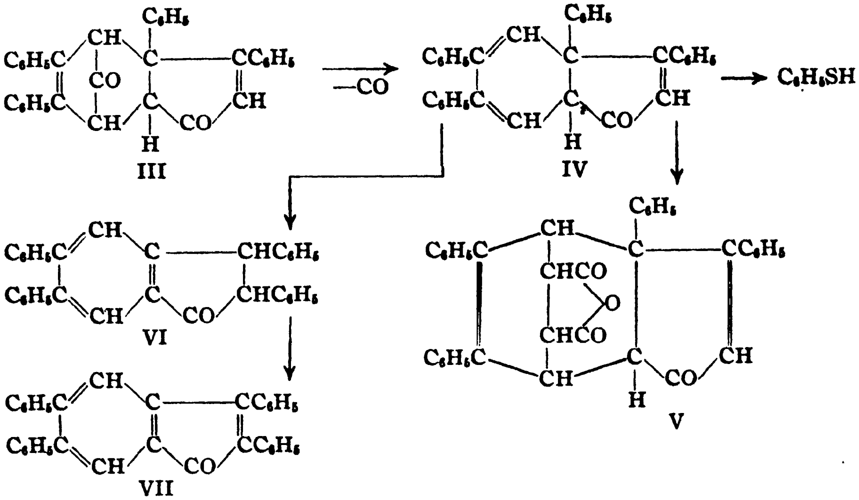
(4) Allen and Spanagel, THIS JOURNAL, **54**, 4338 (1932).

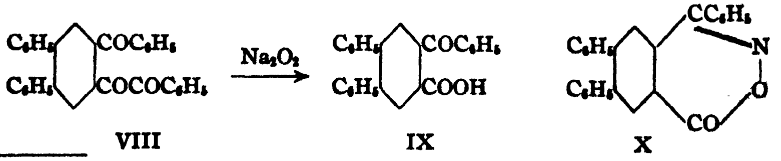
(III), because the ketone (IV) very easily underwent a rearrangement on pyrolysis, resulting in the indanone (VI).



The bicyclic ketone (IV) is pale yellow, forms an oxime and yields thiophenol when heated with sulfur. The use of sulfur to detect alkyl radicals attached to carbon atoms common to two rings has been widely employed by Ruzicka[5] but this is the first instance of which we are aware when an aryl group has been so removed.

The indanone (VI) is colorless; it does not react with maleic anhydride but forms a monophenylhydrazone corresponding in physical properties with the one described by Japp, so that his pyrolysis product was probably (VI); this is to be expected since it is only by working cautiously that (IV) survives the heating necessary to remove the carbonyl bridge. It is easily dehydrogenated by sulfur to the deep red indone (VII); the color of the latter is deeper than that of diphenylindone.[6]

This red ketone forms an oxime and mono-*p*-bromophenylhydrazone, and is readily oxidized to a yellow triketone (VIII), but does not add maleic anhydride. The triketone is cleaved by sodium peroxide to benzoic acid and a ketonic acid (IX); when the preparation of an oxime of the latter was attempted, an indifferent compound containing nitrogen resulted—it was not affected by phosphorus pentachloride and had no active hydrogen, and probably is best represented as the orthoxazine (X).

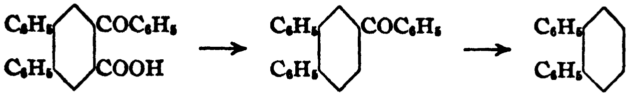


---

(5) Ruzicka, *Helv. Chim. Acta*, **5**, 349 (1922).

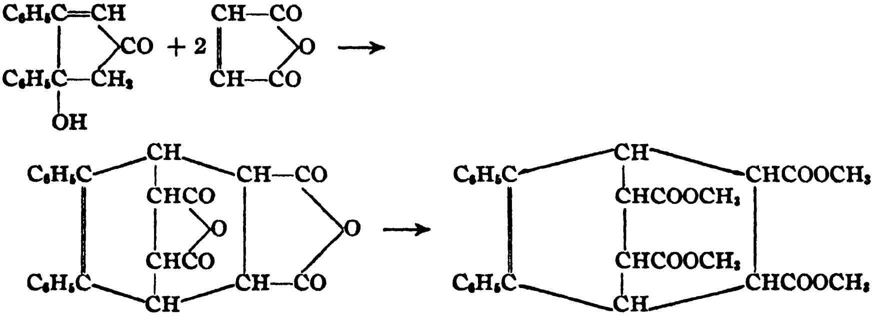
(6) Heyl and Meyer, *Ber.*, **28**, 2776 (1895).

On decarboxylation of the acid (IX) a diphenylbenzophenone was obtained in poor yield; it formed a monoxime which by the Beckmann rearrangement gave an uncrystallizable anilide. This was hydrolyzed to a glass-like amine which, when diazotized in alcoholic hydrochloric acid and warmed with copper powder, gave an oil from which *o*-diphenylbenzene was separated by vacuum distillation.



IX

The transient existence of the cyclopentadienone (II) can be shown by using an excess of maleic anhydride as a dehydrating agent for anhydracetonebenzil; on heating to about 200°, carbon monoxide and water are lost and a solid dianhydride (XI) is formed; the latter is readily converted into a tetramethyl ester. The reaction proceeds in steps, but the description of the intermediate products and their reactions, along with a similar series from tetraphenylcyclopentadienone, will form the subject of a later communication. It is sufficient here to note the similarity to Diels' reactions between coumalin and maleic anhydride.[7]



XI

After a clue had been obtained as to the structure of the bimolecular product, one analogous case was discovered in the literature; Zincke[8] prepared a highly chlorinated cyclopentenone (XII) and found that on reduction with stannous chloride a bimolecular product was obtained; when heated, the latter lost chlorine and carbon monoxide to form a perchlorindone (XIII); the carbonyl group was detected by chlorination with phosphorus pentachloride. He likewise assumed that a cyclopentadienone was the primary product and converted the indone into tetrachlorophthalic acid to show the presence of a benzene ring.

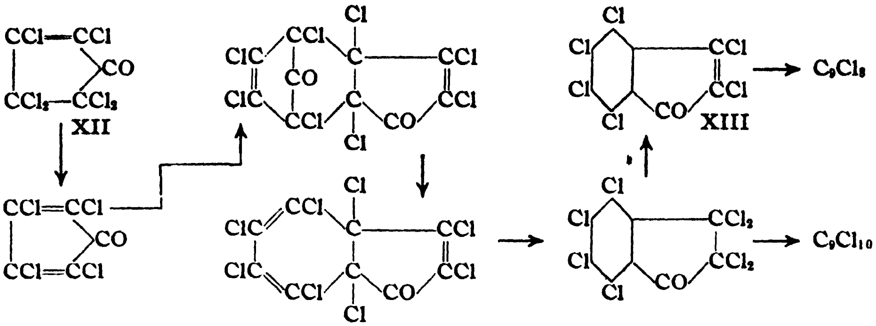
(8) Zincke and co-workers, *Ber.*, **21**, 2719 (1888); **22**, 486 (1889); **23**, 812 (1890); **26**, 2104 (1893); *Ann.*, **272**, 243 (1892); **292**, 135 (1897); **367**, 1 (1909); **394**, 7 (1912).



Since then the structure of dicyclopentadiene has been shown to be of a similar nature.[9]

The above work suggests that the dipyrroles are similarly constituted and should be represented as in formula (XIV). The correctness of this assumption is being tested.

Very few other substances having a carbonyl bridge are known; Stobbe[10] has described two (XV, XVI) and a third (XVII) has been prepared in this Laboratory. None of them lose carbon monoxide when heated unless the molecule is entirely decomposed; from a study of mechanical models it was evident that in the latter type the CO bridge formed part of a strainless ring, whereas it was impossible to construct a model of the diketone (III) described in this paper without great distortion. A previous attempt to prepare an unsaturated bicyclic system having a carbonyl bridge was unsuccessful.[11]

Experimental

A. Dehydrogenation of Anhydracetonebenzil; "the Bimolecular Compound"; 3a,4,7,7a-Tetrahydro-3,3a,5,6-tetraphenyl-4,7-methanoindene-1,8-dione (III).—An almost quantitative yield was obtained by warming a mixture of 60 g. of glacial acetic acid, 50 g. of finely powdered anhydracetonebenzil and 10 cc. of concd. sulfuric acid nearly to boiling with frequent shaking, until the deep red color had changed to a light brown (about ten minutes). The substance separated on cooling and was purified by crystallizing from a benzene–alcohol mixture. It formed two dioximes when treated with hydroxylamine acetate in the usual way. After two hours of heating one was isolated in the form of rods, readily soluble in alcohol, m. p. 176°; the isomer was the

(11) Allen, *Can. J. Res.*, 4, 264 (1931).

principal product after twenty-four hours of heating—it is only slightly soluble in alcohol; m. p. 229°.

Anal. Calcd. for $C_{34}H_{26}O_2N_2$: N, 5.7. Found: (229°) N, 5.7; (176°) N, 5.1.

When acetic anhydride and sulfuric acid are used for the dehydration a small amount of an acetate can be isolated by careful manipulation; this is very soluble in the usual organic solvents; it separates from alcohol in clusters of prisms, m. p. 91°.

Anal. Calcd. for $C_{19}H_{16}O_3$: C, 78.1; H, 5.5. Found: C, 77.9, 77.8; H, 5.3, 5.1

On hydrolysis with dilute ammonia the bimolecular compound resulted, but alcoholic potash gave a new substance that crystallized in thick prisms, m. p. 280°.

Anal. Found: C, 85.2, 84.8; H, 5.3, 6.2.

It does not react with acetyl chloride, or acetic anhydride and sulfuric acid; owing to the small amount available it was not further investigated.

B. **Pyrolysis of (III); Preparation of the Isomers, 3a,7a-Dihydro-3,3a,5,6-tetraphenylinden-1-one (IV) and 2,3,5,6-Tetraphenylindan-1-one (VI).**—In a small flask 25 g. of the bimolecular product was heated by a metal bath at 210° for ten minutes; carbon monoxide was evolved rapidly. The cooled melt was dissolved in benzene and alcohol added to precipitate 10 g. of the white indanone (V); the filtrate slowly deposited 10 g. of the yellow isomer. After purification the white substance melted at 176°, and the pale yellow isomer at 167°; mixed melting points showed a marked depression. The indanone (VI) is fairly soluble in acetone, acetic acid and benzene, but only slightly soluble in alcohol and ether; it crystallizes in characteristic five-sided plates. It did not decolorize permanganate or bromine instantly. It is undoubtedly the substance described by Japp, though he gave a range of melting points.

Anal. Calcd. for $C_{33}H_{24}O$: C, 90.8; H, 5.5. Found: C, 90.9; H, 5.5.

The oxime, prepared in the usual way, separated from alcohol in leaflets, m. p. 225°.

Anal. Calcd. for $C_{33}H_{25}ON$: N, 3.1. Found: N, 3.0.

It gave a phenylhydrazone of m. p. 250° as previously described.

C. **The Yellow Ketone (IV).**—It was difficult to secure this substance unless the temperature of the pyrolysis was very carefully controlled; on heating too long or at a higher temperature it rearranges to the indanone—this change even takes place slowly in boiling alcoholic solutions.

It is readily soluble in acetone, benzene and decalin but sparingly in alcohol and ether; it separates in yellow rods from alcohol, m. p. 167°.

Anal. Calcd. for $C_{33}H_{24}O$: C, 90.8; H, 5.5. Found: C, 90.7; H, 5.4.

The oxime, made by the customary procedure, crystallized from alcohol in fine yellow prisms, m. p. 130° (unsharp).

Anal. Calcd. for $C_{33}H_{25}ON$: N, 3.1. Found: N, 3.5.

It gave a phenylhydrazone, m. p. 250°, probably the same as the one from the indanone, since a mixed melting point showed no depression. This may be accounted for by the ease of rearrangement noted above, which takes place during the sealed tube treatment required to prepare the phenylhydrazone.

Anal. Calcd. for $C_{39}H_{30}N_2$: N, 5.3. Found: N, 5.4.

It added maleic anhydride to form the tetracyclic substance (V), but a large part was isomerized at the same time to the indanone; the new product was more conveniently prepared from the bimolecular compound. The indanone did not react with maleic anhydride.

3a,4,5,7,7a-Hexahydro-1-keto-3,3a,8,9-tetraphenyl-4,7-ethanoindene-5,6-dicarboxylic Anhydride (V).—A mixture of 5 g. of the bimolecular compound and an equal *weight of maleic anhydride was heated by an oil-bath at the boiling point as long as carbon monoxide was given off (fifteen minutes), cooled and 15 cc. of methyl alcohol* added to remove the excess anhydride; the 4 g. of solid that was insoluble was recrystallized from acetic anhydride, from which it separated in rods, m. p. 301°. It is slightly soluble in alcohol, but very soluble in acetic acid, acetic anhydride and acetone.

Anal. Calcd. for $C_{37}H_{26}O_4$: C, 83.1; H, 4.9; mol. wt., 534. Found: C, 83.3; H, 5.0; mol. wt., 549.

It dissolved readily in dilute sodium hydroxide, but the acid obtained by acidification turned into the anhydride so easily that no attempt was made to obtain it pure.

On heating 10 g. of (IV) with 1 g. of flowers of sulfur in a small distilling flask at 325°, under slight suction, for a half hour it became black, but 0.2 g. of thiophenol collected in the receiver; the latter was converted into the 2,4-dinitrophenyl thioether, m. p. 121°, by Bost's procedure;[12] a mixed melting point with an authentic specimen showed no depression, m. p. 121°. Nothing could be separated from the black residue; if the temperature was kept lower, only an odor of thiophenol was noticed, and the rearrangement product (the indanone) was found—this doubtless accounted for the low yield of thiophenol; the sulfur reaction requires a higher temperature than the isomerization.

D. The Indenone (VII).—The indanone was readily dehydrogenated by heating with sulfur to give the new red ketone; the latter was oxidized with scission of the five-membered ring to a 1,2-diketone (VIII) which was readily cleaved by sodium peroxide; the keto acid (IX) thus resulting gave an indifferent substance containing nitrogen when treated with hydroxylamine acetate—presumably the orthoxazine (X).

2,3,6,7-Tetraphenylinden-1-one (VII).—A mixture of 25 g. of the pure indanone and 1 g. of flowers of sulfur in a small distilling flask under slight suction was heated for a half hour at 325°; hydrogen sulfide was evolved and the mass became a deep red. When cold, ether was added, the unused sulfur filtered, and on addition of alcohol and partial evaporation 16 g. (65%) of the red ketone crystallized. It is readily soluble in ether, acetone, acetic acid and benzene, but only slightly soluble in the alcohols; it forms red rods, m. p. 166°.

Anal. Calcd. for $C_{33}H_{22}O$: C, 91.2; H, 6.1. Found: C, 91.1; H, 5.1.

The yield was not increased by varying the temperature, amount of sulfur or addition of copper sulfide. It could be made, without isolation of the intermediates, from pure bimolecular product, if the latter was first heated to 250° for some time before the addition of the sulfur. The oxime, prepared as usual, crystallized from chloroform in fine yellow needles, m. p. 292°.

Anal. Calcd. for $C_{33}H_{23}ON$: N, 3.1. Found: N, 3.2.

The *p*-bromophenylhydrazone was never obtained pure; a brownish product was separated from the reaction mixture and repeatedly crystallized from *n*-butyl alcohol until it had a constant melting point, 226°.

Anal. Calcd. for $C_{39}H_{27}N_2Br$: Br, 13.2. Found: Br, 11.4, 11.9, 13.7.

1,2-Diphenyl-4-benzoyl-5-phenylglyoxylbenzene (VIII).—To a suspension of 10 g. of finely powdered red ketone in 60 cc. of acetic acid was added 8 g. of chromic acid, and the mixture refluxed for ten minutes; on addition of 300 cc. of ice water a fine yellow solid separated. This was filtered, dried and recrystallized from benzene and alcohol, from which it separated in yellow rosets, m. p. 183°. The yield was 7.9 g. (78%). It is slightly soluble in alcohol and ether, but readily soluble in benzene, acetone and acetic acid.

---

(12) Bost, Turner and Norton, This Journal, 54, 1985 (1932).

Anal. Calcd. for $C_{33}H_{22}O_3$: C, 85.0; H, 4.7. Found: C, 85.1, 85.1; H, 5.0, 4.7.

The same substance was obtained in a smaller yield by the use of permanganate in acetone. The quinoxaline was prepared nearly quantitatively in the usual manner; it is sparingly soluble in alcohol, but crystallizes well from that solvent in cubes, m. p. 184°.

Anal. Calcd. for $C_{39}H_{26}ON_2$: N, 5.2; mol. wt., 538. Found: N, 5.0; mol. wt., 540.

E. 2-Benzoyl-4,5-diphenylbenzoic Acid (IX); Cleavage of the Diketone.—A solution of 5 g. of sodium peroxide in 50 cc. of ice water was added slowly with vigorous shaking to a suspension of 10 g. of the finely powdered triketone in 100 cc. of alcohol; the yellow solid slowly dissolved and shiny flakes formed. After a half hour the mixture was poured into water (filtered if necessary) and acidified with acetic acid—the acid slowly separated, was filtered after five hours, and recrystallized from dilute methyl alcohol. It is very soluble in organic solvents and dilute alkaline solutions. The yield was 7.6 g. (90%); m. p. 250°.

Anal. Calcd. for $C_{26}H_{18}O_3$: C, 82.5; H, 4.8. Found: C, 82.0; H, 4.7.

The filtrate was steam distilled and the benzoic acid identified in the usual way. When 1 g. of the keto acid was refluxed with hydroxylamine acetate in alcohol, white needles separated almost quantitatively, after an hour; the new product is almost insoluble in alcohol, but very soluble in benzene and chloroform; it slowly dissolves in dilute potash after long boiling. It melts at 225°.

Anal. Calcd. for $C_{26}H_{17}O_2N$: N, 3.7. Found: N, 3.5, 3.4.

It was recovered unchanged after an attempted Beckmann rearrangement using phosphorus pentachloride in absolute ether for twenty-four hours.

F. The Keto Acid (IX) and its Degradation to *o*-Diphenylbenzene.—The yields in each step were very low from this point on.

3,4-Diphenylbenzophenone.—A mixture of 5 g. of the keto acid and 0.5 g. of copper carbonate was heated at 225° for twenty minutes in a small distilling flask and then distilled *in vacuo;* the pale yellow oil was taken up in acetone—after dilution with methyl alcohol white prisms slowly separated; the yield was 1.5 g. (34%), m. p. 133°. It is soluble in the common organic solvents except alcohol.

Anal. Calcd. for $C_{25}H_{18}O$: C, 89.8; H, 5.4. Found: C, 89.9; H, 5.5.

The oxime crystallized from dilute alcohol in fine, white needles, m. p. 156°; the yield was 50%.

Anal. Calcd. for $C_{25}H_{19}ON$: N, 4.0. Found: N, 4.3.

A mixture of 1 g. of the oxime, 1.5 g. of phosphorus pentachloride and 20 cc. of absolute ether was left for a day at room temperature, then poured into water, the ether layer separated, dried with sodium sulfate and the solvent allowed to evaporate; 1 g. of a viscous oil remained—it could not be purified so was hydrolyzed by refluxing with alcoholic potash; on dilution with water an oil precipitated and was extracted with ether—it gave a strong qualitative test for nitrogen. Since it showed no tendency to crystallize it was taken up in 5 cc. of alcohol, 6 cc. of 1:1 hydrochloric acid added, the mixture well cooled and 0.2 g. of sodium nitrite introduced; when 0.1 g. of copper powder was dropped in gas bubbles became visible, and after a short warming ether was added, the upper layer separated, dried over sodium sulfate and distilled *in vacuo.* The 0.2 g. of pale yellow oil that was obtained slowly crystallized on standing; it had a melting point of 56° and showed no depression when mixed with some authentic *o*-diphenylbenzene.

G. The Reaction of Anhydracetonebenzil with Excess Maleic Anhydride; 7,8-Diphenylbicyclo-(2,2,2)-7-octene-2,3,5,6-tetracarboxylic Acid Dianhydride (XI).—In order to show that diphenylcyclopentadienone (II) was capable of at least a transitory existence,[13] it was heated with maleic anhydride as a dehydrating agent, and a sufficiently large excess used to allow for addition to the diene linkage. Equal weights of the two substances were heated in an oil-bath at 170°; the melt appeared to boil vigorously and carbon monoxide was evolved rapidly and burned with a large blue flame. The temperature was gradually raised until at about 230° the melt suddenly solidified; it was cooled somewhat, *p*-cymene added and the suspension filtered. The excess anhydride was washed out with hot methyl alcohol and the crude product recrystallized from *p*-cymene or acetic anhydride. It formed white flakes, shrinking at 334°, becoming liquid at 346° and giving off a gas at 356°.

Anal. Calcd. for $C_{24}H_{16}O_6$: C, 72.0; H, 4.0. Found: C, 71.5; H, 4.0.

It is insoluble in the alcohols, ether, acetone and carbon tetrachloride, sparingly soluble in *p*-cymene, but very soluble in ethyl acetate and acetic anhydride. It dissolves in sodium hydroxide; on acidification an acid is precipitated in fine needles—the melting point is indefinite as it loses water and re-forms the anhydride.

The tetramethyl ester was prepared by saturating a mixture of 5 g. of the anhydride and 25 cc. of absolute methyl alcohol with hydrogen chloride; the solid dissolved and after a day a new solid separated in the form of white needles. It was recrystallized from absolute methyl alcohol, in which it is sparingly soluble; m. p. 188°.

Anal. Calcd. for $C_{28}H_{28}O_8$: OCH_3, 25.5. Found: OCH_3, 25.3.

This work has been assisted by a grant from the Cyrus M. Warren Fund of the American Academy of Arts and Sciences.

Summary

1. The structure of the bimolecular product resulting from the dehydration of anhydracetonebenzil has been determined. It is a tricyclic ring system, containing a carbonyl bridge.

2. One carbonyl group is lost as carbon monoxide on heating. The resulting product contains a conjugated system and easily adds maleic anhydride; it also forms thiophenol when heated with sulfur, and rearranges to an isomeric indanone.

3. When heated with sulfur, the indanone loses hydrogen sulfide and forms a red indone; the latter was degraded to *o*-diphenylbenzene.

4. Anhydracetonebenzil and excess maleic anhydride give a complex polycyclic dianhydride.

(13) Burton and Shopee [*J. Soc. Chem. Ind.*, 51, 981 (1932)] have criticized the mechanism suggested in the previous paper[8] for the formation of isomeric chlorides on the grounds that the possibility of an anionotropic change was disregarded, and cited as evidence the production of three isomeric dinitrophenylhydrazones for which they wrote three different structures. However, since Bredereck [*Ber.*, 65, 1833 (1932)] has recently shown (1) that stereoisomeric 2,4-dinitrophenylhydrazones are possible, (2) that they are differently colored and (3) that the yellow, less stable form is readily isomerized to the red, stable form, the above evidence is inconclusive, especially as they had both yellow and red hydrazones. Further, *β,β*-dimethylanhydracetonebenzil does not give an isomeric chloride under the same conditions as the parent substance—this point was tested carefully—so that in view of these facts, as well as the production of the various addition products described in this paper, the assumption of an intermediate cyclopentadienone seems justified.

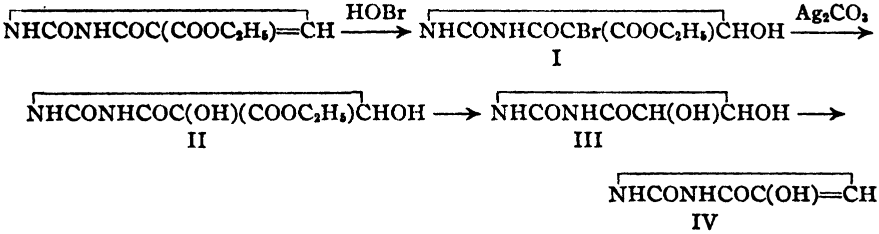
Researches on Pyrimidines. CXXXV. Uracil-glycol

BY TREAT B. JOHNSON AND ELIZABETH DYER[1]

An investigation of methods for synthesizing uracil-glycol (5,6-dihydroxyhydrouracil) was undertaken in order to compare the properties of this pyrimidine with those of the corresponding thymine-glycol previously prepared in this Laboratory.[2]

The method used successfully by Baudisch and Davidson to prepare thymine-glycol is not directly applicable to uracil-glycol because of the nonexistence of the necessary bromoxyuracil.[3] The 5-carbethoxy derivative of uracil glycol (II), however, was obtained in good yield by this method by starting with uracil-5-ethylcarboxylate and operating through the hydroxybromo ester represented by Formula I. The glycol II was obtained by the action of silver carbonate on this hydrogenated pyrimidine I.



$$\mathrm{NHCONHCOC(COOC_2H_5){=}CH} \xrightarrow{\mathrm{HOBr}} \underset{\mathrm{I}}{\mathrm{NHCONHCOCBr(COOC_2H_5)CHOH}} \xrightarrow{\mathrm{Ag_2CO_3}}$$

$$\underset{\mathrm{II}}{\mathrm{NHCONHCOC(OH)(COOC_2H_5)CHOH}} \longrightarrow \underset{\mathrm{III}}{\mathrm{NHCONHCOCH(OH)CHOH}} \longrightarrow \underset{\mathrm{IV}}{\mathrm{NHCONHCOC(OH){=}CH}}$$

The glycol ester (II) was expected to give uracil-glycol (III) upon saponification and decarboxylation. The product obtained, however, was not the desired glycol, but isobarbituric acid (IV). This pyrimidine was produced in all attempts at hydrolysis of the glycol ester (II), even under the mildest of experimental conditions. The intermediate 5-carboxylic acid could not be isolated, since it decomposed as soon as formed with the simultaneous elimination of carbon dioxide and water and the formation of isobarbituric acid. An acetyl derivative of the glycol ester (II) could be prepared, but it too gave only isobarbituric acid on hydrolysis.

The formation of isobarbituric acid instead of uracil-glycol was found to be a general reaction in other procedures designed to give the uracil-glycol. When isodialuric acid was reduced catalytically, isobarbituric acid was obtained. Even when the hydroxyl groups of isodialuric acid were protected through the use of the corresponding diacetate, the product formed was isobarbituric acid or its monoacetyl derivative.

The uracil-glycol configuration is thus seen to be too unstable for isolation. This is in marked contrast to the behavior of thymine-glycol, which

may easily be prepared and purified,[2] and which forms an anhydride only on long standing in acid solution. It may, therefore, be concluded that loss of water takes place in uracil-glycol by withdrawal of the hydroxyl group in the 6-position with the free hydrogen atom in the 5-position of the pyrimidine ring. An analogous mobility of groups in the 6-position of 2,4-dioxypyrimidines has been demonstrated by Biltz.[4]

The tendency of derivatives of uracil-glycol to pass into isobarbituric acid is of interest in connection with the fact that the latter substance is known to be an oxidation product of uracil.[5] Evidence that isobarbituric acid may be an intermediate product in the metabolism of uracil *in vivo* as well as *in vitro* has been presented recently by Cerecedo.[6] It is conceivable that the unstable uracil-glycol may be the precursor of the isobarbituric acid in any metabolic processes involving oxidation.

Experimental Part

5-Carbethoxy-5-bromo-6-hydroxyhydrouracil (I).—Eight grams of powdered 5-carbethoxyuracil[7] was suspended in 70 cc. of water, 2.5 cc. of bromine (1.1 equivalent) was added, and the mixture was allowed to stand for twelve hours at ordinary temperature with occasional shaking. As the original ester dissolved, colorless crystals of the bromoxy ester were formed. The precipitate was filtered, washed with water, dissolved in 150 cc. of boiling water and the solution filtered hot. The pyrimidine crystallized from the cooled solution in the form of long, colorless needles, melting at 178° (corr.) with effervescence; yield 7.3 g. (59%).

Anal. Calcd. for $C_7H_9O_5N_2Br$: N, 9.96; Br, 28.47. Found: N, 9.90, 9.87; Br, 28.29, 28.12.

The ester was decomposed by heat or by acids with the loss of hypobromous acid. By action of silver carbonate it was transformed into the glycol ester (II).

5-Carbethoxy-5,6-dihydroxyhydrouracil (II).—Four grams of (I) and 2.2 g. of powdered silver carbonate (1.1 equivalent) were suspended in 150 cc. of water, and the mixture was stirred for ten hours at room temperature. After adding alcohol to prevent foaming, the precipitated silver bromide was filtered through a norit mat and the excess of silver then removed from the solution with hydrogen sulfide, and the clear colorless filtrate evaporated to dryness *in vacuo* at 40–50°. The crystalline residue was dissolved in a small quantity of dry acetone, filtered from traces of inorganic matter and the filtrate evaporated nearly to dryness. The pure glycol ester was then precipitated by adding ether to the concentrated acetone solution; yield 3.0 g. (97%).

The immediate product of the reaction was a hydrated form of the glycol ester which readily lost one mole of water of crystallization when heated *in vacuo* at 61°. The pure hydrated form, when heated in a melting point tube, softened at 72°, melted partially around 110°, with violent effervescence at 125°. The anhydrous modification melted sharply with effervescence at 135–136° (corr.). The glycol ester is insoluble in ether, but very soluble in alcohol, water and acetone, from which it crystallizes upon evaporation as colorless plates. It gives no blue color with ferric chloride, unlike isobarbituric acid.[8]

Anal. Hydrate: Calcd. for $C_7H_{10}O_6N_2.H_2O$: H_2O, 7.63. Found: H_2O, 7.94. Anhydrous form: Calcd. for $C_7H_{10}O_6N_2$: C, 38.53; H, 4.59; N, 12.84. Found: C, 38.53, 38.10; H, 4.85, 4.61; N, 12.87, 12.79.

Hydrolysis of II.—When a dilute hydrochloric acid solution of the glycol ester II was warmed, carbon dioxide was evolved immediately, and a granular precipitate separated, which was identical in properties and analysis with an authentic specimen of isobarbituric acid.[8] When the glycol ester was saponified with one equivalent of potassium hydroxide in cold absolute alcohol solution, a white amorphous potassium salt was obtained. By careful acidification of this salt in cold aqueous solution, isobarbituric acid was the only product obtained.

Monoacetate of 5-Carbethoxy-5,6-dihydroxyhydrouracil.—A mixture of 1 g. of the glycol ester and 8 cc. of acetic anhydride was boiled for three minutes. The resulting solution was concentrated in a vacuum desiccator until the monoacetate crystallized; yield 0.4 g. (33%). This substance was moderately soluble in cold acetone, from which it crystallized as clusters of colorless needles, melting at 178° (corr.) with effervescence.

Anal. Calcd. for $C_9H_{12}O_7N_2$: C, 41.52; H, 4.65; N, 10.77. Found: C, 41.86; H, 4.84; N, 10.95.

Study of Other Methods Applied for Synthesizing Uracil-glycol

(1) **Bromination of 5-Carboxyluracil.**—Attempts to add one equivalent of hypobromous acid to 5-carboxyluracil[9] suspended in water resulted in the partial decarboxylation of the acid, even in the cold, with the formation of 5,5'-dibromo-6-hydroxyhydrouracil. The product was identical in properties and analysis with a synthetic specimen.[3] The remainder consisted solely of unchanged 5-carboxyluracil. By using two equivalents of bromine water, a 90% yield of the dibromohydroxyhydrouracil was obtained.

(2) **Reduction of Isodialuric Acid and Diacetyl-isodialuric Acid.**—Upon reduction of 4 g. of pure isodialuric acid[10] in ethanol solution with the Adams platinum catalyst,[11] 0.3 g. of isobarbituric acid was isolated together with 3.4 g. of unchanged isodialuric acid. When 2.4 g. of diacetylisodialuric acid[12] was hydrogenated in glacial acetic acid solution, 0.7 g. of isobarbituric acid was obtained. Similarly, when the solvent was a mixture of acetic acid and acetic anhydride, acetyl isobarbituric acid[12] was formed in 66% yield.

(3) **Oxidation of Uracil with Peracetic Acid.**—Uracil was not attacked by treatment with 90% peracetic acid[13] for long periods at 25°, 40° or at 80° under pressure. Experiments were carried out both with and without solvents (water and acetic acid).

(4) **Reduction of Isouramil.**—Attempts to obtain dihydroisouramil by catalytic reduction of isouramil[14] in aqueous ammonia solutions were unsuccessful.

Summary

Free uracil-glycol could not be isolated because of its great tendency to pass into isobarbituric acid with loss of water. The lability of this pyrimidine glycol is in marked contrast to the comparative stability of the corresponding 5-methyl derivative (thymine-glycol) and the 5-carbethoxy derivative described in this paper.

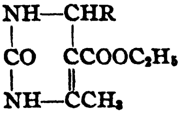
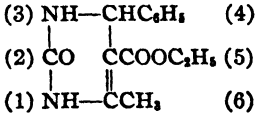
Researches on Pyrimidines. CXXXVI. The Mechanism of Formation of Tetrahydropyrimidines by the Biginelli Reaction[1]

BY KARL FOLKERS[2] AND TREAT B. JOHNSON

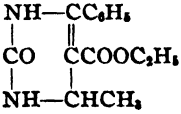
The reaction of numerous aldehydes with urea and a β-keto ester to give a tetrahydropyrimidine was discovered by Biginelli.[3] Structure I, as formulated by Biginelli, may be used to represent these tetrahydropyrimidines, in which R is the grouping joined to —CHO of the particular aryl, alkyl or arylalkyl aldehyde employed in conjunction with urea and ethyl acetoacetate. Accordingly, when benzaldehyde was used, Biginelli obtained a pyrimidine which he considered to be represented by structure II, namely, 2-keto-4-phenyl-5-carbethoxy-6-methyl-1,2,3,4-tetrahydropyrimidine, and he studied this member of his series in greatest detail. In their short study of this reaction, Biginelli's structure II was apparently accepted by Hinkel and Hey;[4] and in a recent extended study[5] of the condensation, no contradictory constitutional evidence was found.



I



II



III

Since a conception of mechanism which was based on experiments designed for the purpose was greatly needed, the authors have studied further the formation of pyrimidine II in an effort to obtain mechanism formations which would be of value in their further application of the condensation. The data obtained and their interpretations are summarized in this paper. As a basis, the Biginelli pyrimidine formula, II, was accepted. Evidence in favor of it with regard to the position of the double bond was the preparation of the isomeric pyrimidine, III, and the hydrogenation of pyrimidine III[6] and pyrimidine II[7] to the same 4-cyclohexylhexahydropyrimidine derivative, and then the saponification of this reduced ester to the 5-pyrimidine carboxylic acid. Very recently, Bergmann and Johnson[8] have confirmed the pyrimidine structure, I, by a new and different synthesis of 2-keto-5-carbethoxy-6-methyl-1,2,3,4-tetrahydropyrimidine of which these pyrimidines may be considered 4-substituted derivatives.

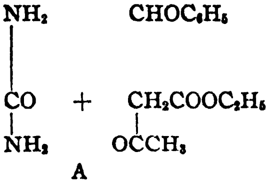
(8) Results that are to be published soon from this Laboratory.

In his original work, Biginelli showed, as his constitutional proof, that pyrimidine II could be obtained experimentally in four different ways. The systems of reactants representing these four methods are: (A) urea, benzaldehyde and ethyl acetoacetate; (B) benzal-bisurea and ethyl acetoacetate; (C) ethyl β-carbamidocrotonate and benzaldehyde; and (D) urea and ethyl α-benzalacetoacetate. Systems B, C and D represented the three primary bimolecular reactions that were possible from system A.



$$\begin{array}{lcl} NH_2 & & CHOC_6H_5 \\ | & & \\ CO & + & CH_2COOC_2H_5 \\ | & & | \\ NH_2 & & OCCH_3 \end{array}$$

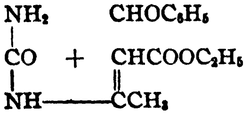
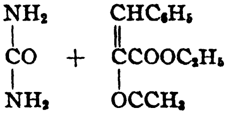
$$\begin{array}{lcl} NH & — & CHC_6H_5 \\ | & & | \\ | & & NHCONH_2 \\ CO & + & CH_2COOC_2H_5 \\ | & & | \\ NH_2 & & OCCH_3 \end{array}$$

B



$$\begin{array}{lcl} NH_2 & & CHOC_6H_5 \\ | & & \\ CO & + & CHCOOC_2H_5 \\ | & & \| \\ NH & — & CCH_3 \end{array}$$

C



$$\begin{array}{lcl} NH_2 & & CHC_6H_5 \\ | & & \| \\ CO & + & CCOOC_2H_5 \\ | & & | \\ NH_2 & & OCCH_3 \end{array}$$

D

Since it seemed improbable that the three components of system A reacted simultaneously to give the pyrimidine, queries that followed were: which reactants (B, C or D) were formed from A and that lead to pyrimidine II and at what rate and to what extent? Which system by itself leads to the pyrimidine most readily and to the greatest extent? Are the true systems leading to the pyrimidine not system B, C or D, but precursors or derived products of them, etc.?

In conjunction with the reactants, the catalytic effects had also to be considered. It has been well demonstrated before, and by this paper, that this condensation proceeds exceedingly slowly, if at all, unless catalyzed by acid, and it has been indicated[5] that when the pyrimidine was

TABLE I[a]

EFFECT OF CATALYST ON THE RATE OF FORMATION OF PYRIMIDINE II

Hydrochloric acid (concd.)	4 drops	67.0
Hydrochloric acid (concd.)	8 drops	74.6

[a] Based on runs of 0.05 mole each of urea and benzaldehyde and 0.075 mole of ethyl acetoacetate dissolved in 20 ml. of abs. ethanol and refluxed for two hours. [b] Obtained by pouring solution into 300 ml. of water and allowing twenty-four hours for crystallization. [c] Yields represent the amount of pyrimidine separating from reacted solution. [d] 5-ml. pipet.

obtained without the use of a definite catalyst, the derived acetic acid was the catalytic factor. Further data on the effect of catalysts on the formation of pyrimidine II are given in Table I. The reacted solution with iodine as catalyst was distinctly acid to litmus, so the acid formed was probably the prime catalytic agent. Quite evidently, within limits, the yield was proportional to the amount of catalyst present. When ten drops of piperidine were used as catalyst, there was no formation of pyrimidine II, but benzaldehyde and the ethyl acetoacetate reacted to give a 39.8% yield of the β_1-form of 1-methyl-2,4-dicarbethoxy-3-phenyl-5-keto-cyclohexanol.[9] Although the chief interests of Table II were the comparative system yields of the pyrimidine, it clearly demonstrated, again for system A and anew for systems B and C, that the yield was proportional to the amount within limits of the catalyst present.

The reaction between citral, urea and ethyl acetoacetate gave two pyrimidines, one of m. p. 150–150.8° and the other of m. p. 109.5–110.5°.[5] On hydrogenation with a platinum catalyst, these isomers each absorbed very easily 2 moles of hydrogen to give the same product, namely, 2-keto-4-(2,5-dimethyl-heptyl)-5-carbethoxy-6-methyl-1,2,3,4-tetrahydropyrimidine. Therefore, the citral employed contained at least two of the known citral isomers, probably the diastereoisomers, each of which gave a pyrimidine, and since the isomerism was in the side chain and not the pyrimidine nucleus, further study of the isomers was irrelevant.

Experimental

There are given in Table II the yields of pyrimidine II as obtained with varying amounts of catalyst by the four systems of reactants under comparable conditions. These same data are presented in part in the curves of Fig. 1 for better visualization and discussion. The quantities of reactants for the systems were: (A) 0.025 mole each of urea, redistilled benzaldehyde and acid-free ethyl acetoacetate; (AA) 0.05 mole of urea and 0.025 mole each of benzaldehyde and ethyl acetoacetate; (B) 0.025 mole each of benzal-bisurea[10] and ethyl acetoacetate; (C) 0.025 mole each of ethyl β-carbamidocrotonate[11] and benzaldehyde; (D) 0.025 mole each of urea and ethyl α-benzalacetoacetate.[12]

The reactants in each run were dissolved in 35 ml. of absolute ethanol. This amount of solvent was not sufficient in all runs to keep the mixture homogeneous. However, it was not desirable to increase the amount of solvent, even to overcome this criticism. Concentrated sulfuric acid was used as the catalyst because of its low volatility and its low water content. It did not seem necessary to try to eliminate the last traces of water from the initial solution because of the water formed in the actual condensation. Each run was refluxed for two hours and then allowed to stand at 25° for twelve to fifteen hours for crystallization. This period of reaction was arbitrary and affixed so that data on the reaction rates would be obtained. Therefore, the yields as secured with the lower

[a] On pouring the reacted solution into 300 ml. of water and allowing to stand for twenty-four hours, there were no crystals of the pyrimidine present. This testified to the scarcity of water in the absolute ethanol and the lack of free acid in the ethyl acetoacetate. [b] Solution refluxed for seven hours instead of two hours. [c] The yield was also zero when four drops of water were added. [d] Yields of 1.5–3.8% of pure pyrimidine were obtained by pouring the solution into 300 ml. of water, etc.

concentrations of catalyst are those from interrupted reactions. The yields of Table II represent that amount of pyrimidine crystallizing out of the original solution. Actually these are the minimum yields, for there is a small amount remaining in solution. However, the systems are best compared on these yields. The solubility of pyrimidine II in 95% ethanol at 25° is about 0.35 g. per 35 ml. In each case the filtrate and the 5 ml. of wash alcohol were poured into 300 ml. of water to precipitate the last of the pyrimidine with a small amount of gummy material. After fifteen hours this solid was filtered and dried. The percentage of pyrimidine in this material decreased as the amount of catalyst for the run was increased, and varied in quantity as follows: (A) 0.6–1.2 g.; (AA) 0.5–0.9 g.; (B) 0.5–0.9 g.; (C) 0.9–1.0 g.; and for (D) the amount was only 0.1–0.25 g. of very pure pyrimidine. For accuracy, the benzaldehyde and ethyl acetoacetate were measured out from burets, and the ethyl α-benzalacetoacetate was measured from a calibrated tube. The urea was weighed to the hundredths and the benzal-bisurea and ethyl β-carbamidocrotonate to the tenths. The absolute ethanol was measured from pipets, and the drops of sulfuric acid were counted from a full 5-ml. pipet.

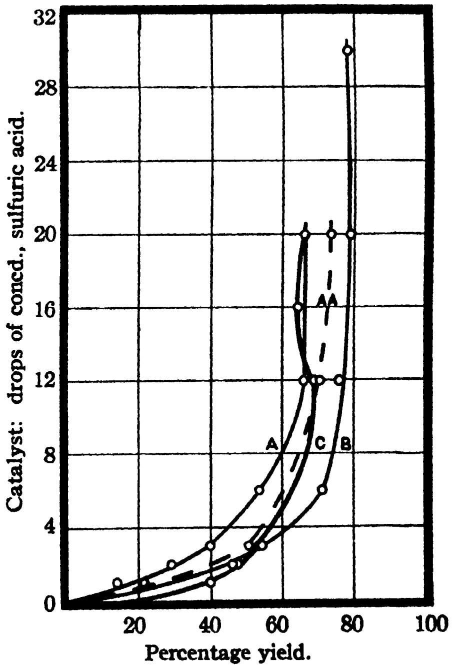

Fig. 1.—Comparative yields and rate of formation of pyrimidine II from the systems.

2-Keto-4-(2,5-dimethylheptyl)-5-carbethoxy-6-methyl-1,2,3,4-tetrahydropyrimidine.—Three and eight-tenths grams each of the pyrimidine of m. p. 109.5–110.5° and m. p. 150–150.8° (obtained by the interaction of citral, urea and ethyl acetoacetate) were reduced separately by dissolving in 80 ml. of glacial acetic acid and shaking under three atmospheres hydrogen pressure for four minutes in the presence of 0.2 g. of platinum catalyst. Each pyrimidine absorbed two moles of hydrogen. The solutions were concentrated under diminished pressure and the residues poured into 100 ml. of water. The oils quickly solidified, and, after two crystallizations from aqueous ethanol, melted (and mixed m. p.) at 131–134°.

Anal. Calcd. for $C_{17}H_{30}N_2O_3$: C, 65.75; H, 9.74. Found: (micro) C, 65.68; H, 9.71.

Discussion of Results

System A.—When only one or two drops of acid were used in the reaction between the three components, there was observed at the starting of refluxing a few white particles, probably benzal-bisurea,[13] which soon disappeared. The formation of this compound was the only indication of mechanism obtained from the three component system.

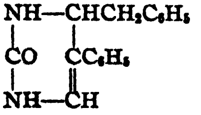
System B.—The reaction between benzal-bisurea and ethyl acetoacetate in the higher acid concentrations gave the highest yields of pyrimidine of any system. In this system there was a second molecular quantity of urea which was initially present in benzal-bisurea. Probably this second urea molecule functioned on the product side of the reaction. Benzal-bisurea was quite insoluble in hot absolute ethanol, and it was not appreciably affected when an alcohol suspension containing acid was refluxed. However, when ethyl acetoacetate was added to the solution, the insoluble benzal-bisurea disappeared and the pyrimidine precipitated, with a velocity proportional to the amount of acid used. If benzal-bisurea had broken down in some manner to give urea and benzaldehyde, then the increased yields of system B might have been due partially or wholly to a mass effect of this excess urea, for it was known that the yield was increased by the mass effect of excess ethyl acetoacetate. System AA was identical with A except for the use of a second molecular quantity of urea, and the increase in yield of system AA with respect to A was a measure of this mass effect. Since this increase in yield was only a part of the increase of B over A, it was concluded that system B constituted a definite step in the mechanism.

System C.—The yields of pyrimidine from the interaction of ethyl β-carbamidocrotonate and benzaldehyde were much greater than those of system A for low concentration of acid, but were almost identical for the higher concentrations of acid. This observation suggested that the mechanism of pyrimidine formation was the same for systems A and C for the higher concentrations of acid. Such a suggestion implied that at these higher concentrations of acid the ethyl β-carbamidocrotonate underwent hydrolysis into urea and ethyl acetoacetate, or, in other words, system C changed into system A. Evidence for such hydrolysis of ethyl β-carbamidocrotonate was found in the two following facts.

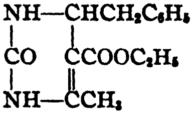
---

(13) Hinkel and Hey expressed their belief that the first action in this condensation consisted in the formation of benzal-bisurea.

First, it was recently discovered[14] that phenylacetaldehyde would react with urea under the same experimental conditions used for the preparation of pyrimidine II to form a new type of pyrimidine derivative, namely, 2-keto-4-benzyl-5-phenyl-1,2,3,4-tetrahydropyrimidine, IV. When phenylacetaldehyde reacted with ethyl β-carbamidocrotonate in the same quality absolute ethanol and under the high concentration of acid used for system C, pyrimidine IV was isolated again in good yield. The urea needed for this condensation could come only by the primary hydrolysis of the ethyl β-carbamidocrotonate.



IV



V

Second, when 0.025 mole each of benzal-bisurea and ethyl β-carbamidocrotonate reacted for two hours in 35 ml. of ethanol with 20 drops of catalyst, there was obtained an 81.5% yield of pyrimidine II. The formation of pyrimidine II, by system B in this case, showed the presence of ethyl acetoacetate which could come only by the hydrolysis of ethyl β-carbamidocrotonate.

Even though such a small quantity of water was present, probably the hydrolysis of ethyl β-carbamidocrotonate differed, with respect to the reactant and medium, only in degree from the reported hydrolysis of ethyl β-aminocrotonate into the ammonium salt and ethyl acetoacetate by an acidic solution at 25°.[15] The nitrogen-carbon bond of the $-N-\overset{|}{C}=\overset{|}{C}-$ group in certain cyclic ureides is known also to be weak in acid solution.

Strong evidence that ethyl β-carbamidocrotonate did react directly with benzaldehyde is found in the much higher yields of pyrimidine II from system C in contrast with A for the low concentration of acid, and the fact that in the above-mentioned reaction between ethyl β-carbamidocrotonate and phenylacetaldehyde there also was isolated the 4-benzylpyrimidine derivative, V.

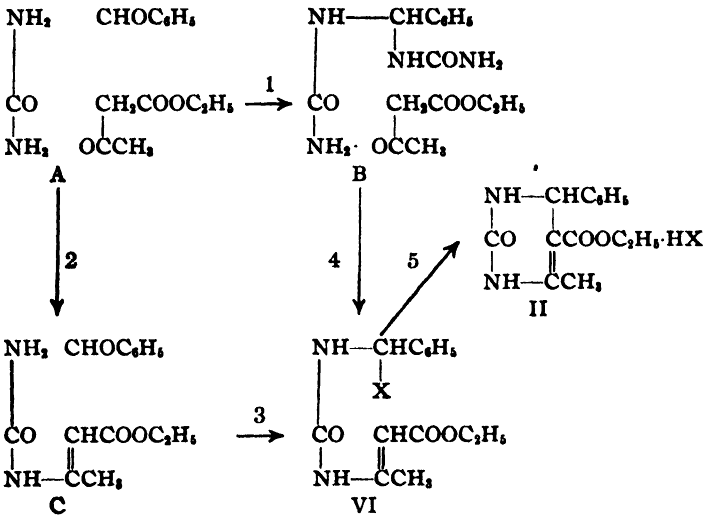
System D.—It was obvious from the exceedingly small yields of pyrimidine obtained by the interaction of urea and ethyl α-benzalacetoacetate that this system did not function directly in the three component process. This small yield of pyrimidine would require further study before statements regarding its formation would be warranted.

Mechanism Formulations.—From these results it appeared quite definite that pyrimidine II could be formed by the direct interaction of benzal-bisurea and ethyl acetoacetate (system B), and ethyl β-carbamidocrotonate and benzaldehyde (system C), and that these two systems were possibly related according to the following scheme:

---

(14) Folkers and Johnson, THIS JOURNAL, **55**, 3361 (1933).

(15) Collie, *J. Chem. Soc.*, **71**, 303 (1898).



(X = —OH, —NHCONH$_2$, —NHCONHR)

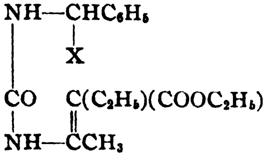
System B, or C, or both, might have first formed from system A. Then either, or both, of these systems, on reacting with the proper remaining component (ethyl acetoacetate for B and benzaldehyde for C) and then undergoing cyclization, formed pyrimidine II. The catalyzed mechanism of any individual step is as yet problematical. For this reason it was desirable to substitute "X" for the radical functioning in structure VI. The extent to which any of these steps proceeded or predominated would be expected to depend upon those factors which influence the relative rates of competitive reactions. There was support for this hypothesis. Step 4, or the formation of the 1,6-linkage, was a union well known in the chemistry of acyclic and cyclic ureides for its ease of formation. The experimental conditions for the preparation of benzal-bisurea indicated the ease of formation of the 3,4-linkage (step 3). Step 5 appeared as the slowest, or the rate-determining, step. Curve B (representing system B) of Fig. 1 is a measure of the combined rates of steps 4 and 5 and curve C of the combined rates of steps 3 and 5; and since steps 4 and 3 are conceived to be fast as compared with 5, then both curves should be an actual measure of step 5. This relationship was borne out by the near quality of yields for 1 to 3 drops of catalyst, as shown by curves B and C. The divergence of curve C for greater amounts of catalyst may be accounted for by the hydrolysis of the ethyl β-carbamidocrotonate. Steps 3 and 5 are somewhat related to the discussion of the condensation of secondary amines with aldehydes and naphthols.[16]

Biginelli and the present authors were unable to isolate a pyrimidine from the system ethyl α-ethylacetoacetate, urea and benzaldehyde. This

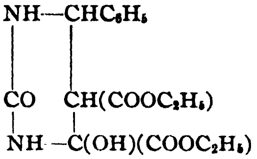
---

(16) Littman and Brode, This Journal, 52, 1655 (1930).

hypothesis would explain such a failure, for the structure VII would have no hydrogen atom available for cyclization.



VII



VIII

By the interaction of ethyl oxalacetate, benzaldehyde and urea, Biginelli obtained the 6-hydroxypyrimidine, VIII, and from this, by dehydration, the tetrahydropyrimidine derivative. This would indicate for step 4 of the hypothesis the addition of the urea molecule to that of the β-keto ester (probably the keto form), followed by dehydration. That the hydroxyl group of the structure $-NHCONHC(OH)(CO_2C_2H_5)$ is stabilized by the negative $-COOC_2H_5$ group is not unexpected. For example, ethylidene urea[17] results from the interaction of acetaldehyde and urea, but if chloral and urea interact, the intermediate product, β-trichloro-α-hydroxyethylurea, $Cl_3CCHOHNHCONH_2$, is isolated in good yields[18] and can then be converted to trichloroethylideneurea.

Summary

From a detailed study of the mechanism of formation of 2-keto-4-phenyl-5-carbethoxy-6-methyl-1,2,3,4-tetrahydropyrimidine from urea, benzaldehyde and ethyl acetoacetate by the Biginelli reaction, it has been concluded that the urea reacted first with benzaldehyde to form benzal-bisurea, or with the ethyl acetoacetate to form ethyl β-carbamidocrotonate. Then, one, or both, of these intermediates further reacted with the proper remaining component (ethyl acetoacetate and benzaldehyde, respectively), and by a final cyclization reaction the pyrimidine was formed. Evidence to support this formulation has been given. Direct interaction between urea and ethyl α-benzalacetoacetate did not appear to function directly in this mechanism.

It has been shown that ethyl β-carbamidocrotonate hydrolyzed with ease into urea and ethyl acetoacetate under the experimental conditions used in this study.

The two previously reported pyrimidine isomers, obtained by the condensation of citral, urea and ethyl acetoacetate, have been shown to have the cause of the isomerism in the heptadienyl side chain, and not the pyrimidine nucleus.

Trialkylethinylcarbinols

BY D. D. COFFMAN, JUNE CHIEN-YU TSAO, L. E. SCHNIEPP AND C. S. MARVEL

In some recent work[1] it has been shown that carbinols containing the group $-CH_2-C{\equiv}C-\overset{R}{\underset{R}{C}}-OH$ behave abnormally when treated with reagents which should yield the corresponding halide. Only two out of the five carbinols previously studied gave the expected halides and even in those cases the halogen compounds were too unstable to be isolated and had to be characterized by conversion to stable derivatives. The further work on compounds of this type has emphasized the peculiar reactions of acetylenic carbinols which have a primary alkyl group adjacent to the carbon atom carrying the triple bond.

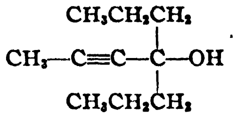
Three new acetylenic carbinols, namely, tripropinylcarbinol (I), trinonadecinylcarbinol (II) and di-*n*-propylpropinylcarbinol (III), have been selected for this study because they exemplify, respectively, the lowest molecular weight compound of this series, a very high molecular weight compound of this series and a compound in which the R group is a primary alkyl group.

$(CH_3-C{\equiv}C)_3COH$

I

$(CH_3(CH_2)_{16}-C{\equiv}C)_3COH$

II



$$CH_3-C{\equiv}C-\overset{CH_3CH_2CH_2}{\underset{CH_3CH_2CH_2}{C}}-OH$$

III

None of these carbinols which have primary alkyl groups attached to the acetylenic group behaved normally when treated with phosphorus trichloride. Neither trinonadecinylcarbinol nor di-*n*-propylpropinylcarbinol would yield a methyl ether on treatment with methyl alcohol and sulfuric acid.[2]

A most unusual reaction was observed when trinonadecinylcarbinol was warmed with sulfuric acid in acetic acid. The simple Meyer and Schuster[3] rearrangement to yield the unsaturated ketone did not occur. Analysis and molecular weight determinations on the product obtained showed that in this reaction two molecules of the carbinol had combined and apparently the acetylenic bonds had been hydrated. The reaction has been formulated as

$$2(CH_3(CH_2)_{16}C{\equiv}C)_3COH \xrightarrow{+\ H_2O} (CH_3(CH_2)_{16}COCH_2)_3-C-O-C(CH_2CO(CH_2)_{16}CH_3)_3$$

However, the carbinol groups may be in the α-position with respect to the ether linkage. This unusual reaction did not occur when either tri-

propinylcarbinol or di-*n*-propylpropinylcarbinol was treated in a similar manner.

The reactions of the tertiary acetylenic carbinols of the type  $-CH_2-C\equiv C-\overset{R}{\underset{R}{C}}-OH$, which are reported in this communication, are quite different from the normal reactions of acetylenic carbinols of the type  $R_3-C-C\equiv C-\overset{R}{\underset{R}{C}}-OH$, which have been described previously.[4] Moreover, they are different from the reactions which Liang[5] has reported for secondary acetylenic carbinols of a related type.

Experimental

Bromo-2-nonadecene-1.—A solution of cetylmagnesium bromide in ether was prepared from 60 g. of cetyl bromide (b. p. 156–160° (1 mm.); m. p. 11.5°; n_D^{20} 1.4625) and 4.7 g. of magnesium in 300 cc. of dry ether according to the standard procedure. The reaction was started by adding a little cetylmagnesium bromide prepared from activated copper–magnesium alloy. The warm solution of cetylmagnesium bromide was filtered under nitrogen and then added to a well-cooled solution of 60 g. of dibromo-2,3-propene-1 in 100 cc. of anhydrous ether. The reaction mixture was then heated under a reflux condenser for about eighteen hours. During all of these operations a nitrogen atmosphere was maintained to avoid excessive oxidation of the Grignard reagent. After working up the reaction mixture in the usual way,[6] the bromo-2-nonadecene-1 was purified by fractional distillation under reduced pressure. The yield was about 10 g. (14.8% of the theoretical amount).

The residues from the fractional distillation were recrystallized from ether and gave some dotriakontane, m. p. 68–70°. If care was not taken to avoid oxidation of the Grignard reagent cetyl alcohol was present in the final mixture of products and could not be separated entirely from the bromo-2-nonadecene-1.

Bromo-2-nonadecene-1 is a colorless liquid; m. p. 10–10.5°; b. p. 168–172° (0.5 mm.); d_4^{20} 0.9781; n_D^{20} 1.4670; M_D, calcd. 97.24; found, 97.86.

Anal.[7] Calcd. for $C_{19}H_{37}Br$: Br. 23.19. Found: Br, 23.29.

Nonadecine-1.—The acetylene derivative was prepared from the bromo compound by the action of sodamide in xylene suspension.[6] A solution of 79 g. of the bromide in 50 cc. of xylene was added to a suspension of 30 g. of sodamide in 350 cc. of boiling xylene. After twelve hours the suspension was cooled, diluted with 1 liter of ether and worked up in the usual manner. On distillation under reduced pressure 40 g. (73% of the theoretical amount) of nonadecine-1 was obtained; b. p. 144° (1.5 mm.); m. p. 37–38°.

Anal. Calcd. for $C_{19}H_{36}$: C, 86.27; H, 13.73. Found: C, 86.51; H, 13.67.

Dinonadecinyl mercury was prepared by the method of Johnson and McEwen.[8] After recrystallization from *n*-butyl alcohol the product melted at 96–97°.

Anal. Calcd. for $C_{38}H_{70}Hg$: Hg, 27.59. Found: Hg, 27.76.

[7] This analysis was made by Mr. G. A. Jones.

[8] Johnson and McEwen, THIS JOURNAL, 48, 469 (1926).

Trinonadecinylcarbinol.—This carbinol was prepared from nonadecinylmagnesium bromide and diethyl carbonate[4] in yields of 43% of the theoretical amount. The product was purified by repeated recrystallization from absolute alcohol–ether mixtures; m. p. 71–72°.

Anal. Calcd. for $C_{58}H_{106}O$: C, 85.00; H, 13.05; mol. wt., 819. Found: C, 84.82; H, 12.97; mol. wt., 895.

The carbinol liberated the theoretical amount of ethane from a solution of ethylmagnesium bromide.

Methyl Trinonadecinylmethyl Ether.—To a solution of trinonadecinylcarbinol in benzene was added an ether solution of ethylmagnesium bromide. When the theoretical amount of ethane had been liberated, four times the calculated amount of dimethyl sulfate was added and the mixture was allowed to stand for about two days. The solvent was removed and absolute alcohol was added. On cooling the methyl trinonadecinylmethyl ether separated. After recrystallization from absolute alcohol, the product melted at 44–45°. The yield was better than 90% of the theoretical amount.

Anal. Calcd. for $C_{59}H_{108}O$: C, 85.00; H, 13.07. Found: C, 84.85; H, 12.94.

This ether could not be cleaved to yield a metallic alkyl by sodium–potassium alloy in ether solution. After this treatment the original ether was recovered.

Action of Sulfuric Acid on Trinonadecinylcarbinol.—When 1 g. of trinonadecinylcarbinol dissolved in 30 cc. of either ethyl alcohol or acetic acid was treated with 10 cc. of concentrated sulfuric acid and the solution was boiled for about one-half hour, a blue color developed. On dilution of the reaction mixture with water 0.6 g. of a blue compound was obtained by filtration. After recrystallization from ethyl acetate this product melted at 56–58°. An ether solution of this compound was blue in color but when this solution was treated with aqueous alkali the color changed to light brown. The blue color was regenerated on shaking the ether solution with dilute sulfuric acid. The blue compound did not contain sulfur.

Anal. Calcd. for $C_{116}H_{222}O_7$: C, 80.56; H, 12.95; mol. wt., 1728. Found: C, 80.61, 80.65; H, 12.50, 12.40; mol. wt., 1688, 1705.

Attempts to Prepare Trinonadecinylmethyl Bromide and Chloride.—When 2 g. of the carbinol was treated with 2 g. of acetyl bromide in ether or benzene at about 35° or when a solution of 5 g. of the carbinol in 5 cc. of ether was refluxed for forty-eight hours with 5 cc. of 40% aqueous hydrobromic acid, there was obtained a light yellow bromine-containing compound which melted at 37–38° after recrystallization from a mixture of benzene and alcohol. The bromine in this compound could not be removed with molecular silver but was removed completely by the action of 40% sodium amalgam or liquid sodium–potassium alloy. No metallic alkyl was produced by this latter treatment. The analysis and molecular weight indicate that the substance is not the expected bromide. No satisfactory explanation of the reaction involved here can yet be given.

Anal. Calcd. for $C_{58}H_{105}Br$: C, 78.93; H, 12.00; Br, 9.06; mol. wt., 882. Found: C, 74.33, 74.33, 74.8; H, 11.43, 11.23, 11.51; Br, 13.68, 13.68; mol. wt., 1132, 1167.

The carbinol in ether solution was treated with thionyl chloride and pyridine. There was thus obtained a chloro compound, m. p. 40–42°, which was also anomalous.

Anal. Calcd. for $C_{58}H_{105}Cl$: C, 89.74; H, 12.64. Found: C, 78.57; H, 11.71.

Tripropinylcarbinol.—Propine was prepared by heating 1390 g. of propylene bromide in a solution of 1750 g. of potassium hydroxide in 2 liters of *n*-butyl alcohol. The gaseous hydrocarbon was passed through two large U-tubes containing anhydrous calcium chloride and phosphorus pentoxide in order to remove alcohol and any possible moisture. The purified propine was passed into a solution of three moles of ethylmagnesium bromide in ether. This operation required about thirty-six hours. Unless this large excess of propine was used, ethylmagnesium bromide remained in the solution and produced mixtures of products.

To this solution of propinylmagnesium bromide was added 118 g. of diethyl carbonate over a period of about ten hours and the reaction carried out as usual for the preparation of acetylenic carbinols.[4] On final evaporation of the ether the carbinol remained as a dark colored solid weighing about 100 g. After repeated crystallization from hot benzene–petroleum ether (1–100) mixtures about 60 g. (41% of the theoretical amount) of yellow crystals (m. p. 134–135°) was obtained. Usually it was necessary to use decolorizing charcoal on the hot benzene solution to remove the deep color. The petroleum ether was then added and the crystals were obtained by cooling to 0° for several hours.

Anal. Calcd. for $C_{10}H_{10}O$: C, 82.15; H, 6.90; mol. wt., 146. Found: C, 82.58, 81.98; H, 7.07, 6.86; mol. wt., 141, 144, 145.

The structure of the carbinol was established by catalytic reduction to tri-*n*-propylcarbinol. A solution of 8 g. of the acetylenic carbinol in 150 cc. of 95% alcohol in the presence of 0.1 g. of platinum oxide catalyst[9] was reduced by hydrogen in about one hour. On working up the solution about 3 cc. of tri-*n*-propylcarbinol was isolated. This product had the following constants: b. p. 89–90.5° (21 mm.); d_0^{20} 0.8304; n_D^{20} 1.4337. A known sample of tri-*n*-propylcarbinol was found to have the following properties; b. p. 90–93° (21 mm.); d_0^{21} 0.8338;[10] n_D^{20} 1.43557.[10] No solid derivatives could be prepared for comparison.

Action of Phosphorus Trichloride on Tripropinylcarbinol.—A solution of 3 g. of the carbinol in 30 cc. of dry benzene was treated with 1 g. of phosphorus trichloride in 10 cc. of the same solvent under the conditions previously used for the conversion of acetylenic carbinols to the corresponding halides.[2,11] The product obtained after recrystallization from a mixture of alcohol and ether weighed 2 g. It was a yellow crystalline compound melting at 153–154° with violent decomposition. Analysis showed that the chlorine content was that expected but molecular weight determinations showed that the compound was a dimer.

Anal. Calcd. for $C_{10}H_9Cl$: Cl, 21.06; mol. wt., 164.5. Found: Cl, 21.03; mol. wt., 319, 324.

The chlorine in the dimer was not removed by shaking with molecular silver at ordinary temperature during three days. Sodium amalgam (40%) removed the halogen but did not form a metallic alkyl.

Some evidence was obtained that the monomeric chloride was formed and could be dehalogenated by silver if the reactions were all carried out at temperatures below −10°. However, it was impossible to obtain a hydrocarbon of sufficient stability to characterize.

Di-*n*-propylpropinylcarbinol.—The propine prepared from 606 g. of propylene bromide was passed into a solution containing 0.75 mole of ethylmagnesium bromide. Then 80 g. of di-*n*-propyl ketone was added and the reaction carried out in the usual fashion.[4] The carbinol boiled at 196–197° at atmospheric pressure. The yield was 64 g. (59% of the theoretical amount); d_{20}^{20} 0.8709; n_D^{20} 1.4518.

Anal. Calcd. for $C_{10}H_{18}O$: C, 77.92; H, 11.77. Found: C, 77.02, 77.49; H, 11.61, 11.58.

Catalytic reduction[9] of this carbinol gave tri-*n*-propylcarbinol; d_{20}^{20} 0.8340; n_D^{20} 1.4357.

[11] Moureu, Dufraisse and Mackall, *Bull. soc. chim.*, [4] **33**, 934 (1923).

Treatment of the carbinol with phosphorus trichloride or tribromide gave liquid products which decomposed on distillation and were too low melting to crystallize. The same difficulty was met when thionyl chloride was used in place of phosphorus trichloride.

Summary

Three new acetylenic carbinols, tripropinylcarbinol, trinonadecinylcarbinol and di-*n*-propylpropinylcarbinol, which contain the group $-CH_2-C\equiv C-\overset{R}{\underset{R}{C}}-OH$ have been characterized. Their behavior toward various reagents shows that they do not react in the manner which would be predicted from the knowledge gained previously from the study of closely related acetylenic carbinols containing the group $R_3C-C\equiv C-\overset{R}{\underset{R}{C}}-OH$.

The Direct Carboxylation of Carbon Compounds. II

BY CORLISS R. KINNEY AND OWEN W. WARD

In a recent study of the equilibrium $C_6H_5CO_2H \rightleftarrows C_6H_6 + CO_2$ it was found that benzene was carboxylated directly by carbon dioxide.[1] Temperatures of about 300° and pressures of about 30 atmospheres were used and the catalyst was of the Zn–Cu–Cr oxide type. Since the yield of acid product as well as the rate of the reaction was quite low, we have continued the search for a more active catalyst. In addition we have studied the direct carboxylation of a variety of compounds.

The experiments were all conducted in glass bomb tubes having a volume of 160 to 200 cc. Pressures of 20 to 30 atmospheres were obtained by introducing into each tube before sealing 0.1 mole of solid carbon dioxide. The tubes were heated for eight hours in a Carius furnace at the temperatures recorded in the table for each specific substance.

A catalyst was found to be quite essential for the carboxylation under the conditions given. The catalyst mentioned in the first paper was replaced by a similar mixture of oxides, but supported on asbestos. This change increased the activity of the catalyst based on the weight of metal oxides in the mixture. It was made by mixing thoroughly the well washed moist hydroxides obtained from 99 g. of $Zn(NO_3)_2{\cdot}6H_2O$ and 93.5 g. of $Cu(NO_3)_2{\cdot}3H_2O$ by precipitation with ammonium hydroxide, with 7.7 g. of chromic oxide and 40 g. of asbestos. After drying the mixture was ignited to convert the hydroxides to oxides. This type of catalyst was found to decrease in activity with use. Upon using the same catalyst over

---

(1) Kinney and Langlois, THIS JOURNAL, 53, 2189 (1931).

for a second and a third time the yield of acid from toluene dropped from 0.36 to 0.15% and to 0.05% for the third run.

In attempting to avoid some of these difficulties a Ni–Co oxide catalyst was developed that was of approximately equal activity. It was made by dissolving 20 g. of $Ni(NO_3)_2 \cdot 6H_2O$ and 24 g. of $Co(NO_3)_2 \cdot 6H_2O$ in a small amount of water and mixing the solution with 15 g. of dry asbestos fiber. After drying the asbestos was ignited until no more oxides of nitrogen were evolved, when the catalyst was ready for use. This catalyst induced a yield of 0.33% of crude acid product from toluene as compared with 0.36% using the Zn–Cu–Cr oxide catalyst, consequently the latter catalyst was used in all the experiments recorded in the table.

After heating the various substances with carbon dioxide, two methods were used to isolate the products of carboxylation depending upon whether the substance was phenolic or not. In case the substance was not phenolic the contents of the tube were extracted with hot half normal potassium hydroxide. The acids were liberated with dilute sulfuric acid and extracted from the solution with several small portions of ether. The ether extract was dried with anhydrous sodium sulfate, filtered and the ether evaporated. The residue of crude acid was then treated as described below.

The reaction products from the phenolic compounds were extracted with a 10% sodium bicarbonate solution that had just been saturated with carbon dioxide. Since carboxylic acids displace carbonic acid from its salts while phenols do not it was possible to extract the phenolic compounds from the bicarbonate solution by repeated ether extractions. After making at least five such extractions with ether the bicarbonate solution was boiled with activated carbon and acidified with dilute sulfuric acid. The liberated acids were next extracted by several portions of ether, and isolated as described for the product from the non-phenolic substances above.

The crude acid products from toluene, anisole, nitrobenzene and styrene were purified by sublimation. In all other cases, the melting points and mixed melting points recorded in the table were obtained with the crude product.

The yields given in the table may not be the maximum obtainable since only two

or three variations in temperature were made at most for any one substance. However the yields given were checked by duplicate runs. In addition, eight hours may be insufficient for the reaction to come to equilibrium as the rate of the reaction is probably low.

The melting point of the acid product in some cases was quite low compared to that of the pure acid used for comparison. For example the sublimed acid product from toluene melted 40–50° lower than the pure *p*-toluic acid used for the mixed melting point. The low melting point was probably due to the presence of a small amount of benzoic acid coming from the oxidation of the toluene by the oxide catalyst. This was verified by heating toluene with the catalyst in the absence of carbon dioxide, whereby a trace, compared to the yield of acid obtained when carbon dioxide was present, of a sublimable acid was obtained. If the impurity in the product from toluene was benzoic acid a study of mixed melting points showed that the sublimed acid contained only about 5% benzoic acid.

The products obtained from the dihydroxybenzenes were also very low melting. Again it appeared likely that the impurities were oxidation products as evidenced by their high color. In any event the impurity could not have been the unreacted phenolic compound as the method employed to separate artificial mixtures of the phenols and the corresponding carboxylated product was highly satisfactory. No explanation for the large yield from resorcinol can be offered at this time.

The carboxylation of diphenylmethane, triphenylmethane and styrene were of particular interest because of the carboxylation of aliphatic carbon-hydrogen bonds.

$$\mathrm{(C_6H_5)_2CH_2 + CO_2 \rightleftharpoons (C_6H_5)_2CHCOOH}$$
$$\mathrm{(C_6H_5)_3CH + CO_2 \rightleftharpoons (C_6H_5)_3CCOOH}$$
$$\mathrm{C_6H_5CH{=}CH_2 + CO_2 \rightleftharpoons C_6H_5CH{=}CHCOOH}$$

The products of these three reactions were relatively pure and could be identified without trouble.

Likewise, bromobenzene, anisole, dimethylaniline and nitrobenzene gave fairly pure para carboxylation products considering the probability of simultaneous carboxylation in other positions.

In all cases studied thus far, with the possible exception of phenol, carboxylation has occurred. The reaction takes place with both aromatic and aliphatic carbon to hydrogen bonds; and, although the reaction is highly reversible with the position of equilibrium far on the side of decarboxylation, the reaction appears to be of a quite general nature.

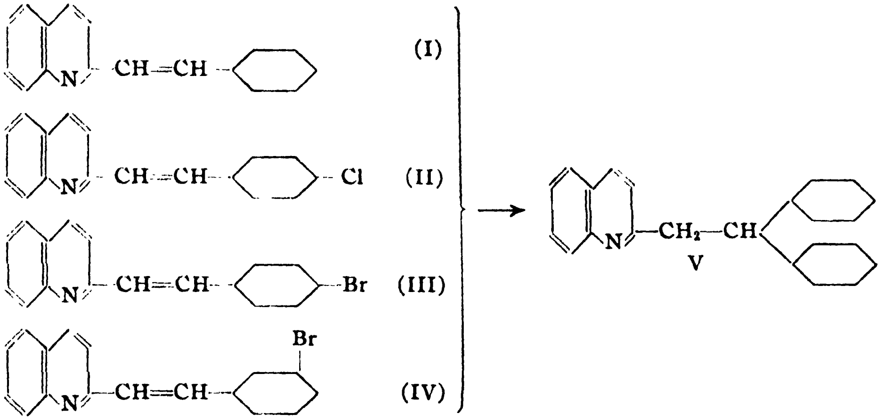
The Reversible Addition of Aromatic Compounds to Conjugated Systems

BY REYNOLD C. FUSON, A. P. KOZACIK AND J. T. EATON

In a study of ring-chain conjugation in the quinoline series[1] it has recently been shown that benzalquinaldine (I) reacts with benzene in the presence of aluminum chloride to give α-benzohydrylquinaldine (V). This condensation is analogous to the addition under similar conditions of aromatic hydrocarbons to α,β-unsaturated carbonyl compounds—a reaction which has been observed by a number of investigators.[2]



However, with p-chlorobenzalquinaldine the reaction appeared to take a different course, for the product was not the expected α-(p-chlorobenzohydryl)-quinaldine but the chlorine-free α-benzohydrylquinaldine (V). This anomalous result has been subsequently investigated and the results are being reported in the present paper.

An early suggestion was that the removal of the chlorine might be due to the action of aluminum chloride alone; experiment showed, however, that p-chlorobenzalquinaldine was unaffected by long contact with aluminum chloride.

That the nature of the halogen atom or its position on the benzene ring might have a bearing on the result was also considered. It was found, however, that both p-bromobenzalquinaldine (III) and its meta isomer (IV) reacted smoothly to give α-benzohydrylquinaldine (V).

It now became apparent that the reaction involved not merely the

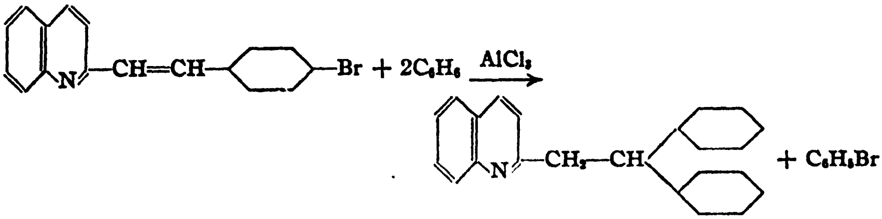
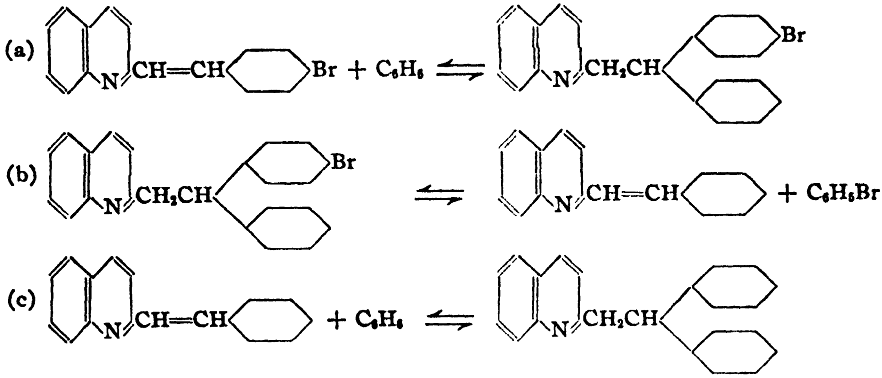
replacement of the halogen atom but that of the entire halophenyl radical. Experiments with *p*-bromobenzalquinaldine confirmed this deduction; it was found that *bromobenzene was produced in the reaction.* The reaction therefore is to be represented by the equation

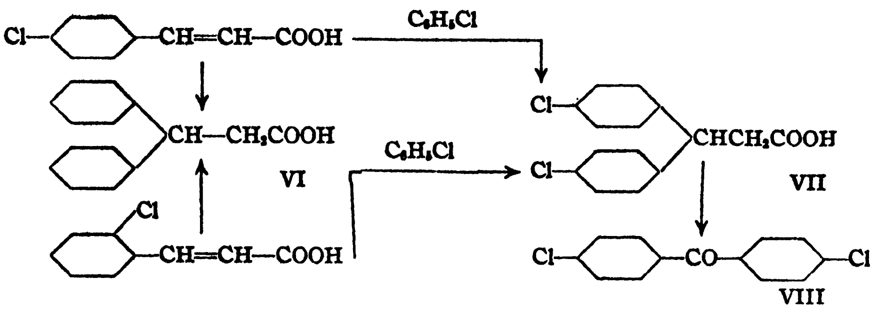


A possible explanation of these results is that the condensation is *reversible.* The reaction could then be resolved into the following three phases.



In a search for further evidence for the proposed mechanism it was found that the quinaldine derivatives were frequently difficult to handle, and efforts were made to determine whether the reaction was general for systems of the α,β-unsaturated carbonyl type. Nuclear halogen derivatives of cinnamic acid were found to behave in a manner entirely analogous to that observed with the halobenzalquinaldines and, consequently, subsequent studies have been carried out with the simpler system.

The Addition of Benzene and Chlorobenzene to *o*- and *p*-Chlorocinnamic Acids.—In the work with the chlorocinnamic acids it was first shown that both the *ortho* and the *para* chloro derivatives reacted with benzene in the presence of aluminum chloride to yield β,β-diphenylpropionic acid (VI). A crucial test of the theory was afforded by the addition of chlorobenzene to the two chlorocinnamic acids. It was found *that the addition products in the two cases were identical.* The product was β,β-di-(*p*-chlorophenyl)-propionic acid (VII). The positions of the chlorine atoms were established by degradation of the acid to the known *p,p'*-dichlorobenzophenone (VIII).



The mechanism suggested provides a satisfactory explanation of the result. Obviously, in the case of the *o*-chlorocinnamic acid the primary addition product is β-(*p*-chlorophenyl)-β-(*o*-chlorophenyl)-propionic acid, from which the *o*-chlorophenyl group is eliminated as chlorobenzene; the latter then condenses with the *p*-chlorocinnamic acid simultaneously produced. When chlorobenzene adds to the unsaturated acid, however, it reacts preferentially at the *para* position. It is evident that all of the facts obtained thus far are in agreement with the predictions based on the theory that the condensation is reversible.

Similar results have been obtained in work with α,β-unsaturated ketones. These will be reported separately but it may be said here that the later results furnish even more striking evidence in favor of the theory that the condensation takes place reversibly.

Experimental

***p*-Chlorobenzalquinaldine.**—The treatment of *p*-chlorobenzalquinaldine with aluminum chloride and benzene described in the preceding paper[1] was repeated except that the benzene was replaced by carbon disulfide and no hydrogen chloride was introduced. The yellow addition compound formed immediately but no further reaction took place; at the end of twelve hours the original base was recovered.

***m*-Bromobenzalquinaldine.**—This compound was prepared from *m*-bromobenzaldehyde and quinaldine by a procedure similar to that already described for the *p*-chlorobenzalquinaldine.[1] After recrystallization from alcohol the crystals melted at 96°.

Anal. Calcd. for $C_{17}H_{12}NBr$: Br, 25.8. Found: Br, 25.5.

The dibromide melted at 185–186°.

Anal. Calcd. for $C_{17}H_{12}NBr_3$: Br, 51.1. Found: Br, 51.3.

The action of benzene, aluminum chloride and hydrogen chloride on *m*-bromobenzalquinaldine was tested in the manner described for *p*-chlorobenzalquinaldine.[1] Here also the product was α-benzohydrylquinaldine.

***p*-Bromobenzalquinaldine.**—This base, prepared by the method already described for *p*-chlorobenzalquinaldine, melted at 137–138°.

Anal. Calcd. for $C_{17}H_{12}NBr$: Br, 25.8. Found: Br, 26.1.

The dibromide melted at 194–195°.

Anal. Calcd. for $C_{17}H_{12}NBr_3$: Br, 51.1. Found: Br, 51.3.

The action of benzene, aluminum chloride and hydrogen chloride on *p*-bromobenzalquinaldine gave α-benzohydrylquinaldine.

The excess benzene was washed with dilute acid, then with dilute carbonate solution and finally with water. The greater part of the benzene was distilled; the residue contained halogen and gave a refractive index (n^{20}_{D} 1.5145) somewhat higher than that of pure benzene (n^{20}_{D} 1.5010). Calculations based on the refractive index indicated that the residual liquid contained about 3 g. of bromobenzene, or 60% of the theoretical amount. This residual liquid (15 cc.) was placed in the usual Grignard apparatus and was treated with 0.5 g. of magnesium and 100 cc. of dry ether. When most of the magnesium had dissolved, 0.5 g. of phenyl isocyanate was added in small portions. There was a vigorous reaction. The mixture was heated under reflux for two hours after the addition was complete and then poured upon a mixture of 50 cc. of concentrated hydrochloric acid and 200 g. of ice. The solid which remained when the ether and benzene were evaporated was recrystallized from alcohol; colorless leaflets, melting at 160°. A mixture of these crystals with a sample of benzanilide also melted at 160°. The yield of benzanilide was 20% of the theoretical amount.

***p*-Chlorocinnamic Acid.**—This acid was prepared by the Perkin method, using potassium acetate in place of sodium acetate.[3] The yield was 66% of the theoretical amount; melting point, 246–247° (uncorr.).[4]

The action of benzene and aluminum chloride[5] on *p*-chlorocinnamic acid resulted in the formation of β,β-diphenylpropionic acid. To an ice-cold mixture of 20 g. of *p*-chlorocinnamic acid and 75 cc. of dry benzene was added 24 g. of pulverized anhydrous aluminum chloride. The flask containing the reaction mixture was kept in an ice-bath during the addition and was shaken frequently. When the evolution of hydrogen chloride had moderated the ice-bath was replaced by a water-bath maintained at a temperature of 35–40°. The shaking was continued and after an hour the mixture was decomposed by the addition of a mixture of 75 g. of ice, 75 g. of water and 24 g. of concentrated hydrochloric acid. The excess benzene was then removed by steam distillation and the product was extracted with ether. The solution was dried, the ether was distilled and the product was recrystallized from benzene. The β,β-diphenylpropionic acid melted at 153–154°. Eijkman[2a] gives the melting point as 154–155°.[6]

The action of chlorobenzene, aluminum chloride and hydrogen chloride was tested in the manner just described. In this case, however, the steam distillation was omitted and the product was separated from excess chlorobenzene by extraction with a solution of dilute alkali. The alkaline solution was then acidified and extracted with ether. Evaporation of the ether left the product as a viscous residue; recrystallization from alcohol gave crystals of β,β-di-(*p*-chlorophenyl)-propionic acid melting at 188–189°.

Anal. Calcd. for $C_{15}H_{12}O_2Cl_2$: Cl, 24.0. Found: Cl, 24.3.

***o*-Chlorocinnamic Acid.**—This acid was prepared by the method of Lasch,[3,7] yield, 73% of the theoretical amount.

The action of benzene and aluminum chloride was determined by use of the procedure already outlined for the preparation of β,β-diphenylpropionic acid from *p*-chlorocinnamic acid. The product was identical with that obtained in the experiment with the para isomer.

The action of chlorobenzene, aluminum chloride and hydrogen chloride, as in the case of *p*-chlorocinnamic acid, gave an acid which melts at 188–189° and which was shown by the mixed melting point method to be β,β-di-(*p*-chlorophenyl)-propionic acid.

---

(3) This is an adaptation of the method used by Lasch [*Monatsh.*, **34**, 1653 (1913)] in the preparation of the ortho compound.

(4) Reich, Araus, Potok and Tempel [*Helv. Chim. Acta*, **3**, 793 (1920)], who made the acid by a similar procedure, give the melting point as 245°.

(5) In this case the introduction of hydrogen chloride was not necessary.

(6) See also Henderson, *J. Chem. Soc.*, **59**, 734 (1891).

(7) A similar method was used by Stoermer, *Ber.*, **44**, 637 (1911).

Oxidation.—A 1-g. sample of β,β-di-(*p*-chlorophenyl)-propionic acid was oxidized by heating it for six hours with a solution of 4 g. of potassium permanganate in 80 cc. of water. The alkali-insoluble product was crystallized from alcohol; melting point, 144–145°. This is the melting point given by Dittrich[8] for *p,p'*-dichlorobenzophenone.

Summary

It has been shown that in the presence of aluminum chloride and hydrogen chloride benzene adds to halobenzalquinaldines and to chlorocinnamic acids. In all of these cases the halophenyl group is replaced by an unsubstituted phenyl group, giving a benzohydryl derivative in place of the halobenzohydryl derivative which was to be expected.

In the case of *p*-bromobenzalquinaldine it has been shown that bromobenzene is a product of the reaction.

Chlorobenzene adds to *o*- and *p*-chlorocinnamic acids in the presence of aluminum chloride to give, in both instances, β,β-di-(*p*-chlorophenyl)-propionic acid.

It has been suggested that the condensation of aromatic compounds with α,β-unsaturated carbonyl compounds and similarly constituted systems is a reversible process. An interpretation of the results, based on this assumption, has been given.

Preparation of Tetramethylmethane (Neopentane) and Determination of its Physical Constants[1]

BY FRANK C. WHITMORE AND GEO. H. FLEMING[2]

Tetramethylmethane has been prepared by relatively few workers and only its boiling point and freezing point have been reported. Because of the importance of the neopentyl system in rearrangements[3] the preparation and properties of the parent hydrocarbons have been studied.

This hydrocarbon has been obtained from petroleum,[4] also synthesized by the reaction of dimethylzinc with *tert*-butyl halides,[5] dimethyl sulfate with *tert*-butyl Grignard,[6] Grignards with halides,[7] and the hydrogenation of trimethylethylene in a silent electric discharge.[8] This formation is most interesting from the point of view of the current theory of rearrangements.[3]

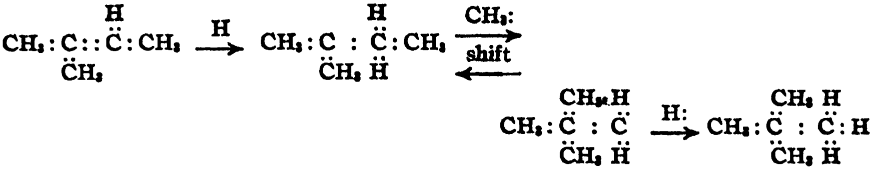
(7) Späth, *Monatsh.*, **34**, 1965–2014 (1913).

(8) Meneghini and Sargato, *Gazz. chim. ital.*, **62**, 621 (1932).

All the predictable products were obtained. The formation of neopentane may take place as follows



$$CH_3{:}\underset{\ddot{C}H_3}{C}{::}\overset{H}{\ddot{C}}{:}CH_3 \xrightarrow{H} CH_3{:}\underset{\ddot{C}H_3}{C}\ :\ \underset{\ddot{H}}{\overset{H}{\ddot{C}}}{:}CH_3 \underset{\longleftarrow}{\xrightarrow[\text{shift}]{CH_3:}} CH_3{:}\underset{\ddot{C}H_3}{\overset{CH_3}{\ddot{C}}}\ :\ \underset{\ddot{H}}{\overset{H}{\ddot{C}}} \xrightarrow{H:} CH_3{:}\underset{\ddot{C}H_3}{\overset{CH_3}{\ddot{C}}}\ :\ \underset{\ddot{H}}{\overset{H}{\ddot{C}}}{:}H$$

The fact that this involves the reverse of the ordinary rearrangement process[3] explains the small amount of neopentane found in the products. It is important to note that the fragment containing a carbon with only six electrons is formed by the *addition of a positive group* (H, in this case) instead of by the *removal of a negative group* with a complete octet of electrons.[3] This phenomenon is being intensively studied in this Laboratory.

Preparation of Neopentane

The work of Lwow was repeated using *tert*-butyl chloride and bromide as well as the iodide. The procedure consisted of adding a tetralin solution of the halide to the dimethylzinc, also in tetralin, at about 35°. The yields of neopentane were as follows: *tert*-butyl chloride, 51.2%; *tert*-butyl bromide, 46.1%; *tert*-butyl iodide, 42.0%.

Ferrario and Fagetti[6] report a 75% yield of neopentane by reaction of *tert*-butylmagnesium iodide with dimethyl sulfate in ether. This work was repeated using *tert*-butylmagnesium chloride in place of the iodide. A negligible quantity of neopentane was found. No improvement was obtained by using a higher boiling solvent (toluene).

E. Späth[7] treated methylmagnesium iodide with *tert*-butyl bromide but did not determine the yield of neopentane. This reaction was repeated and the yield found to be 18.2%. A toluene solution of the bromide was added to the Grignard reagent in ether and toluene at 40–49°.

The sodium salt of *tert*-butylacetic acid was fused with (1) soda-lime, (2) sodium hydroxide and (3) sodium methoxide, but in each case the yield of neopentane was negligible.

According to H. Fay[9] fatty acids are decomposed by uranyl nitrate in the presence of sunlight to give carbon dioxide and hydrocarbons. This reaction was tried with *tert*-butylacetic acid but even after two months' exposure only a very small quantity of gas was liberated.

Sabatier and Senderens,[10] and Mailhe[11] have found that fatty acids are decomposed by a nickel catalyst into carbon dioxide and hydrocarbons. When *tert*-butylacetic acid was decomposed in this manner at 350° it gave a 28.2% yield of neopentane. The apparatus used was of such design that the acid was distilled into a horizontal tube (30 × 1.2 cm.) containing 5.5 g. of freshly reduced nickel. By means of a reflux condenser the unchanged acid or other condensable material was returned to the flask. The gases formed by the decomposition were collected in gas-holders. It was found that starting with 10 g. of acid, only 4.1 g. was decomposed in thirteen hours.

The method finally adopted for the preparation of neopentane was the action of *tert*-butyl chloride and methylmagnesium chloride, both in toluene, at 45–50°. Consistent yields of 42–50% were obtained repeatedly.

Determination of Physical Constants of Neopentane.—The neopentane, free from olefins, was fractionated through a packed column (42 × 1.2 cm.) provided with total condenser and variable take-off.[12] The jacket of the column was maintained at 9–10° and the reflux condenser at 0–3°, by circulating suitably cooled water through them. The head of the column was heavily lagged with asbestos.

The distillate from the first fractionation, which consisted of 3.6 moles, was allowed to vaporize and after being scrubbed with 85% sulfuric acid, 25% potassium hydroxide, and dried with phosphorus pentoxide, was condensed. The middle cuts (2.6 moles) were combined and fractionated, the distillate being collected in four cuts. The freezing points of these cuts were found to be approximately −30, −25, −21 and −19°, respectively.

Refractive Index.—Refractive indices of the four cuts mentioned above were determined from 0 to +6° and the following values were obtained for cut 4 for n_D: 0°, 1.3513; 2°, 1.3498; 4°, 1.3486; 6°, 1.3476.

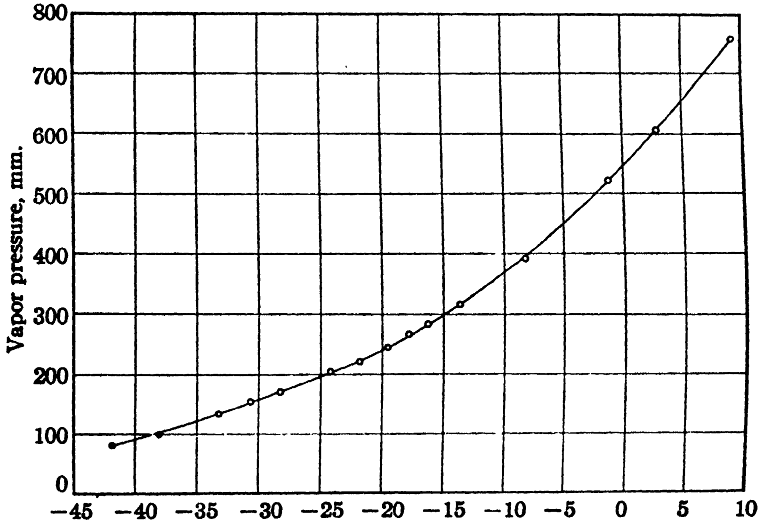

Fig. 1.

Boiling Point.—The Cottrell boiling point on cut 4 was 9.4° (760 mm.). This temperature remained constant for two-thirds of the distillation, which was started with 30 cc. of hydrocarbon.

Freezing Point.—A temperature–time curve on cut 4 indicated its freezing point to be −19.5° (corr.).

Density.—The density of cut 4 was d_0^0 0.613.

Molecular Refraction.—Calcd. for C_5H_{12}, 25.12; obs., 25.36.

Vapor Pressure *vs.* Temperature.—The apparatus consisted of a long-necked 10-cc. flask connected to one arm of a mercury gage which was provided with bulbs at the top of the two arms. The other arm of the gage led to a 10-gallon carboy which was connected to a vacuum pump, a mercury manometer and to the atmosphere. The temperature in the Dewar flask which surrounded the flask was maintained fairly constant by mixtures of ice and hydrochloric acid and acetone and solid carbon dioxide. The temperature in the flask was observed by means of an alcohol thermometer whose

---

(12) Whitmore and Lux, THIS JOURNAL, 54, 3451 (1932).

bulb was immersed completely in the liquid. The accuracy of this apparatus was determined by measuring the vapor pressure of acetone at 0°. The value found was 71.5 mm. compared to the "I. C. T." value of 72.0 mm.

The flask and connection to the mercury gage were freed from air by boiling, and in doing so the vapor was pulled through the gage. With neopentane the system was boiled out six times, the last three readings being constant.

OBSERVED VAPOR PRESSURES AT DIFFERENT TEMPERATURES

Temperature, °C.	9.4	3.1	−1.0	−8.0	−13.4	−15.8	−17.2	−17.6

Hexamethylethane

BY FRANK C. WHITMORE, C. J. STEHMAN AND JOHN M. HERNDON

Since hexamethylethane contains two neo carbon atoms it is of particular interest in the field of intramolecular rearrangements.[1] Because the literature contains no satisfactory method for the preparation of this substance, an extended study has been conducted on this subject and the present paper contains two satisfactory methods for its preparation. The study of the halogenation products of hexamethylethane is in progress in this Laboratory.

Experimental

The summary of the methods tried in the work on the preparation of hexamethylethane follows.

		Yield of hexamethylethane, %
1	Ether solution of *tert*-butylmagnesium bromide added to *tert*-butyl chloride	4
2	Ether solution of *tert*-butylmagnesium bromide added to a parafin oil solution of *tert*-butyl chloride	0
3	Ether solution of *tert*-butylmagnesium chloride added to an ether solution of tetramethylethylene dibromide	0
4	Ether solution of *tert*-butylmagnesium chloride added to a cooled, well-stirred suspension of silver bromide in dry ether	18–19
5	*Tert*-butyl chloride added to sodium pellets in ether	0
6	*Tert*-butyl chloride added to a xylene solution of *tert*-butylmagnesium chloride heated to 50°	0
7	Mercuric chloride added to an ether solution of *tert*-butylmagnesium chloride and *tert*-butyl chloride	0
8	Cupric chloride added to an ether solution of *tert*-butylmagnesium chloride	0
9	Ether solution of pentamethylethyl chloride added to an ether solution of methylmagnesium chloride	3
10	Xylene solution of pentamethylethyl bromide added to a xylene solution of methylmagnesium chloride, heated to 60°	10
11	Xylene solution of pentamethylethyl bromide added to a xylene solution of zinc dimethyl	50

In addition, hexamethylethane as a by-product in reactions involving an ether solution of *tert*-butylmagnesium chloride has been obtained with the following reagents in ether solution: (1) allyl bromide, 8%; (2) acetaldehyde, 7%; (3) *n*-butyraldehyde, 5%; (4) isobutyraldehyde, 4%.

Experimental

Preparation of Hexamethylethane

A. By Reaction of Pentamethylethyl Bromide with Dimethylzinc.—Pentamethylethyl alcohol[2] was prepared in 25% yield from *tert*-butylmagnesium chloride and purified acetone. The corresponding bromide[3] was prepared in 85% yield by the reaction of hydrogen bromide with pentamethylethyl alcohol in cold ether solution.

---

(1) Whitmore and co-workers, THIS JOURNAL, 54, 3274, 3431, 3435, 3714 (1932).

(2) Edgar, Calingaert and Marker, *ibid.*, 51, 1483 (1929).

Dimethylzinc was prepared by the method of Noller[4] and distilled at atmospheric pressure.

Eight grams (0.084 mole) of dimethylzinc in 50 cc. of xylene was placed in a 500-cc. 3-necked round-bottomed flask fitted with a 100-cc. dropping funnel, a mechanical stirrer, reflux condenser and a thermometer well. The flask was surrounded by a water-bath. Twenty-eight grams (0.16 mole) of pentamethylethyl bromide in 56 cc. of dry xylene was added from the dropping funnel during three hours to the well-stirred solution of dimethylzinc in xylene kept at 32°. This temperature was maintained almost entirely by the heat of the reaction. A few minutes after all of the bromide had been added the reaction was complete as evidenced by a fall in temperature. The mixture was then heated to 43° for fifteen minutes, after which a mixture of 70 cc. of water and 15 cc. of concentrated hydrochloric acid was added in ten minutes from the dropping funnel to decompose any excess dimethylzinc.

The xylene and water layers were separated and the xylene layer dried over 20 g. of anhydrous potassium carbonate for twenty-four hours. A rapid distillation was then made through a 70 × 1.1 cm. indented column[5] equipped with a heating unit on the side arm. The following fractions were collected at 740 mm.: 1, b. p. 75–85°, 2.8 g., $n^{20°}_{D}$ 1.4067; 2, b. p. 85–98°, 1.2 g., $n^{20°}_{D}$ 1.4112; 3, 98–119°, 11.3 g. (solid at room temperature); 4, 119–130°, 4 g., partly solid. The residue of xylene was 80 g. Fractions 2 and 3 combined and cooled in ice–salt mixture gave 9.0 g., 50% yield of hexamethylethane, m. p. 101°. A lowering of the melting point resulted when this material was mixed with a sample of the solid alcohol hydrate and with a sample of pentamethylethyl bromide.

B. By Reaction of Tert-butylmagnesium Chloride with Silver Bromide.—This type of reaction has been run previously and the silver bromide used in this experiment was prepared accordingly.[6]

This preparation of *tert*-butylmagnesium chloride was recently described.[7]

In a 2-liter round-bottomed flask, fitted with a mechanical stirrer, dropping funnel, reflux condenser arranged for the collection of gases, surrounded by an ice–salt bath, was placed 93.9 g. (0.5 mole) of silver bromide and 200 cc. of dry ether. Vigorous stirring was started and an ether solution (volume 190–200 cc.) of 0.5 mole of *tert*-butylmagnesium chloride was slowly added from the dropping funnel. After the first few cc. of the Grignard solution was added the black precipitate of silver could be seen and the ether began to reflux. The remainder of the Grignard reagent was then added at such a rate that a gentle refluxing was maintained. When the reaction was complete, all of the Grignard reagent added and the ether no longer refluxed, the reaction mixture was poured on 1.5 kg. of cracked ice contained in a 3-liter flask. As soon as the reaction mixture was added to the ice the 3-liter flask was securely stoppered until the separation of the phases was complete. The ether layer was removed and kept in a closed container during the extraction of the aqueous portion with 200 cc. of ether. The combined ether portions were dried over 20 g. of anhydrous potassium carbonate. After the careful removal of the ether through a 90 × 2.2 cm. glass-packed column[8] the remaining oil was quickly transferred and distilled through a 68 × 1.1 cm. indented column. The forerun was collected as one fraction 2.0 g. up to 92° when the hexamethylethane began to solidify in the head of the column. The flask was then cooled and the hexamethylethane solidi-

Some Aspects of the Tschugaeff Reaction for Dehydrating Alcohols[1]

BY FRANK C. WHITMORE AND C. T. SIMPSON[2]

Tschugaeff was the first to suggest the dehydration of alcohols by decomposition of their xanthates.[3] His original paper dealt with the preparation of menthene from menthol, and gave two possible alternative reactions for the decomposition of the xanthate upon heating

$$C_nH_{2n-1}OCS_2R \xrightarrow{\text{Heat}} C_nH_{2n-2} + COS + RSH \qquad (1)$$

$$C_nH_{2n-1}OCS_2R \xrightarrow{\text{Heat}} C_nH_{2n-2} + CS_2 + ROH \qquad (2)$$

It has since been found that (1) is the reaction. The yield is best when R is methyl.

By the same method Tschugaeff[4] also prepared thujene from thujyl alcohol, limonene from carvone, cholesterylene from cholesterylin, and bornylene from borneol. Others have extended the application of the method. Gandurin[5] prepared guajene from guajol. Kurssanoff[6] dehydrated benzhydrol to give tetraphenylethylene and phenylcyclohexylcarbinol to give benzylidene cyclohexane.

In the aliphatic series Fomin and Sochanski[7] prepared tertiary-butylethylene from pinacolyl alcohol. More recently Stevens[8] dehydrated *dextro*-2-methyl-3-ethoxybutanol-2 to secure *dextro*-3-ethoxy-2-methylbutene-1.

In all these preparations the general method was the same. Sodium or potassium (preferably the latter) reacted with the alcohol in a solvent such as xylene. Carbon disulfide was added to form the xanthate of the metal, which was then converted to the methyl xanthate by refluxing with methyl iodide or sulfate. The methyl xanthate gave the olefin when strongly heated.

Apparently in all these instances only the normal dehydration product was formed, that is, no rearrangement took place. The method thus appeared satisfactory for certain secondary and tertiary alcohols, but it was untried for primary alcohols until the present research. It has now been found to give normal dehydration here also. It is suitable for the preparation of pure isopropylethylene from isoamyl alcohol and of pentene-1 from *n*-amyl alcohol. Capryl alcohol gives a mixture of almost equal parts of octene-1 and octene-2.

The particular advantage of the Tschugaeff method is that it avoids rearrangements. This has been confirmed in the present work by the conversion of isoamyl alcohol to pure isopropylethylene, whereas trimethylethylene is the chief product when isoamyl alcohol is subjected to other methods of dehydration. However, the Tschugaeff method is generally avoided since in the original form it was dangerous and inconvenient. This objection was overcome in the present work by modifying the preparation of the metallic xanthate. This consists in reaction of the alcohol with equimolecular quantities of sodium or potassium hydroxide and carbon disulfide, thus forming the xanthate in one step in a larger yield than is secured by the original method. The best results are obtained when an excess of the alcohol is used, with no other solvent, but by using only equimolecular quantities of the alcohol and a neutral solvent such as a mixture of diethyl ether and carbon tetrachloride the yields are lowered only slightly. This modification makes the Tschugaeff reaction much less hazardous and more practicable than the original method. The following reactions represent the modified reaction

$$\mathrm{ROH} + \mathrm{NaOH} + \mathrm{CS_2} \longrightarrow \mathrm{H_2O} + \mathrm{ROCS_2Na} \xrightarrow{\mathrm{MeI}} \mathrm{ROCS_2Me} \xrightarrow{\mathrm{Heat}} \text{Olefin} + \mathrm{COS} + \mathrm{MeSH}$$

The chief obstacle in applying the method to primary alcohols was found to be the comparatively great stability of the primary xanthates toward heat. They can be distilled *in vacuo*, and even when boiled at atmospheric pressure their decomposition is slow and incomplete, so that only small yields of olefins can be secured. Apparently the secondary and tertiary xanthates are much less stable and, consequently, give better yields of olefins.

Experimental

The alcohols were carefully purified by distillation, and only the purest fractions were used in these experiments. The other liquid chemicals were purified by distillation after drying.

Each of the three alcohols was dehydrated by both the original and the modified

Tschugaeff method, and it was found that the latter gave slightly better yields, as may best be indicated by comparing the yields of xanthates.

The yields of about 15% listed for isopropylethylene and pentene-1 may be regarded as conservative and may be almost doubled by more care in purifying and distilling the products obtained from the decomposition of the xanthates.

Original Tschugaeff Method on Isoamyl Alcohol.—A 2-mole run will be taken as typical of the procedure of this method.

Clean potassium (84 g.) was placed in a 5-liter flask containing 1500 cc. of xylene. The flask was attached to a trident fitted with a mechanical stirrer, a Pyrex reflux condenser and a dropping funnel; then 180 g. of isoamyl alcohol was added dropwise with very vigorous stirring and the mixture was warmed to about 65° to melt the potassium and form tiny beads which reacted vigorously so that the reaction was practically all completed in three hours. Then the mixture was diluted with 1500 cc. of diethyl ether and 305 g. of carbon disulfide added with stirring. After standing overnight the mixture was warmed and stirred for three hours longer, and then 570 g. of methyl iodide was added dropwise and the mixture was stirred and refluxed for six hours. After filtering off the potassium iodide the lower-boiling constituents were removed by distillation and the residual xanthate was distilled at 10 mm. through a 68 × 1.1 cm., indented, total-condensation column.[9] The yellow distillate, b. p. 100–105°, weighed 230 g. Redistillation gave 216 g., b. p. 101–103°, while a third distillation gave 142 g., b. p. 102.5–103° (10 mm.), n_D^{20} 1.5230 and d_4^{20} 1.036.

The material of b. p. 101–103° (216 g.) was heated in a 1-liter flask under a partial-reflux column for seven and one-half hours by a free flame, the distillate being condensed by a copper coil packed in an ice–salt mixture. The undecomposed residue amounting to 43 and 45 g. of colorless distillate was collected. The distillate was purified by three extractions with 40% potassium hydroxide solution and one treatment with 20 cc. of saturated mercuric chloride solution to remove the mercaptan; then it was dried over anhydrous sodium sulfate and distilled through the 68 × 1.1 cm. column. It boiled at 19–20° (740 mm.). It was thus mainly isopropylethylene.

Original Method on *n*-Amyl Alcohol.—Practically the same procedure was followed here as in the case of isoamyl alcohol. For a 2-mole run, 180 g. of alcohol gave 207 g. of xanthate, b. p. 108–108.5° (10 mm.), n_D^{20} 1.5247, d_4^{20} 1.040. After heating for nine hours there remained 66 g. of residue, while the distillate amounted to 50 g., which after purification distilled at 28.5–29.0° (735 mm.). This boiling point checks that recently established for pentene-1 by Dykstra, Lewis and Boord.[10]

Original Method on Capryl Alcohol.—261 g. of alcohol gave 98 g. of olefin, distilling at 120.5–121.2° (725 mm.), n_D^{20} 1.4113, after purification by refluxing over sodium. In this case the xanthate could not be distilled because it was found to decompose upon boiling, even at 5 mm. At atmospheric pressure, heating in an oil-bath at 165° gave almost complete decomposition.

Modified Tschugaeff Method on Isoamyl Alcohol.—This was a 1-mole run. In a 2-liter flask were placed 40.5 g. of finely pulverized sodium hydroxide, 89 g. of isoamyl alcohol, 600 cc. of diethyl ether and 50 cc. of carbon tetrachloride. The flask was attached to the same apparatus as in the original method, and the mixture was stirred for half an hour to dissolve part of the base and form a finely divided suspension of the remainder. Then 76 g. of carbon disulfide was added during one hour, with the temperature below 30°. After three hours of stirring, 149 g. of methyl iodide was added dropwise and the mixture was stirred and refluxed for six hours longer. The remainder of the procedure was the same as for the original method described above. Distillation of the xanthate gave 126 g., b. p. 100–102° (10 mm.), n_D^{20} 1.5234.

---

[9] Whitmore and Lux, THIS JOURNAL, 54, 3451 (1932).

[10] Dykstra, Lewis and Boord, *ibid.*, 52, 3396 (1930).

A run using potassium hydroxide gave the same yield. Still another run, using no other solvent than excess isoamyl alcohol, gave slightly higher yields than when ether and carbon tetrachloride were used as solvents.

Modified Method on *n*-Amyl Alcohol.—From 90 g. of alcohol was obtained 112 g. of xanthate, b. p. 105–107.5° (10 mm.), n^{20}_{D} 1.5253. The olefin boiled at 29° (740 mm.).

Modified Method on Capryl Alcohol.—This was a 2-mole run using 260 g. of capryl alcohol which had been distilled through the 16-meter column;[11] 134 g. of crude olefin was secured by decomposing the crude xanthate. The residue was practically all capryl alcohol. The olefin was purified as usual. The distillate boiled at 120–122° (738 mm.), n^{20}_{D} 1.4115, and weighed 108 g. This was allowed to stand over sodium for several days and was distilled through the 90 × 2.1 cm. partial condensation column built by Franklin Johnston and described in a paper by Whitmore and Lux.[12]

No definite cuts could be obtained, but 12 g. of n^{20}_{D} 1.4095 and 23 g. of n^{20}_{D} 1.4143 were obtained at the lower and upper extremes, respectively. These two fractions were identified by ozonolysis, etc.,[13] as containing octene-1 and octene-2, as follows. The aldehydes secured by decomposing the ozonides were identified by mixed melting points of their semicarbazones and 2,4-dinitrophenylhydrazones with known samples of these same derivatives made from pure heptaldehyde and pure hexaldehyde kindly supplied by John M. Herndon[13] of this Laboratory.

The Tschugaeff reaction applied to capryl alcohol thus gave a mixture of octene-1 and octene-2 of n^{20}_{D} 1.4115, which represents a mixture of about 47% octene-2 and 53% octene-1, according to data supplied by Mr. Herndon, who found octene-1 had n^{20}_{D} 1.4149 and octene-2 n^{20}_{D} 1.4085.

Summary

1. Isoamyl alcohol, *n*-amyl alcohol and capryl alcohol have been dehydrated by the Tschugaeff method.
2. Isoamyl alcohol gave isopropylethylene, *n*-amyl alcohol gave pentene-1 and capryl alcohol gave a mixture of equal parts of octene-2 and octene-1.
3. Primary xanthates are much more stable to heat than are secondary and tertiary xanthates.
4. An advantageous modification of the Tschugaeff technique has been developed.

Dehydroperillic Acid, an Acid from Western Red Cedar (Thuja Plicata Don)[2]

BY ARTHUR B. ANDERSON AND E. C. SHERRARD

A compound $C_{10}H_{12}O_2$ was isolated from western red cedar heartwood by Blasdale[3] in 1907. He describes this compound as being a white crystalline substance melting at 80° and having a cedar-like odor. In 1929 Sherrard and Sondern[4] also isolated a compound $C_{10}H_{12}O_2$ from western red cedar, which they reported as being an acid and melting at 86.5°. The present authors have isolated two compounds from cedar, one being an acid $C_{10}H_{12}O_2$ which when pure is odorless and melts at 88°. The other compound to which we also assign the formula $C_{10}H_{12}O_2$ (tentative) is a white crystalline substance, m. p. 82°, having a slight odor and which seems to be phenolic. In that Blasdale was only able to give a melting point and an empirical formula of the compound, it is not known which of the above compounds he has isolated. We have obtained the acid in sufficient quantities so that we are able to propose a structural formula as a result of a series of reactions carried out at the Forest Products Laboratory.

Sowder[5] has shown that the water extractives obtained from western red cedar are very toxic to the wood-destroying fungus *Lentinus lepideus*, but no direct evidence has been reported as to the actual chemical nature of the toxic principle or principles in western red cedar. The phenolic compound that we have isolated from cedar is very toxic to *Fomes annosus.* A concentration of 0.005 to 0.007% of this compound in agar is sufficient to kill or inhibit the growth of this wood-destroying fungus. It is about ten times more toxic than creosote to this particular organism. This compound, undoubtedly, is one of the toxic compounds that renders western red cedar wood so resistant to decay. A report on the experimental work on the determination of the formula of this phenolic compound and a detailed study of its toxic properties will appear in a subsequent publication. This paper will be concerned with the evidence we have obtained in support of the structural formula for the new acid, $C_{10}H_{12}O_2$. This compound is non-toxic but seems to have a slight corrosive reaction to iron and copper.

Dehydroperillic acid, as we propose to call it for reasons given below, was isolated from western red cedar sawdust by steam distillation. The melting point of the acid has been raised to 88°, but the empirical formula originally assigned to it has been confirmed. The white crystalline acid, when kept in glass-stoppered bottles over a period of several weeks, gradually becomes yellow and acquires a strong odor but can be readily repurified by redistilling with steam. It will remain colorless for a long period of time in a vacuum desiccator over concentrated sulfuric acid.

[4] Sherrard and Sondern, unpublished report, Forest Products Laboratory, Madison, Wis., September, 1929.

[5] Sowder, *Ind. Eng. Chem.*, 21, 981 (1929).

The acid is insoluble in cold water and forms an insoluble oil in hot water. It is readily soluble in ether, acetone, alcohol, ethyl acetate, chloroform and acetic acid. It is optically inactive in either acetone or alcohol. It decolorizes potassium permanganate immediately and slowly reacts with bromine in chloroform solution, but forms no definite product with the latter.

Dehydroperillic acid, when refluxed with 3% hydrochloric acid solution using dilute acetic acid as a solvent, was quantitatively converted into an isomeric compound, cuminic acid (*p*-isopropylbenzoic acid). It absorbed 3 moles of hydrogen on catalytic hydrogenation, using palladium black as a catalyst. The compound can also be reduced with sodium, in either ethyl or amyl alcohol, but no definite product could be isolated. The acid forms a liquid methyl ester which readily solidifies, m. p. 34.5°. Upon hydrolyzing the ozonide, formaldehyde, formic acid, acetaldehyde, acetic acid, oxalic acid, carbon dioxide and probably β,γ-diketovaleric acid were obtained.

Experimental

Isolation and Purification of Dehydroperillic Acid.—Western red cedar heartwood sawdust was distilled with steam in a copper cylinder, capacity about 5 kg. The distillation was continued until the distillate was no longer acid to litmus (approximately 100 liters). The first 20 liters of the distillate was quite cloudy, a very small amount of volatile oil finally settling at the bottom. After separating the volatile oil, the total distillate was made alkaline with a concentrated barium hydroxide solution. The yellow precipitate that formed was filtered off, the barium salt of the acid being soluble. Twenty-liter portions of the alkaline distillate were then reduced to a volume of about 300 cc. in large evaporating dishes over a gas flame (the acid is very stable in alkaline solution). After cooling, the concentrated solution was filtered and the resulting clear, yellow filtrate was acidified with dilute hydrochloric acid. After standing a short time, large, flake-like crystals were obtained which were recovered by filtration with suction. Since they were contaminated by a slight brownish impurity, they were purified by solution in sodium bicarbonate and filtered from the insoluble gummy residue. The acid was reprecipitated by acidifying with dilute hydrochloric acid. After repeating this procedure several times a nearly colorless crystalline substance was obtained which was finally purified by steam distillation. The acid obtained in this manner has a melting point of 88°. The yield of the acid varied greatly, depending upon the portion of the tree from which the sawdust was obtained; yields on the basis of oven-dry wood varied from 0.03 to 0.30%.

Anal. Calcd. for $C_{10}H_{12}O_2$: C, 73.13; H, 7.37. Found: C, 73.10, 72.90, 72.81; H, 7.25, 7.41, 7.35. *Mol. wt.* Calcd. for $C_{10}H_{12}O_2$: 164.1. Found: 163.8, 165.2 (neut. equiv.); by cryoscopic method (Rast), 170.

Methyl Ester.—The ester was prepared by refluxing 7 g. of the silver salt of the acid with 65 g. of methyl iodide for five hours. The ester was isolated in the usual manner. The yield was practically quantitative. The ester thus obtained was a colorless liquid having a pleasant odor; b. p. (14 mm.) 112–113°; d_4^{22} 1.0225; n_D^{22} 1.5130; M_R calcd., for $C_{11}H_{14}O_2$ and 3F, 51.154; M_R found, 52.354.

Anal. Calcd. for $C_{11}H_{14}O_2$: C, 74.11; H, 7.92. Found: C, 73.90; H, 7.91.

The ester can be solidified readily by scratching the walls of the tube containing the ester with a glass rod, the entire liquid immediately solidifying, m. p. 34.5 to 35.0°. Upon saponifying either the liquid or solid ester with alcoholic potassium hydroxide and liberating the acid with dilute sulfuric acid, dehydroperillic acid was again obtained, m. p. 88°.

Cuminic Acid (*p*-Isopropylbenzoic Acid).—About 1 g. of dehydroperillic acid was heated under a reflux condenser with 15 cc. of 3% hydrochloric acid. After the mixture began to boil just enough glacial acetic acid was added to dissolve the acid. After boiling for thirty minutes the reaction mixture was poured into cold water, causing the precipitation of small white needles. Recrystallization from hot water gave a colorless crystalline compound, m. p. 116°. This acid no longer decolorized a chloroform solution of bromine, nor did it oxidize in the presence of cold alkaline potassium permanganate. It had the same empirical formula $C_{10}H_{12}O_2$ as dehydroperillic acid. This isomeric compound thus formed gave no depression of the melting point when mixed with cuminic acid, which was prepared according to R. Meyer's[6] method from cuminal with potassium permanganate. For further confirmation the nitro-[7] and hydroxy-[8] derivatives of cuminic acid were prepared and compared with the corresponding derivatives of the substance obtained from dehydroperillic acid. The nitro derivative of each of the above compounds alone and mixed melted at 156–157°. Likewise, the hydroxy derivative alone and mixed melted at 155–156°. Therefore it is apparent that dehydroperillic acid is rearranged by aqueous hydrochloric acid to form the isomeric compound cuminic acid.

Catalytic Reduction of Dehydroperillic Acid.—A solution of 1 g. of dehydroperillic acid in 10 cc. of alcohol was added to an alcoholic suspension of palladium black which had been previously reduced. The whole was shaken in hydrogen, of which 450 cc. was absorbed in twenty-five minutes and no further absorption took place (calcd. for 3 mols. at 22° and 740 mm., 467 cc.). The catalyst was filtered off and the alcohol removed under reduced pressure. The liquid residue was taken up in ether and dried over anhydrous sodium sulfate. This was filtered and the ether removed under reduced pressure. The colorless liquid that remained distilled at 150 to 152° (16 mm.); d_4^{25} 0.9925; n_D^{25} 1.4670; M_R calcd. for $C_{10}H_{18}O_2$, 47.71; M_R found, 47.56.

Anal. Calcd. for $C_{10}H_{18}O_2$: C, 70.58; H, 10.67. Found: C, 70.49; H, 10.61

The reduced product did not decolorize a dilute alkaline potassium permanganate solution, indicating that the compound $C_{10}H_{18}O_2$ is saturated and therefore must contain one cycle. This compound, to our knowledge, has never been reported. We believe it to be the liquid isomer of hexahydrocuminic acid. The solid isomer of hexahydrocuminic acid has been prepared by Markownikoff.[9]

Preparation and Hydrolysis of the Ozonide.—Dehydroperillic acid (10.46 g.) was dissolved in 100 cc. of absolute ethyl acetate, and the solution cooled in a salt–ice mixture. A current of oxygen containing about 4 to 5% ozone was passed through the solution at a velocity of 18 liters per hour for twelve hours. The ethyl acetate was then

(7) Cahours, *ibid.*, **69**, 243 (1849).

(8) Meyer, *Ber.*, **11**, 1284 (1878).

(9) Markownikoff, *J. prakt. Chem.*, [2] **57**, 95 (1898).

distilled off under reduced pressure in the presence of carbon dioxide at 15°. The resulting ozonide was a very heavy, nearly colorless liquid. Previous trials with chloroform as a solvent gave a waxy ozonide, which did not hydrolyze as readily as the ozonide prepared in the above manner.

The ozonide thus obtained, together with 120 cc. of water, was put into a flask provided with a reflux condenser. The latter was successively connected with three flasks, the one (A) containing 100 cc. of cold water, and the other two (B and C) each containing 400 cc. of 0.2 *N* barium hydroxide solution in order to retain any volatile and gaseous products that might be formed during the decomposition. The flask was carefully warmed on a water-bath while a current of hydrogen was passed slowly through the whole apparatus. After several hours of careful heating the ozonide was completely decomposed, leaving a light red solution.

In flasks B and C barium carbonate was precipitated. After filtering off the precipitate, the excess of barium hydroxide was titrated with standardized sulfuric acid. The quantity of carbon dioxide amounted to 1.54 g.

The solution in flask A was decidedly acidic as well as aldehydic in reaction. An acetic acid solution of *p*-nitrophenylhydrazine was added to a small portion of the solution and a yellow precipitate immediately formed. After filtration and recrystallization from alcohol a crystalline substance was obtained, m. p. 128°, which produced no depression of the melting point when mixed with the *p*-nitrophenylhydrazone of acetaldehyde. The remainder of the solution in flask A was neutralized with *N*/10 sodium hydroxide solution, the amount of alkali consumed for neutralization corresponded to 0.66 g. of acid, calculated as formic acid. This alkaline solution was very carefully distilled; the first portion of the distillate was decidedly volatile. To this an acetic acid solution of *p*-nitrophenylhydrazine was added, forming a precipitate. This was filtered off and recrystallized from alcohol, yielding a crystalline substance, m. p. 180°, which produced no depression of the melting point when mixed with the *p*-nitrophenylhydrazone of formaldehyde. The alkaline solution in the distilling flask was acidified with dilute sulfuric acid and distilled. This distillate gave the following characteristic reactions of formic acid: (1) reduced a neutral silver nitrate solution, (2) formed an insoluble precipitate of mercurous chloride when heated with a solution of mercuric chloride, and (3) formed a black metallic mercury precipitate when subjected to the mercuric oxide test.

The hydrolyzed solution of the ozonide was next steam distilled. The distillate, which was acidic, was neutralized with sodium hydroxide solution and distilled. No aldehydes or ketones could be detected in the distillate. The alkaline solution was evaporated to dryness, acidified with sulfuric acid and distilled. The fraction distilling below 105° was identified as formic acid. The fraction distilling above 105° was identified as acetic acid, by preparing its *p*-nitrobenzyl ester, m. p. 78°.

The non-volatile portion of the hydrolyzed ozonide was concentrated to a sirup at 35° under reduced pressure. This sirup upon cooling partially solidified. The crystals were filtered off and dried on a porous plate. The substance melted at 100°, and gave no depression of the melting point when mixed with oxalic acid. The liquid that remained after filtration was diluted with water. To a portion of this aqueous solution an acetic acid solution of *p*-nitrophenylhydrazine was added, forming a dark red precipitate. This was filtered off and washed well with water. The dark red precipitate was then dried in a vacuum desiccator containing solid potassium hydroxide and concentrated sulfuric acid, m. p. 294–295° (with decomposition).

Anal. (Micro) 5.315 mg. gave 0.040 mg. of ash or 0.75%; 4.303 mg. gave 0.784 cc. of N_2 at 23° and 743 mm.; 4.915 mg. gave 0.904 cc. of N_2 at 24° and 732 mm. Calcd. for $C_{17}H_{16}N_6O_6$, N, 20.99. Found: N, 20.54, 20.31. The amount available was too small for further purification.

The melting point (295°) of this compound corresponds to the *p*-nitrophenylosazone of β,γ-diketovaleric acid prepared by Harries and Kircher.[10] The acid also formed a green copper salt with copper acetate, similar to the one described by Harries for β,γ-diketovaleric acid.

To the remainder of the aqueous solution of the ketonic acid an acetic acid solution of *p*-bromophenylhydrazine was added which soon formed a precipitate. This was filtered, recrystallized from alcohol, and dried, m. p. 220°. This compound was ash free.

Anal. (Micro) 2.865 mg. gave 0.308 cc. of N_2 at 23° and 731 mm.; 2.087 mg. gave 0.219 cc. of N_2 at 23° and 731 mm.; 2.551 mg. gave 0.276 cc. of N_2 at 23° and 731 mm.[11] Calcd. for the *p*-bromophenylosazone of β,γ-diketovaleric acid, $C_{17}H_{16}N_4O_2Br_2$, N, 11.98. Found: N, 11.89, 11.60, 11.95.

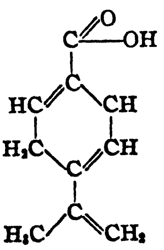
The analysis indicates that this compound is probably β,γ-diketovaleric acid.

Thus, the following compounds were obtained as the result of the hydrolysis of the ozonide prepared from dehydroperillic acid, formaldehyde, formic acid, acetaldehyde, acetic acid, oxalic acid, carbon dioxide and probably β,γ-diketovaleric acid.

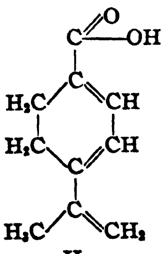
Discussion

Since the acid $C_{10}H_{12}O_2$ is so readily converted quantitatively into the isomeric compound, cuminic acid, and since it contains three double bonds as was established by catalytic hydrogenation, we propose the paramenthane structure as the underlying carbon skeleton of the acid. Consequently, the saturated acid obtained by the above method would be the liquid isomer of the solid hexahydrocuminic acid prepared by Markownikoff.[9]

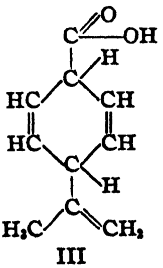
The identification of formaldehyde and formic acid among the products of hydrolysis from the ozonide implies the presence of a terminating methylene group somewhere in the molecule. The paramenthane carbon structure has three terminating carbon atoms. The only two with which we are concerned, however, are carbon atoms 7 and 9. Because carbon atom 7 is in the form of a carboxyl group, the terminating double bond could only be between carbon atoms 8 and 9. Excluding optically active formulas, there are three possible structures having a terminating methylene group, namely,



I



II



III

The only compound with the foregoing structures that would yield β,γ-diketovaleric acid as the result of the hydrolysis of its ozonide would be structure No. I. Should oxalic acid be of any diagnostic value in determining the structure of the compounds above, it would suggest structure II as being correct. However, since these compounds are so highly unsaturated, the formation of oxalic acid is probably of no direct value in determining the position of the double bonds. The formation of acetaldehyde and acetic acid could arise from the further degradation of either oxalacetic acid, semialdehyde of malonic acid, malonic acid or β,γ-diketovaleric acid.

---

[10] Harries and Kircher, *Ann.*, **374**, 353–356 (1910); *Ber.*, **40**, 1651 (1907).

[11] The authors are indebted to Dr. E. Schoeffel, of the University of Wisconsin, for the above microanalysis.

The further establishment of conjugated double bonds thus excluding structure III was evident from the molecular refraction exaltation observed from the methyl ester of the acid. The observed molecular refraction was 52.354, as compared with the calculated value, 51.154, for $C_{11}H_{14}O_2$ containing three double bonds. Further evidence of α,β-unsaturation or conjugated double bonds was suggested by the ease with which dehydroperillic acid reduced with sodium in the presence of either ethyl or amyl alcohol.

A careful investigation of the chemical literature indicates that no compound with the properties here described has been previously reported. We are convinced, therefore, that the acid described is new and suggest structure I for it. Since it has one more double bond than perillic acid, we propose to call it dehydroperillic acid (4 isopropylene-Δ^{3-6}-cyclohexadiene-1-carboxylic acid), in conformity with the name "dehydrogeranic acid" proposed by Cahn, Penfold and Simonsen,[12] for the olefinic acid $C_{10}H_{14}O_2$, which was isolated in the form of its geranyl ester from *Callitropsis araucarioides*.

With the exception of dehydrogeranic acid, dehydroperillic acid is probably the most highly unsaturated acid, containing as few as ten carbon atoms isolated from nature. To our knowledge this is the first menthatriene derivative that has been found to occur in nature.

The authors wish to acknowledge their indebtedness to J. Alfred Hall, Biochemist of the Forest Products Laboratory, for advice and criticism received throughout the course of this investigation.

Summary

The isolation of a new acid, dehydroperillic acid, from the heartwood of western red cedar is described. Experimental results show that this compound is an isomer of cuminic acid and a structural formula is suggested.

The methyl ester of dehydroperillic acid is described. It is a convenient derivative for identification. The liquid isomer of hexahydrocuminic acid is also described.

A toxic compound (tentative $C_{10}H_{12}O_2$) has been isolated from western red cedar, the identification of which is now being carried out at the Forest

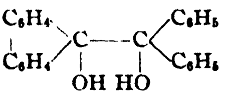
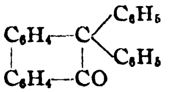
The Pinacol–Pinacolone Rearrangement. IV. The Rearrangement of Pinacols Containing the Biphenylene Group

BY W. E. BACHMANN AND HELEN R. STERNBERGER[1]

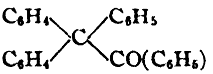
Meerwein[2] found that diphenylbiphenyleneglycol (I) on treatment with sulfuric acid gives 10,10-diphenylphenanthrone (II) but does not give any of the isomeric benzoylphenylfluorene (III) by migration of the phenyl group. Recently, Bergmann and Schuchardt[3] observed that dehydration by acetyl chloride gives benzoylphenylfluorene (III) and no diphenylphenanthrone. Furthermore, their discovery that benzoylphenylfluorene is isomerized into diphenylphenanthrone by sulfuric acid makes it appear probable that benzoylphenylfluorene is the true product of the rearrangement.



(I)



(II)

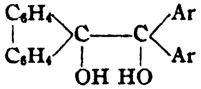


(III)

We find that diphenylbiphenyleneglycol (I) when treated with acetyl chloride actually gives a mixture of diphenylphenanthrone and benzoylphenylfluorene and not a single product as has been reported. Similarly,

TABLE I

REARRANGEMENT OF PINACOLS



Group Ar	Products	%	Group migrated
Phenyl	Benzoylphenylfluorene	78	Phenyl
	Diphenylphenanthrone	22	Biphenylene
m-Tolyl	*m*-Toluyl-*m*-tolylfluorene	54	*m*-Tolyl
	Di-*m*-tolylphenanthrone	46	Biphenylene
p-Tolyl[4]	*p*-Toluyl-*p*-tolylfluorene	14	*p*-Tolyl

[1] Presented in partial fulfilment of the requirements for the Ph.D. degree.

[2] Meerwein, *Ann.*, **396**, 200 (1913).

[3] Bergmann and Schuchardt, *ibid.*, **487**, 225 (1931).

[4] Bergmann and Schuchardt obtained a single rearrangement product.

two rearrangement products, corresponding to (II) and (III), are obtained from four other pinacols. The results are presented in Table I.

Giving a value of unity to the migration aptitude of the phenyl group one has the following series representing the relative migration aptitudes of the groups in biphenylene pinacols: phenyl, 1.0; *m*-tolyl, 0.33; biphenylene, 0.31; *p*-tolyl, 0.046; phenetyl, 0.012; anisyl, 0.006. The migration aptitudes of five of these groups, phenyl, *m*-tolyl, *p*-tolyl, phenetyl and anisyl, have been determined when they are situated in symmetrical pinacols.[5] In Table II is given a comparison of the relative migration aptitudes of these five groups in the two types of pinacols.

TABLE II

MIGRATION APTITUDES

Group	M_s (symmetrical pinacol)	M_b (biphenylene pinacol)	$1/M_b$
Phenyl	1.0	1.0	1.0
m-Tolyl	1.95	0.33	3.0
p-Tolyl	15.0	.046	22
Phenetyl	66	.112	83
Anisyl	70+	.006	170

It is observed that the order in the two series is exactly reversed; moreover, the reciprocals of the values for the migration aptitudes in the biphenylene pinacols are roughly of the same order as the values for the symmetrical pinacols. We are preparing and rearranging a large number of pinacols in order to determine whether the relation holds true for the whole class of biphenylene pinacols.

Experimental

Preparation of the Pinacols.—The pinacols were prepared by the action of a Grignard reagent on the methyl ester of biphenyleneglycolic acid.[2,4] A solution of 15 g. of the methyl ester was added to the Grignard reagent which had been prepared from 0.25 gram mole of aryl halide (*m*-bromotoluene, *p*-bromophenetole, etc.). After being refluxed for twelve hours the mixture was hydrolyzed. In this manner, dianisylbiphenyleneglycol, prepared by Bergmann and Schuchardt in 37% yield, was obtained by us in 80% yield. The yields and properties of the two new pinacols, di-*m*-tolylbiphenyleneglycol and diphenetylbiphenyleneglycol, are given in Table III.

Rearrangement of the Pinacols.—The pinacols were rearranged by a twenty-four hour treatment with acetyl chloride in benzene and acetic acid.[5] This agent does not isomerize benzoylphenylfluorene.

Analysis of Pinacolone Mixtures.—The mixture of benzoylphenylfluorene and diphenylphenanthrone from 3.64 g. (0.01 mole) of diphenylbiphenyleneglycol was heated with a solution of 6 g. of potassium hydroxide in 100 cc. of absolute alcohol for six hours. This process cleaved the benzoylphenylfluorene into benzoic acid and phenylfluorene but left the diphenylphenanthrone unchanged. Five separate runs gave an average of 0.0070 gram mole of benzoic acid. This represents a 78% migration of the phenyl group since a 95% yield of total products was obtained and a 95% yield of benzoic acid resulted by scission of pure benzoylphenylfluorene.

---

(5) Bachmann and Moser, THIS JOURNAL, 54, 1124 (1932), and unpublished results.

Practically the same results were obtained when both the benzoylphenylfluorene and the diphenylphenanthrone were cleaved, the latter being converted to 2-benzhydryl-2'-carboxylbiphenyl. The mixture of pinacolones was heated with a solution of 25 g. of potassium hydroxide in 100 cc. of methanol for three days. After removal of the solvent the product was treated with a mixture of water and benzene; potassium benzoate dissolved in the water while the potassium salt of the 2-benzhydryl-2'-carboxylbiphenyl was contained in the benzene layer along with phenylfluorene. Treatment with hydrochloric acid converted the salt to the free acid; when the mixture of phenylfluorene and acid was dissolved in hot *n*-propyl alcohol and the solution was allowed to cool, the phenylfluorene deposited first. The 2-benzhydryl-2'-carboxylbiphenyl was obtained in large colorless prisms; m. p. 175° with previous softening.[6] The potassium salt of the acid is little soluble in dry benzene but dissolves readily in wet benzene or in wet ether; it can be obtained as colorless leaflets by recrystallization from methanol.

The mixtures of pinacolones obtained from the other pinacols were analyzed in a similar manner; the values given in Table I represent the averages of several runs which checked each other closely. Di-*p*-tolylphenanthrone and dianisylphenanthrone are cleaved into the biphenyl acids by six hours of heating with 6% potassium hydroxide in ethanol; the properties of the acids and of other compounds are given in Table III. The yields are based on recrystallized product.

TABLE III

YIELDS AND PROPERTIES OF NEW COMPOUNDS

Compound	Yield, %	M. p., °C.	Recryst. solvents	Cryst. form	Analyses, % Calcd.	Analyses, % Found
Di-*m*-tolylbiphenyleneglycol	55	143.5–144.5	Acetone + alc.	Needles	C, 85.7 H, 6.2	85.2 6.2
Diphenetylbiphenyleneglycol	51	147–150	Acetone + alc.	Cubes	C, 79.6 H, 6.2	79.2 6.1
Di-*m*-tolylphenanthrone	62	198.0–198.5	Acetic acid	Diamond plates	C, 89.8 H, 5.9	89.6 6.0
Diphenetylphenanthrone	77	135.0–135.5	*n*-Propyl alc.	Fine needles	C, 82.9 H, 6.0	83.2 6.4
2-(Di-*p*-methylbenzhydryl)-2'-carboxybiphenyl[a]	76	193–194	*n*-Propyl alc.	Diamond plates	C, 85.7 H, 6.2	85.5 6.2
2-(Di-*p*-methoxybenzhydryl)-2'-carboxylbiphenyl	75	136–137	*n*-Propyl alc.	Heavy needles	C, 79.2 H, 5.7	78.9 6.2

[a] Bergmann and Schuchardt obtained an amorphous solid which they considered to be this acid from the reaction between ditolylphenanthrone and alkali.

Summary

Five pinacols containing the biphenylene group have been rearranged by acetyl chloride to mixtures of pinacolones. The order and extent of migration of the groups is the reverse of the migration aptitudes of the groups in symmetrical pinacols.

The Supposed Enolizing Power of Organic Magnesium Compounds

BY E. P. KOHLER AND DONALD THOMPSON

In a paper entitled "Researches on the Enolization of Ketones," Grignard and Blanchon[1] described the formation of a number of halomagnesium enolates by the action of isopropylmagnesium bromide on saturated ketones. In proof that their magnesium derivatives were enolates, they converted them into acetates with acetyl chloride and hydrolyzed the acetates to keto-enol mixtures in which they determined the enol content by the method of Job and Reich.[2]

Since the formation of an acetate by the action of acetyl chloride on a halomagnesium enolate which has no substituent in the alpha position is contrary to our experience,[3] we decided to repeat one of the experiments of Grignard and Blanchon in the hope of discovering the reason for the discrepancy, selecting for this purpose the reaction with cyclohexanone because cyclohexenyl acetate can be prepared by a method that leaves no doubt as to its structure.[4]

We began by operating as nearly as possible in accordance with the directions of the authors, but although we repeated their experiment a number of times, employing carefully purified cyclohexanone and isopropyl bromide, we were unable to isolate any cyclohexenyl acetate. By careful distillation under diminished pressure it was possible to secure a fraction which boiled approximately at the specified temperature, but the boiling point at the ordinary pressure (174–175°) and an analysis showed that this fraction was almost pure cyclohexyl acetate.

Anal. Calcd. for $C_8H_{14}O_2$: C, 67.6; H, 9.9. Found: C, 68.1; H, 10.1.

We then prepared pure cyclohexenyl acetate by the method of Mannich and Hancu and hydrolyzed it as directed by Grignard and Blanchon. But here also, in spite of many attempts, we were unable to duplicate their results; our hydrolysis product was always pure cyclohexanone.

Finally, in order to determine the primary products we added cyclohexanone to isopropylmagnesium bromide as directed, but decomposed the resulting magnesium compounds with ammonium chloride in the ordinary manner. We thus obtained two liquids, the one boiling at 160–161°, the other at 115–116° (2 mm.). The lower boiling liquid was identified as cyclohexanol by its boiling point, its index of refraction (n_D^{20} 1.4660) and the melting point of its phenyl urethan (82.5°). The higher boiling frac-

(4) Mannich and Hancu, *Ber.*, **39**, 1594 (1906); **41**, 564 (1908).

tion was identified as cyclohexylidene cyclohexanone by an analysis and a comparison of its semicarbazone (m. p. 177°) with that of an authentic sample. The yields were 34 g. or 68% of cyclohexanol and 11.6 g. or 26% of cyclohexylidene cyclohexanone from 49 g. of the ketone.

From the foregoing account it is evident that under the conditions favored by Grignard and Blanchon, at least 94% of the product of the reaction between cyclohexanone and isopropylmagnesium bromide is composed of substances which are not due to enolization but to reduction and to condensation. Lower temperatures, which according tot he French authors are less favorable to enolization, are in reality less favorable to reduction, the reduction product being in part replaced by the normal addition product. Thus at $-5°$ the yield of cyclohexanol was only 28%.

In view of these results we are compelled to conclude that Grignard and Blanchon were misled by the method of Job and Reich, and that they mistook cyclohexyl acetate for cyclohexenyl acetate, cyclohexanol for cyclohexenol. Grignard reagents containing secondary and tertiary hydrocarbon residues frequently act as condensing and reducing agents, but we can find no evidence that they are more effective than others in inducing enolization, and we also fail to find any evidence that any Grignard reagents can convert mono ketones into enolates unless the hindrance to addition is prohibitive.

Summary

An examination of the reaction between isopropyl magnesium bromide and cyclohexanone showed that Grignard and Blanchon must have mistaken reduction for enolization.

Some New Local Anesthetics Containing the Piperazine Ring

By John H. Gardner and John H. Schneider

As piperazine can be regarded as a double secondary amine, it seemed of interest to prepare and study a series of esters of piperazine-dialkanols, which could be regarded as compounds of the procaine type and therefore would be expected to possess local anesthetic activity. The only compound of this type noted in the literature was β-1,4-piperazine-diethyl benzoate which was described by Pyman. He stated that this substance shows[1] marked local anesthetic activity but is quite toxic.

In the present investigation, β-1,4-piperazine-diethanol and γ-1,4-piperazine-dipropanol were prepared by the condensation of piperazine with ethylene chlorohydrin or with trimethylene chlorohydrin. γ-1,4-Piperazine-dipropyl benzoate was prepared by the action of benzoyl chloride on the corresponding alcohol in pyridine solution. The phenyl urethans were formed by the action of phenyl isocyanate on the alcohols in anhydrous acetone, and the cinnamates were prepared with cinnamoyl chloride in acetone. The hydrochlorides were prepared by treating alcoholic solutions of the esters with hydrogen chloride in alcohol.

---

[1] Pyman, *J. Chem. Soc.*, **93**, 1802 (1908).

No quantitative pharmacological data have as yet been obtained on these compounds, but all show decided local anesthetic activity on the tongue. All of the compounds give rather acid solutions and are precipitated from solution at rather low *P*H values.

Experimental

β-1,4-Piperazine-diethanol.—This was prepared by the method of Pyman.[1]

γ-1,4-Piperazine-dipropanol.—This was prepared in a similar manner, using trimethylene chlorohydrin in place of ethylene chlorohydrin; yield, 48%, m. p. 142–143°.

Anal. Calcd. for $C_{10}H_{22}O_2N_2$: N, 13.88. Found: N, 13.87.

Ester Hydrochlorides.—The yields, properties and composition of the new hydrochlorides are shown in Table I.

TABLE I

			Analyses, %			
	Yield,	M. p.,	Calcd.		Found

A Group of Isomeric Esters[1]

BY JOHN R. RUHOFF[2] AND E. EMMET REID

The preparation and investigation of the group of esters having the formula RCOOR′, where R and R′ are normal saturated aliphatic residues, containing fifteen carbon atoms together, were undertaken in connection with other work on the general problem of the relation of structure to physical properties. The present paper describes the synthesis and the determination of the more common physical constants of these compounds. Further physical and chemical studies are being carried on in this Laboratory.

Although certain of these esters have been prepared before, it was felt desirable, in order to make significant comparisons of physical properties, to have samples of comparable purity. All of the fifteen isomers have been made in quantities sufficient (usually 1 mole, 256 g.) to permit of a

high degree of purification and to allow the determination of a wide range of physical and chemical properties.

Emphasis was placed primarily on the preparation of compounds of the highest purity consistent with the attendant experimental difficulties, rather than on high yields. Yields are therefore not reported, but in almost all reactions they were 70% or more. All distillations were carried out in precision stills.[3] Each intermediate was fractionated; except in a few instances, the portion used for synthesis boiled with a range of 0.4° or less.

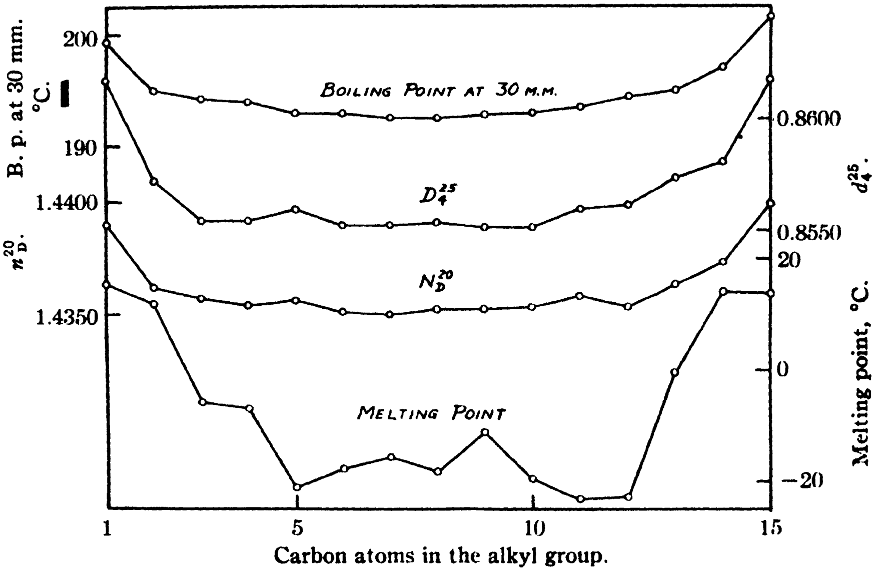

Fig. 1.

The results of the physical measurements are given in Table I and summarized in Fig. 1. When the data are plotted against the number of carbon atoms in the alcohol, the curves obtained for the boiling points, refractive indexes, and densities are very similar. Distinct alternation of the refractive indexes and densities occurs near the ends of the curves; the values for the middle five esters are practically identical. It is noteworthy that high values are found for the 5-11 and 11-5 compounds. The boiling points are remarkably close together; the extreme range is 9° and all except three of the compounds boil within 2.5° of each other. The melting points, on the other hand, cover a range of almost 40°; for the most part they show alternation.

Experimental

(A) **Alcohols.**—Amyl alcohol was prepared by the Grignard reaction from butyl bromide and formaldehyde. Hexyl, nonyl, undecyl, tridecyl, tetradecyl, and penta-

decyl alcohols were prepared by the reduction of an ester of the corresponding acid with sodium in butyl alcohol.[4] Octyl, decyl and dodecyl alcohols were obtained by the fractionation of "Lorol," purchased from Germany. Heptyl alcohol was prepared by the reduction of heptaldehyde with iron filings in acetic acid,[5] with a small amount of nickel chloride as a catalyst. Baker 40-mesh degreased cast iron fillings were used. In over fifty reductions made in this Laboratory, the reaction has never failed to occur when nickel chloride was added.

(B) **Acids.**—Valeric, tridecylic and pentadecylic acids were prepared from the proper bromides and potassium cyanide.[6] Caproic and pelargonic acids were prepared by the malonic ester synthesis from butyl and heptyl bromides, respectively. Anhydrous butyl alcohol was used as a solvent. Caprylic, capric, lauric and myristic acids were obtained by the fractionation of the ethyl esters made from coconut oil acids. Undecylic acid was obtained by the hydrogenation of ethyl undecylenate at 220°, using a high speed stirrer[7] and 4% of nickel formate as a catalyst. Heptoic acid was prepared by the oxidation of heptaldehyde with potassium permanganate and 20% sulfuric acid at 20°.

(C) **Esters.**—**Methyl pentadecylate, ethyl myristate and propyl tridecylate** were prepared by heating together 1 mol of the acid, 4 mols of alcohol containing 3–5% of anhydrous hydrochloric acid, and 30 g. of anhydrous calcium chloride.

Butyl Laurate.—To 1 mol of lauric acid was added 3 mols of anhydrous butyl alcohol, containing 20 g. of anhydrous hydrochloric acid. After the solution had been refluxed a short time two layers formed. The lower (water) layer was removed, and the butyl alcohol distilled off slowly.

Amyl Undecylate, Hexyl Caprate, Heptyl Pelargonate, Octyl Caprylate, Nonyl Heptoate, Decyl Caproate and Undecyl Valerate.—One mol of alcohol, 1 mol plus 10 g. of acid, and 15 g. of anhydrous hydrochloric acid were warmed together until two layers were formed. The lower layer was removed, and the residue was gradually heated to 180° during the course of two hours while a slow stream of carbon dioxide was passed through it.

Dodecyl Butyrate and Tridecyl Propionate.—One mol of alcohol, 1.5 mols of acid (3 mols in the case of the propionic acid), and 25 g. of anhydrous hydrochloric acid were distilled together slowly until the boiling point rose to that of the acid.

Tetradecyl acetate was prepared from the alcohol, acetic anhydride and sodium acetate by the usual well-known procedure.

Pentadecyl Formate.—One hundred and eighty grams of pentadecyl alcohol, 460 g. of 90% formic acid and 400 cc. of carbon tetrachloride were heated in a continuous esterification apparatus for twenty-four hours; at the end of that time the reaction was 85% complete. The pentadecyl formate and the residual pentadecyl alcohol were separated and refluxed for six hours with 460 g. of anhydrous formic acid.[8] The ester layer was separated and distilled slowly with 600 cc. of carbon tetrachloride and 230 g. of anhydrous formic acid until the boiling point rose to 100°.

Purification of Esters.—The esters, with the exception of pentadecyl formate, were washed twice with warm water, then with warm 1 to 50 ammonia water, twice with warm water again, dried with calcium chloride, filtered, and distilled at 30 mm.

Freezing Points.—The freezing points were determined with a copper–constantan thermocouple in an apparatus designed by R. H. Smith, and similar to that described by Andrews, Kohman and Johnston.[9]

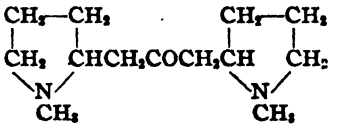
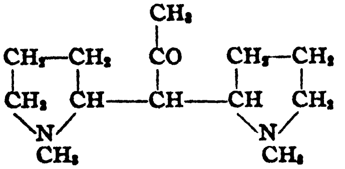
The Structure of Cuscohygrine. Synthesis of Ethyl Homohygrinate

BY W. E. SOHL AND R. L. SHRINER

Two structures have been proposed for cuscohygrine, one of the alkaloids associated with cocaine occurring in "cusco" leaves, a variety of South American coca. The structure (I) was suggested by Liebermann and Cybulski,[1] who were the first to isolate and study the alkaloid. Hess and his associates[2] have suggested the isomeric formula (II). Both structures



I



II

are in agreement with the fact that cuscohygrine gives the typical reactions for a ketone group[2a] and that oxidation with chromic acid yields hygrinic acid (III) whose structure had been established by Willstätter.[3] Although Formula I is the only one which is consistent with the formation of *n*-undecane and *n*-undecanol-6 by an exhaustive methylation and degradation[4] of dihydrocuscohygrine, the structure represented by II has been

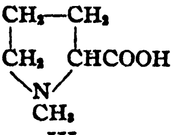
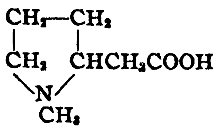
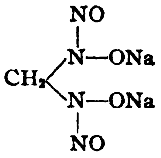
favored chiefly because the degradation of cuscohygrine by Traube's reaction[5] (nitric oxide plus sodium ethoxide) produced homohygrinic acid (IV) and the sodium salt of methylene di-isonitramine[2a] (V) which was supposed to come from the methyl ketone group of Formula (II).



III



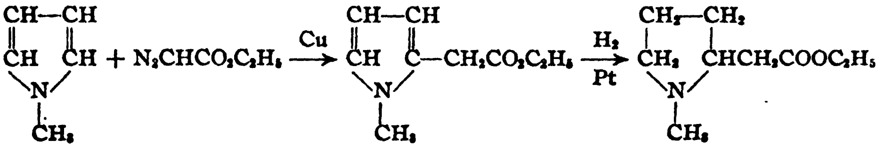
IV



V

Homohygrinic acid was also produced in very small amounts in the chromic acid oxidation of cuscohygrine.[6] Its structure was deduced from analyses and has not previously been confirmed by synthesis. In the present study the structure of homohygrinic acid (IV) has been definitely established by the synthesis of its ethyl ester.

All attempts to rearrange ethyl 1-pyrrylacetate resulted only in the formation of pyridine,[7] but by means of the recently described reaction[8] between 1-methylpyrrole and diazoacetic ester the 1-methyl-2-pyrrylacetic ester (I) was readily obtained. By means of a special reduction procedure this pyrrole compound was reduced catalytically to the 1-methyl-2-pyrrolidine acetic ester (II) with hydrogen and a platinum catalyst.[9]



I II

For purposes of comparison, a sample of cuscohygrine whose composition and molecular weight were checked was subjected to the Traube reaction[5] following exactly the procedure described by Hess[2a] and ethyl homohygrinate isolated. The data in Table I show the comparisons between the synthetic product and that obtained from cuscohygrine.

Although the product obtained by degradation distilled within a one-degree range it was not quite pure as evidenced by the differences in density and refractive index. Since the amount of ethyl homohygrinate obtained was about one gram it was impossible to fractionate it further in order to check the physical constants exactly. Hence, three solid derivatives were prepared and recrystallized to constant melting point. The mixed melting point determinations of all three pairs of solid derivatives

Refractive index	1.4501^{20}	1.4490^{20}	....

showed no depression and all analyzed correctly, thus establishing the structure of homohygrinic acid as IV.

Moreover, a study of the conditions under which ketones react with nitric oxide and sodium ethylate according to Traube's procedure demonstrated that the sodium methylene di-isonitramine (V) was produced from the ethyl alcohol used as a solvent[10] and not from cuscohygrine at all. This salt was formed from ethyl alcohol in the absence of cuscohygrine and no such precipitate was obtained when the reaction was carried out in methyl alcohol. In addition, Traube[5] showed that in ketones of the formula CH_3COCH_2R, the nitric oxide and sodium ethylate attacked the methylene group and not the methyl group. The same is true of methyl acetoacetic ester where it is the methine carbon atom which reacts.

Finally, it was established that cuscohygrine does not give the iodoform test which is characteristic of methyl ketones. In order to be certain that the tertiary amino group did not affect adversely the application of this test, the ketone $(C_2H_5)_2NCH_2CH_2COCH_3$ was synthesized and found to give a positive iodoform test. Sodium hypobromite and cuscohygrine gave no bromoform and no acetic acid; the production of which represents one other possible phase of the haloform reaction.[11]

Two remaining objections to Formula I have been cited. It is stated that such a compound should condense with benzaldehyde whereas no such reaction seems to take place. Although diethyl ketone does condense with benzaldehyde[12] the methyl ketones generally react much more readily[13] and hence the non-reactivity of cuscohygrine with benzaldehyde really counts as evidence against formula II.

Treatment of cuscohygrine with bromine yielded a red compound containing three atoms of bromine. This derivative, which may be a mono-

---

(10) Stechow [*Ber.*, **57**, 1615 (1924)] has also pointed out that ethyl alcohol, nitric oxide and sodium ethylate produce sodium methylene di-isonitramine and that conclusions regarding structure cannot be drawn from this phase of the Traube reaction.

bromo-dihydrobromide or a perbromide, liberated iodine from potassium iodide and on treatment with acetone produced bromoacetone and regenerated cuscohygrine as its dihydrobromide salt.

The last objection cited against formula (I) is that it does not explain the formation of two isomeric hydrazones. It should be pointed out that there are two similar asymmetric carbon atoms and hence the two reported hydrazones may be derived from the meso and racemic forms of (I), respectively.

Experimental

Ethyl 1-Methyl-2-pyrrylacetate.—In a flask equipped with dropping funnel and reflux condenser was placed 70 g. of 1-methylpyrrole with 2 g. of fine copper bronze. The liquid was warmed on the steam cone and 35 g. of ethyl diazoacetate was added during one hour and heated for an additional half hour. The copper was removed by filtration and the liquid fractionated. Fifty grams of 1-methylpyrrole was recovered and 24.7 g. (67.3%) of 1-methyl-2-pyrrylacetic ester was obtained as a light yellow liquid boiling at 115–118° (10 mm.) and 105–110° (6 mm.).

Reduction of Ethyl 1-Methyl-2-pyrrylacetate.—The reduction was carried out in a special vessel made by joining the neck of a 200-cc. round-bottomed flask through a 5-mm. Pyrex glass stopcock to the bottom of a second 200-cc. round-bottomed flask. This arrangement permitted the catalyst (0.6 g. platinum oxide) to be reduced separately and the ester (7.5 g.) could be introduced and the apparatus freed from air. Additional catalyst could be added as needed.

After the reduction was completed (twenty-four hours) the catalyst was removed by filtration and 15 cc. of concentrated hydrochloric acid added to the filtrate. The alchol and acetic acid were removed by distillation under vacuum. The residue was then treated with cold saturated potassium carbonate solution, extracted with ether and dried over solid potassium carbonate. The ether was then evaporated and the ester fractionated; b. p. 88–89° (10 mm.), 78° (6 mm.); d_4^{20} 0.96838; n_D^{20} 1.4465; M_D calcd., 47.35; found, 47.30.

Anal. Calcd. for $C_9H_{17}O_2N$: N, 8.18. Found: N, 8.33.

Cuscohygrine.—Thirty-five grams of cuscohygrine dinitrate was dissolved in 25 cc. of water and an excess of saturated sodium hydroxide solution added. The free base separated as a clear oil. The aqueous lower layer was extracted five times with ether. The extracts were combined and dried over anhydrous magnesium sulfate for several days. The ether solution was then filtered and the ether distilled.

The cuscohygrine was distilled at 2 mm. pressure and boiled at 118–125° (corr.); d_4^{20} 0.9733; n_D^{20} 1.4832; M_D calcd., 66.02; found, 65.75. *Mol. wt.* (cryoscopic in benzene). Calcd. for $C_{13}H_{24}ON_2$: 224. Found: 223.

Anal. Calcd.: N, 12.50. Found: N, 12.27.

Cuscohygrine gave no iodoform when treated with sodium hypoiodite and no bromoform with sodium hypobromite as the reagent. A careful examination of the products of the latter reaction showed that no acetic acid was produced.[11]

No condensation products with benzaldehyde could be obtained in the presence of either alkali or acid using the customary procedures.[12,13]

Preparation of Ethyl Ester of Homohygric Acid from Cuscohygrine.—A three-necked, one-liter flask equipped with a mercury-sealed stirrer, a dropping funnel and a tube for entrance of nitric oxide gas was swept free of air with nitric oxide which was generated in a Kipp apparatus by the action of dilute (1:1) nitric acid on copper. The nitric oxide was washed with water to remove higher oxides of nitrogen and then dried in a tube filled with soda lime. When the brown color due to the presence of higher oxides of nitrogen disappeared the flask was considered to contain no air.

Six-tenths mole of sodium was dissolved in 250 cc. of absolute alcohol and then run into the nitric oxide filled flask. The cuscohygrine was added and stirring started. The nitric oxide was absorbed very rapidly at first and then at about 15 cc. per minute. After eighteen hours the absorption had ceased. About 30 cc. of water was added to the cherry-red solution which caused a slimy solid to precipitate. This solid was filtered, dissolved in 100 cc. of water and the solution acidified with acetic acid. Addition of lead acetate gave a precipitate which on decomposition with sulfuric acid gave lead sulfate. No pure organic compound could be isolated from this solution.

The alcoholic filtrate from which the slimy precipitate was removed was next acidified with hydrochloric acid and filtered. The alcohol was evaporated and the residual solution was made alkaline with sodium hydroxide and extracted six times with ether to remove unchanged cuscohygrine which amounted to 5 g.

The alkaline residue was acidified with hydrochloric acid and evaporated to dryness over water-bath, then dried completely in a vacuum over phosphorus pentoxide. The brown hard residue was broken up and placed in a 500-cc. round-bottomed flask with 250 cc. of absolute alcohol and the mixture saturated with dry hydrogen chloride. This mixture was refluxed for one day, then cooled to below 0° in an ice-salt-bath and made alkaline with saturated solution of potassium carbonate. The alcohol ester layer was separated and dried with magnesium sulfate. The alcohol was distilled and a high boiling fraction collected. This high boiling material was next refractionated and the portion boiling at 72–73° (6–7 mm.) collected. This amounted to about 1 g., n^{20}_{D} 1.4501; d^{20}_{4} 0.9900.

Anal. Calcd. for $C_9H_{17}O_2N$: N, 8.18; C, 63.10; H, 10.02. Found: N, 10.27, 10.24; C, 62.75; H, 10.24.

These analyses show that the degradation product was not pure but the amount available was insufficient for further fractionation.

Preparation of Derivatives.—Three solid derivatives of the synthetic ester and of the ethyl homohygrinate from cuscohygrine were prepared. Their properties and analyses are summarized in Table II.

Table II

Derivatives of Ethyl 1-Methyl-2-pyrrolidineacetate

		Synthetic			From cusocohygrine		
			Analysis, %			Analysis, %	
	Formula	M. p., °C.	Calcd.	Found	M. p., °C.	Calcd.	Found
Picrate	$C_{15}H_{20}O_9N_4$	112–113	N, 14.00	14.58	112–113	N, 14.00	14.27
Methiodide	$C_{10}H_{20}O_2NI$	121–122	I, 40.54	40.46	120–121	I, 40.54	40.89
Chloraurate	$C_9H_{17}O_2N\cdot AuCl_3\cdot 2H_2O$	133–134	Au, 38.61	38.40	134–135	Au, 38.61	38.90

The chloroplatinate and methyl *p*-toluene sulfonate were liquids and the flavianic acid salts were too soluble.

Action of Bromine on Cuscohygrine.—The free base was dissolved in 90 g. of glacial acetic acid and 10 g. of acetic anhydride and treated with 6.4 g. of bromine whereupon an oily red precipitate formed which later solidified. This was removed by filtration. The product could not be recrystallized and hence the analysis for bromine was high.

Anal. Calcd. for $C_{13}H_{25}N_2OBr_3$: Br, 51.56. Found: Br, 53.37.

The red substance on treatment with acetone precipitated a white powder melting at 236° with decomposition at 240°.

Anal. Calcd. for $C_{13}H_{26}N_2OBr_2$: Br, 41.40. Found: Br, 40.70.

A sample of cuscohygrine dihydrobromide was prepared from cuscohygrine and hydrobromic acid. It melted at 239° and was identical with the above product.

1-Diethylaminobutanone-3.[14]—In a 500-cc. flask fitted with a reflux condenser was placed 43 g. of formalin solution, 54.7 g. of diethylamine hydrochloride and 145 g. of acetone. The mixture was refluxed for twelve hours and the acetone and some water removed by distillation. The residue was treated with potassium carbonate solution and extracted with ether. The ether extract was dried over potassium carbonate and then fractionated. The amino ketone boiled at 84° (30 mm.) and 53° (4 mm.); yield, 31 g. or 42%.

Anal. Calcd. for $C_8H_{17}ON$: N, 9.79. Found: N, 9.80.

Treatment of this amino ketone with sodium hypoiodite yielded yellow crystals of iodoform melting at 118–119°.

Summary

1. Ethyl 1-methyl-2-pyrrolidineacetate has been synthesized by the catalytic reduction of the ethyl 1-methyl-2-pyrrylacetate which was prepared from 1-methylpyrrole and ethyl diazoacetate.

2. This synthetic ester was identical with ethyl homohygrinate obtained as a degradation product of cuscohygrine by the action of nitric oxide and sodium ethylate.

3. Cuscohygrine did not react with benzaldehyde and failed to give an iodoform test.

4. These data together with previous investigations indicate that cuscohygrine is probably a *sym-bis*-(1-methylpyrrolidyl)-acetone.

Synthesis and Resolution of Phenyl-α-(β-methoxynaphthyl)-aminomethane

BY FRANCIS EARL RAY AND WILLIAM A. MOOMAW

In a previous paper[1] the authors described the effect of negative substituents in the benzene ring on the amines resulting from the condensation of aromatic aldehydes with β-naphthol and ammonia. It was found that the presence of negative substituents decreased the stability of the amines.

As it was thought that the tautomerism of the β-naphthol contributed to the instability of the amine we sought to replace the ionizable hydrogen with a methyl group.

When, however, β-methoxynaphthalene was mixed with benzaldehyde and ammonia no reaction took place. It was necessary, therefore, to use other means to synthesize the desired amine. Attempts to methylate or acetylate the hydroxy group, I, were unsuccessful as the amino group reacted first.[2] If the amino group was first blocked the hydroxyl group could be methylated or acetylated but it was then impossible to remove the amino acetyl group without decomposing the compound.

---

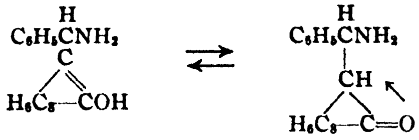
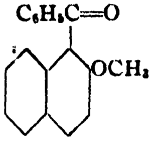
[2] Nzeer Ahmed, Master's Thesis, University of Cincinnati, 1933



I II

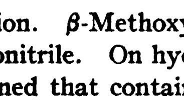


III

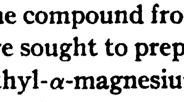
An attempt was made to prepare the desired amine by first making the ketone, III, by the Friedel–Crafts reaction, converting this into the oxime, and finally reducing the oxime to the amine, IV.

The ketone, III, was readily prepared but it did not react with hydroxylamine or phenylhydrazine. This is an extension of Meyer's rule[3] to the effect that when a carbonyl group is connected to an aromatic nucleus which contains two substituents ortho to it no oxime or hydrazone is formed. In view of the fact that the phenylhydrazone was prepared by indirect means it may also be possible to find conditions that will give the desired oxime. The problem of steric hindrance as applied to these compounds is being studied further in this Laboratory.

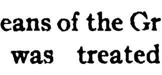
There was also the possibility that the methyl group might, under the influence of aluminum chloride, migrate from oxygen to a carbon of the nucleus, a somewhat general reaction of the phenol ethers.[4]



IV



V



m. p. 98°

VI

In order to determine if the compound from the Friedel–Crafts condensation had the structure III, we sought to prepare it by means of the Grignard reaction. β-Methoxynaphthyl-α-magnesium iodide was treated with benzonitrile. On hydrolysis with water and dilute acid a compound was obtained that contained iodine. When this compound was treated with alkali an iodine-free basic substance was obtained which was identified as phenyl-α-(β-methoxynaphthyl)-ketimine, V. Hot alkali or boiling acid hydrolyzed this to the ketone, III, identical with that prepared by the Friedel–Crafts reaction. Each was separately reduced to the identical alcohol,[5] VI, thus proving that no rearrangement had occurred in the reaction with aluminum chloride. The same alcohol was obtained by

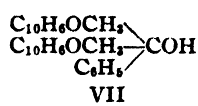
---

(3) Meyer, *Ber.*, **29**, 830 (1896); compare the esterification rule of Meyer and Sudborough, *ibid.*, **27**, 510, 1580, 3146 (1894).

(4) Smith, This Journal, **55**, 849 (1933).

(5) Bauer [*Ber.*, **42**, 2589 (1909)] has reported a melting point of 237° for this compound but gives no analytical data. This melting point is entirely out of line with that of similar compounds; diphenylcarbinol 68°, α-naphthylphenylcarbinol 86°, di-α-naphthylcarbinol 147°.

reaction of β-methoxynaphthyl-α-magnesium iodide with benzaldehyde. When the Grignard reagent was treated with methyl benzoate there was isolated in addition to the ketone, III, the tertiary alcohol, VII.



$$\left.\begin{array}{l}C_{10}H_6OCH_3\\C_{10}H_6OCH_3\\C_6H_5\end{array}\right\rangle COH$$

VII

It is interesting to note that although the ketone gave no hydrazone the ketimine, V, readily reacted with phenylhydrazine to give the required phenylhydrazone, VIII.

$$\underset{\text{V}}{C_6H_5(C_{10}H_6OCH_3)C{=}\boxed{NH\ \ H_2}NNHC_6H_5} \longrightarrow \underset{\text{VIII}}{C_6H_5(C_{10}H_6OCH_3)C{=}NNHC_6H_5}$$

Though we were unable to use the ketone in the preparation of the amine due to our inability to prepare the intermediate oxime, our objective was reached by reducing the ketimine, V, to the amine, IV, with sodium amalgam. This amine was resolved into its enantiomorphous forms by means of *l*-malic acid.

The new amine showed none of the tendency to decompose that had been noted for the amines with a free naphtholic group; the specific rotation was over three times as great; and the compound was more basic.

Phenyl-β-naphtholaminomethane may be recrystallized from acetone but our amine reacts with acetone at ordinary temperatures giving a sparingly soluble Schiff base that is excellent for purposes of identification. Benzaldehyde also reacts with our amine to give a similar Schiff base.

Experimental Part

Phenyl-α-(β-methoxynaphthyl) Ketone.—This compound was prepared by condensing benzoyl chloride and β-methoxynaphthalene by means of aluminum chloride in carbon disulfide. After reacting, the mass was poured into water and steam distilled. The residue was recrystallized from alcohol; m. p. 125° corr.; yield 85%.

Anal. Calcd. for $C_{18}H_{14}O_2$: C, 82.44; H, 5.34. Found: C, 82.6; H, 5.4. *Mol. wt.* (Rast method) Calcd.: 262. Found: 270.

α-Iodo-β-naphthol, m. p. 94°, was prepared in 72% yields according to the method of Mendola.[6]

α-Iodo-β-methoxynaphthalene.—This was obtained from the above-mentioned compound by treatment with methyl sulfate and 10% alkali. One recrystallization from alcohol gave cream colored plates melting at 88°. The yield was 80%.

Anal. Calcd. for $C_{11}H_9OI$: C, 46.49; H, 3.17. Found: C, 46.8; H, 3.2.

β-Methoxynaphthyl-α-magnesium Iodide.—This Grignard reagent was prepared by using the magnesium iodide catalyst prepared according to Gilman's[7] method. The concentration was determined by titration and a conversion as high as 80% was obtained.

Phenyl-α-(β-methoxynaphthyl)-carbinol.—The Grignard reagent prepared as described was treated with redistilled benzaldehyde. On decomposition of the addition product the alcohol was obtained. Recrystallization from alcohol in which it was rather soluble gave the pure compound melting at 98° corr.; yield 70%.

---

(6) Mendola, *J. Chem. Soc.*, **47**, 526 (1885).

(7) Gilman, Peterson and Schulze, *Rec. trav. chim.*, **47**, 19 (1927).

Anal. Calcd. for $C_{18}H_{16}O_2$: C, 81.79; H, 6.10. Found: C, 81.5; H, 6.0. *Mol. wt.* (Rast method) Calcd. 264. Found: 265.

This alcohol was also obtained by reducing the ketone prepared by the Friedel–Crafts reaction with sodium amalgam. Mixed melting points showed them to be identical.

Phenyl-α-(β-methoxynaphthyl)-ketimine Hydriodide.—Twenty grams of α-iodo-β-methoxynaphthalene was converted into the Grignard reagent and filtered from the undissolved magnesium. Six grams (0.87 mol) of pure benzonitrile in 25 cc. of ether was slowly added. The addition product first settled as an oil but after refluxing for four hours it changed to a yellow crystalline solid. The ether was decanted and the residue was treated with ice and dilute sulfuric acid. At first the product of hydrolysis separated as an oil but soon solidified to a yellow crystalline mass. When recrystallized from hot water it melted at 180° corr. An alcoholic solution when treated with silver nitrate gave a precipitate of silver iodide. The iodide is soluble in alcohol, benzene, acetone and chloroform as well as hot water. It is sparingly soluble in ether and cold water; yield 90% based on the Grignard concentration.

Anal. Calcd. for $C_{18}H_{16}ONI$: C, 55.53; H, 4.14; I, 32.79. Found: C, 55.7; H, 4.2; I, 33.0.

The ketimine hydroiodide was remarkably stable. Boiling with dilute hydrochloric acid for two hours resulted in only a 25% hydrolysis to the ketone. This product melted at 125° and was identical with the ketone prepared by methods already described.

Phenyl-α-(β-methoxynaphthyl)-ketimine was prepared from the hydroiodide by neutralizing in ice-cold alcoholic solution with an equal volume of dilute potassium hydroxide. After standing some hours a coarse granular precipitate of the free ketimine separated. An almost quantitative yield of the base resulted, melting at 98–99°. The free ketimine was very soluble in alcohol, ether and benzene, but was only sparingly soluble in water and petroleum ether. It dissolved in dilute mineral acids on warming with the formation of salts similar to the hydroiodide.

Anal. Calcd. for $C_{18}H_{15}ON$: C, 82.78; H, 5.75; N, 5.36. Found: C, 82.5; H, 5.8; N, 5.4.

The phenylhydrazone could not be prepared directly from the ketone. It was, however, obtained by warming 0.7 g. of the ketimine in 10 cc. of alcohol with 0.5 g. of phenylhydrazine and one cc. of glacial acetic acid. Two cc. of water was added and the mixture allowed to stand. After six hours one gram of material (80% of theoretical) had settled out. It was washed with alcohol and melted at 183.5° corr.

Anal. Calcd. for $C_{24}H_{20}ON_2$: C, 81.82; H, 5.72; N, 7.95. Found: C, 81.6; H, 5.7; N, 8.35.

Phenyl-di-α-(β-methoxynaphthyl)-carbinol.—The reaction between the Grignard reagent and methyl benzoate gave largely the ketone melting at 125°, which was extracted from the reaction mass with hot alcohol. The residue proved to be the tertiary alcohol. It was recrystallized from nitrobenzene, washed with hot alcohol and found to melt at 202–203° corr.

Anal. Calcd. for $C_{29}H_{24}O_3$: C, 82.82; H, 5.76. Found: C, 82.1; H, 5.8. *Mol. wt.* Calcd. 420. Found: 426.

Phenyl-α-(β-methoxynaphthyl)-aminomethane.—The ketimine was reduced to the amine by the following method. To 100 g. of 2% sodium amalgam was added 40 cc. of dry benzene, 20 cc. of dry ether and 15 cc. of absolute alcohol. To this was added in small portions 8.5 g. of the ketimine. The flask was shaken after each addition. When the ketimine had been added the flask was shaken at five-minute intervals for twenty-five minutes. The organic liquid was decanted, dried with sodium sulfate and evaporated to dryness. This residue was well washed with petroleum ether to remove the coloring matter and twice recrystallized from alcohol. It then melted at 102° corr.; yield 70%. The amine was readily soluble in cold benzene and hot alcohol and moderately soluble in cold alcohol, ether and chloroform.

Anal. Calcd. for $C_{18}H_{17}ON$: C, 82.13; H, 6.46; N, 5.32. Found: C, 82.0; H, 6.6; N, 5.6.

Schiff Base with Acetone.—One-half gram of the amine was dissolved in 5 cc. of alcohol. Two cc. of acetone was added and the mixture heated to boiling. After standing one and one-half hours 0.47 g. of material separated. The crystals were washed with alcohol; m. p. 162° corr.

Anal. Calcd. for $C_{21}H_{21}ON$: C, 83.13; H, 6.98; N, 4.62. Found: C, 83.5; H, 7.2; N, 4.97.

Schiff Base with Benzaldehyde.—Seven-tenths gram of the amine was dissolved in 8 cc. of hot alcohol. Five-tenths gram of benzaldehyde was added and the solution allowed to stand. After two hours an oil separated which was removed and rubbed with a few drops of alcohol to induce crystallization. The crystals were washed with alcohol. A yield of 0.73 g. melting at 98° corr. was obtained.

Anal. Calcd. for $C_{25}H_{21}ON$: C, 85.43; H, 6.03; N, 3.99. Found: C, 85.7; H, 6.3; N, 4.0.

N-Acetyl-phenyl-α-(β-methoxynaphthyl)-aminomethane.—One gram of the amine was dissolved in 10 cc. of benzene and 3 cc. of ether. An excess (0.5 cc.) of acetyl chloride was added and the mixture treated with pyridine. One-half gram melting at 186.5–187° was obtained. By mixed melting points this was shown to be the same as the compound obtained by first acetylating and then methylating phenyl-β-naphthol-aminomethane.[3]

Anal. Calcd. for $C_{20}H_{19}O_2N$: N, 4.59. Found: N, 4.7.

Phenyl-α-(β-methoxynaphthyl)-aminomethane Hydrochloride.—This compound was prepared by treating an alcoholic solution of the amine with dilute hydrochloric acid. It melted with decomposition at 237–240°.

Anal. Calcd. for $C_{18}H_{18}ONCl$: Cl, 11.84. Found: Cl, 12.0.

Resolution of the Amine.—One mol (2.53 g.) of the amine was dissolved in 60 cc. of alcohol at 40°. To this was added 1.27 g. (one mol) of *l*-malic acid in 10 cc. of alcohol. Crystals soon appeared and after standing for four hours they were filtered and washed with alcohol. A yield of 1.81 g. of the salt melting at 186° was obtained. Three more fractions were obtained from the mother liquor, the next to the last being the purest which melted at 164°. When dissolved in methyl alcohol the salts showed but slight optical activity.

The salts were treated with potassium hydroxide and extracted with ether. The first fraction showed the highest dextro rotation and gave α_D +3.05°, $[\alpha]^{25}_D$ +197°, for 0.1550 g. of amine in 10 cc. of ether in a 1-dm. tube.

The third fraction contained the levo rotatory amine and 0.1229 g. of the free base in 10 cc. of ether gave α_D −2.49°, $[\alpha]^{25}_D$ −202°.

As yet neither of the active forms of the amine has been obtained in a crystalline state. When small amounts of *d*- and *l*-amines were mixed they at once solidified to give the racemic compound.

Summary

Phenyl-α-(β-methoxynaphthyl)-aminomethane has been prepared and resolved into its optical antipodes. Many of the derivatives have also been prepared.

This amine is quite stable in contrast to phenyl-β-naphtholaminomethane. This lends weight to the theory that the tautomerism of the hydroxyl group in the latter compound contributes to its instability.

The Spatial Configuration of the Valences in Tricovalent Carbon Compounds[1]

BY EVERETT S. WALLIS AND FREDERIC H. ADAMS

The tetrahedral configuration of the valences of quadricovalent carbon has been generally accepted since the classical researches of van't Hoff and Le Bel. However, the spatial arrangement of the groups in compounds containing a tricovalent carbon atom has not been definitely proved. For the sake of clearness in discussion all tricovalent carbon compounds may be divided into three classes: (1) "carbanions"[2]  $\left[R_2:\overset{R_1}{\underset{R_3}{\ddot{\underset{..}{C}}}}:\right]^-$, (2) free radicals  $\left[R_2:\overset{R_1}{\underset{R_3}{\ddot{\underset{..}{C}}}}\cdot\right]$, and (3) carbonium ions  $\left[R_2:\overset{R_1}{\underset{R_3}{\ddot{\underset{..}{C}}}}\right]^+$. Much interest is attached to the possibility of the existence of a non-planar configuration in these compounds. If such a spatial arrangement be true, asymmetry would be possible when the three aryl groups around the central carbon atom are different. A study of the behavior of such compounds toward polarized light would also enable us to determine the degree of stability of the antimeric configurations. It is hardly possible experimentally to resolve such substances directly into *dextro* and *levo* forms. It would be necessary to prepare the corresponding quadricovalent compound in its enantiomorphic modifications, and then to determine whether the rotatory power of such compounds is retained or lost upon transition into the tricovalent state, and return to the quadricovalent condition. If optical activity of the final product is retained, it would necessarily imply that the tricovalent molecule from which it was formed was also optically active. An asymmetric spatial configuration would therefore be experimentally demonstrated. If, however, on assuming the tricovalent state the substituted groups move into the plane of the central carbon atom, or acquire any other arrangement[3] which prevents the maintenance of asymmetry, then enantiomorphic modifications cannot exist and the preparation of these substances in optically active form is impossible. Previous attempts by several investigators[4] to settle this question failed because they were unable to obtain the necessary starting materials in optically active form. However, the resolution[5] of phenylbiphenyl-α-naphthylmethylthioglycolic acid has made it possible to obtain the optically active triarylmethane derivatives which are necessary for this polarimetric investigation.

---

(1) This paper is based upon a thesis submitted by Frederic H. Adams to the Faculty of Princeton University in partial fulfilment of the requirements for the degree of Doctor of Philosophy. Communicated in the form of two papers to the Division of Organic Chemistry at the 83rd and 85th meetings of the American Chemical Society held at New Orleans, La., March 28 to April 1, 1932, and at Washington, D. C., March 26 to 31, 1933, respectively.

(2) The above word is here proposed for a negatively charged carbon ion in contrast to the term "carbonium," which indicates a positively charged ion.

It was the aim of these investigations to test more thoroughly this method of resolution, to prepare if possible other asymmetric carbinols in their optically active modifications, and to study the behavior of these compounds and their derivatives toward polarized light when they are made to undergo chemical change to the tricovalent state. Furthermore, a study has been made of the optical stability of certain asymmetric groups during reactions in which they apparently go through the free radical stage, notably in the Kolbe synthesis by electrolysis of the potassium salts of fatty acids, and in the Wurtz reaction.

Attention was first directed toward the resolution of aliphatic and mixed aliphatic–aromatic carbinols by means of their thioglycolic acid derivatives. In all cases these were unsuccessful. One illustration follows.

Methylethylphenylcarbinol was converted into its chloride, and the latter compound was made to react with thioglycolic acid according to the equation

$$(CH_3)(C_2H_5)(C_6H_5)CCl + HSCH_2COOH \longrightarrow \underset{\text{(I)}}{(CH_3)(C_2H_5)(C_6H_5)CSCH_2COOH} + HCl$$

The resulting compound (I), m. p. 137–138°, was found to combine with brucine and other alkaloids, but such salts showed a tendency to decompose into unsaturated hydrocarbons and alkaloid thioglycolates. No resolution was effected.

Investigations were therefore directed to the further applicability of this method of resolution to methane derivatives of the true aryl type. In such compounds decomposition reactions of the above type would be avoided. It was also thought to be of scientific interest to resolve if possible a triarylmethane derivative in which two of the aryl groups are bound together to form a heterocyclic ring. A comparison of the spatial stability of such a

---

(3) Researches of this kind are well suited to clarify the question of the benzenoid or quinonoid constitution of these tricovalent compounds when they contain aryl groups. The question whether such substances can assume the quinonoid state and at the same time maintain an asymmetric configuration has previously been discussed [Wallis, THIS JOURNAL, 53, 2253 (1931)].

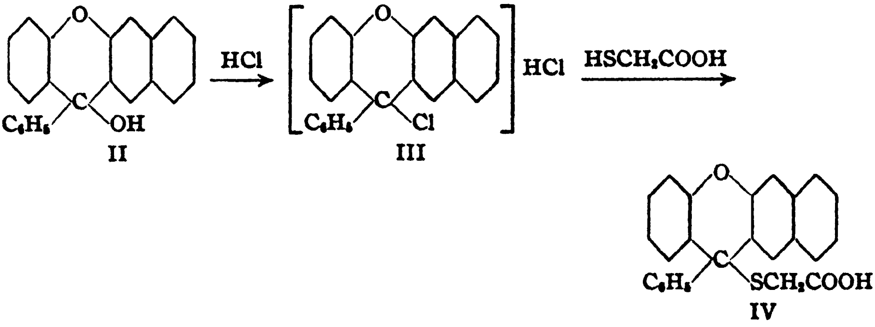
(5) (a) Wallis, *Proc. Nat. Acad. Sci.*, 16, 215 (1930); (b) Wallis, THIS JOURNAL, 53, 2253 (1931); (c) 54, 1693 (1932).

compound with that of phenylbiphenyl-α-naphthylmethylthioglycolic acid, in which the substituents are simple aryl groups, might give us an indication of the strain set up in the molecule by the "internuclear" bridge, and also the amount of distortion from the normal tetrahedral grouping.

Accordingly 12-phenyl-12-β-benzoxanthenol (II) was prepared and converted into its orange-red chloride–hydrochloride (III) according to the method of Gomberg and Schoepfle.(6) The latter compound in benzene solution reacted with thioglycolic acid to give a good yield of 12-phenyl-12-β-benzoxanthenethioglycolic acid (IV), a colorless crystalline solid melting at 187–188°.



Resolution of this acid by fractional crystallization of its brucine salt gave a *levo* modification $[\alpha]^{20}_{D}$ −48.5° in acetone. From the mother liquors were obtained samples of mixed *dextro* acid of varying rotations up to $[\alpha]^{20}_{D}$ +28.9°.

This compound (IV) was found to be much more easily racemized than phenylbiphenyl-α-naphthylmethylthioglycolic acid.

It was also found to turn orange slowly when exposed to diffuse light and rapidly when exposed to sunlight. Mineral acids, such as concentrated hydrochloric acid or sulfuric acid, dissolve it with the formation of deep orange-colored solutions. In fact this color was observed when any compound containing the 12-phenyl-β-benzoxanthenyl radical was treated with concentrated mineral acid. These reactions were always accompanied by racemization.

The Spatial Configuration of the Valences in Tricovalent Carbanions.—The work of Kuhn and Albrecht, and of Shriner and Young(7) on the sodium salts of optically active secondary nitroparaffins has shown that in all probability optically active anions of the type  $\left[R_2 : \overset{R_1}{\underset{\cdot\cdot}{C}} : NO_2\right]^-$ are capable of existence. It must be pointed out, however, that the alternative formula for such ions,  $\left[\begin{array}{c} R_1 \\ R_2:\ddot{C}:\ddot{N}:\ddot{O}: \\ :\ddot{O}: \end{array}\right]^-$, has not yet been definitely disproved. A study of the spatial configuration of an anion of the type $\left[\begin{array}{c} R_1 \\ R_2:\ddot{C}: \\ R_3 \end{array}\right]^-$ in which R_1, R_2 and R_3 are different aryl groups should therefore be of interest, for in this case no such alternative formula is likely, and the presence of optical activity can only be explained by the asymmetric non-planar arrangement of the three substituent groups and the electron pair.

The salt-like nature of the sodium compounds of triphenylmethyl and its analogs in ether solution has been demonstrated by Schlenk and Marcus.[8] Kraus and his co-workers[9] have prepared these organo-metallic compounds by the action of sodium on triarylchloromethanes in liquid ammonia, and have shown by conductivity measurements that the C–Na bond in this solvent is ionic and not covalent.

As has been noted,[10] *l*-12-phenyl-12-β-benzoxanthenethioglycolic acid (IV) has been subjected to the action of sodium in liquid ammonia in the absence of oxygen. The deep orange-brown sodium triarylmethyl so formed was then treated with a slight excess of dry ammonium bromide. The solution was immediately decolorized, and the colorless methane derivative, 12-phenyl-β-benzoxanthene, precipitated out. This material was found to be free from sulfur and optically active; in one experiment it exhibited $[\alpha]^{20}_{D}$ −11.7° in acetone solution. From these data it is evident that a triarylmethyl anion can exist in the optically active state for an appreciable length of time, and that its three covalence bonds are not coplanar with the central carbon atom.

The Spatial Configuration of the Valences in Tricovalent Carbonium Ions.—It is a well-known fact that an atom attached to an asymmetric carbon atom can be replaced by another atom without occurrence of complete racemization. In many of these reactions it would appear that the replacement involves an exchange of anions, and that two electrons are withdrawn from the octet of the asymmetric carbon atom. This interpretation involves the momentary existence of a carbonium ion,  $\left[\begin{array}{c} R_1 \\ R_2:\ddot{C} \\ R_3 \end{array}\right]^+$ which is sufficiently stable to maintain an asymmetric configuration. Several investigators[11] have made use of this concept to explain their experimental results. However, there are recorded facts which indicate that in the absence of a special mechanism which leads to Walden inversion such a carbonium ion is optically unstable. In a study of certain spontaneous migrations of optically active groups from oxygen to sulfur, Kenyon and Phillips[12] have shown that the rearrangement is accompanied by racemization.

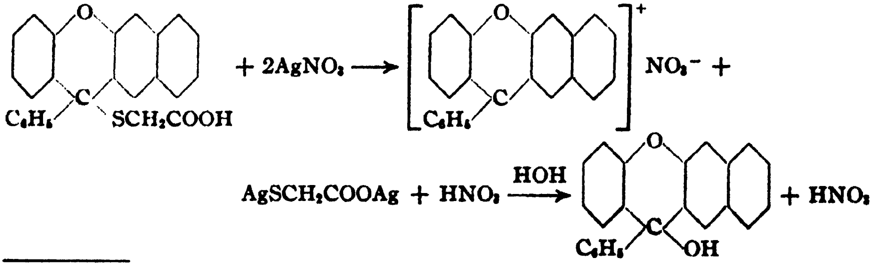
In the light of these experiments it therefore seemed important to investigate the problem further. There are many reactions which indicate that triarylmethyl radicals exist as carbonium ions. The physical and chemical properties of solutions of triarylmethyl halides in liquid sulfur dioxide may be cited as an example. Many investigators[13] also believe that such ions are present in the halochromic compounds of triarylmethyl derivatives with inorganic acids and salts. In a recent publication[5b] from this Laboratory this question has been discussed, and experimental facts were submitted which have a direct bearing on the constitution of these compounds. The triarylmethyl derivatives also undergo many reactions which involve substitution on the methane carbon atom. These reactions would imply an exchange of anions and the momentary withdrawal of two electrons from the octet of the central carbon atom. The present investigations include a study of such replacements when the central carbon atom is asymmetric. If the substitution is accompanied by racemization it would appear that not even momentarily can a triarylmethyl positive radical maintain its asymmetry in the absence of a special mechanism which leads to Walden inversion. On the other hand, if optical activity persists after such transformations one must conclude that such positive groups for a certain length of time are able to keep their covalent linkages non-planar with the central carbon atom, and do not "oscillate between the two forms of opposite configuration."

Two optically active triarylmethane derivatives were used for this purpose, *d*- and *l*-12-phenyl-12-β-benzoxanthenethioglycolic acid (IV) and *d*- and *l*-phenylbiphenyl-α-naphthylmethylthioglycolic acid (V). Many of our experiments gave results which seemed to support the first conclusion. When compound (IV) was dissolved in acetone containing small amounts of water, and treated in the cold with an aqueous solution of silver nitrate, the —SCH_2COOH group was replaced by —OH. In all cases, however, the carbinol so formed was inactive. The reaction may be formulated as



---

[12] Kenyon and Phillips, *J. Chem. Soc.*, 1676 (1930).

[13] Baeyer and Villiger, *Ber.*, **35**, 1189, 3013 (1902); Hantzsch, *ibid.*, **54**, 2573, 2613 (1921); **63B**, 1181 (1930); Dilthey, *J. prakt. Chem.*, [2] **109**, 273 (1925); **118**, 321 (1928); **124**, 81 (1929).

If the reaction was carried out in ethyl alcohol solution, the corresponding ethyl ether was produced. This compound also showed no appreciable rotation. Certain experiments with (V) gave similar results. Replacement of the $-SCH_2COOH$ group by the action of halogens or thionyl chloride gave in every instance an inactive triarylmethyl halide.

However, certain observations[14] have been made which might indicate that a positive radical of the above type under certain conditions can maintain an asymmetric configuration. When compound (V) was treated with silver nitrate under the same conditions as were used in our experiments with compound (IV), optically active products were obtained. It is to be noted that in the case of the carbinols the replacement was accompanied by a change in the sign of the rotatory power. This, however, did not take place when the corresponding optically active ethyl ethers were produced.

If we compare these results with those obtained with compound (IV) it would appear that the stability of the group is somewhat dependent upon the nature of the substituents present. If the molecule is of such a nature that distortion of the valences around the central carbon atom is pronounced, as is most certainly the case in molecules of the above type containing an internuclear oxygen bridge, then such a radical, even though it exists but momentarily, may well lose its asymmetry.

A much clearer case for optical instability was obtained when attempts were made to prepare the corresponding active halides of phenylbiphenyl-α-naphthylcarbinol. They were invariably unsuccessful.

It therefore seems probable that only under special conditions can triaryl substituted groups of the above type maintain even momentarily an asymmetric configuration, and whenever a replacement takes place in such a manner as to involve the intermediate formation of a true carbonium ion racemized products will inevitably result. We would explain this optical instability as being due to the inability of the positive ion to maintain its covalent linkages non-planar with the central carbon atom. When the group X is removed from the central carbon atom in these types of compounds, and takes its pair of electrons with it, the remaining valence electrons and their attached groups are in such an energy state that they readily pass through the plane of the carbon atom, and an optically inactive product is produced.

The Spatial Configuration of the Valences in Free Radicals.—The third possible state in which a group containing a tricovalent carbon atom can exist is that of a neutral free radical. Since it was not found possible to prepare optically active triarylmethyl halides, Gomberg's classical method for the preparation of free radicals could not be used in the present study of the optical stability of these tricovalent carbon compounds. It was therefore necessary to carry out experiments along somewhat different lines. Schlenk and Herzenstein[15] have reported that triphenylmethyl in some of its reactions behaves like a metallic element. For instance, it undergoes an equilibrium reaction with phenyldibiphenylchloromethane to form triphenylchloromethane and phenyldibiphenylmethyl. It seemed, therefore, that similar reactions could be carried out on *l*-phenylbiphenyl-α-naphthylmethylthioglycolic acid. This was found to be the case. Triphenylchloromethane in dry ether was allowed to react with mercury in the presence of *l*-phenylbiphenyl-α-naphthylmethylthioglycolic acid. The triphenylmethyl so formed was found to react slowly with the thioglycolic acid derivative. The progress of the reaction could be followed by observing a gradual change of color from yellow to reddish-brown. When this reaction was carried out in a specially constructed polarimeter tube, a gradual decrease of rotation to zero was observed. On admitting air to the apparatus peroxides were formed and precipitated out. These were tested in the polarimeter and found to be inactive. The filtrate was also inactive. Although the reaction did not go to completion, nevertheless optical inactivity resulted. This is undoubtedly due to the fact that the phenylbiphenyl-α-naphthylmethyl formed is unable to maintain its original configuration and therefore racemizes. When this radical returns again to the quadricovalent state as it would do in an equilibrium reaction, the corresponding thioglycolic acid derivative would consist of both *d*- and *l*-forms in equal amounts. Racemization in solution therefore becomes complete. If, as some investigators believe, such free radicals in solution consist of an equilibrium mixture of the benzenoid and quinonoid forms the presence of the latter form would be enough to account for the loss in optical activity in the above experiment. In order to preclude any possibility of tautomerism involving quinonoid forms, experiments were next conducted with aliphatic compounds. Here quinonoidation is obviously impossible.

---

[14] Wallis, THIS JOURNAL, 54, 1695 (1932).

The Kolbe reaction for the synthesis of hydrocarbons by the electrolysis of the alkali metal salts of fatty acids may be explained by assuming the momentary existence of free radicals. Petersen[16] has shown that when *dl*-methylethylacetic acid is electrolyzed in the form of an aqueous solution of its potassium salt, one of the products of the reaction is a hydrocarbon, 3,4-dimethylhexane. Accordingly Petersen's work was repeated with *l*- and *d*-methylethylacetic acid. In each case the hydrocarbon obtained was optically inactive.

In the Wurtz reaction also the intermediate formation of free radicals has been postulated. Therefore this synthesis was carried out with optically active halides of the type R_1R_2CHX and the hydrocarbon products examined for optical activity. In this case any loss of rotatory power can

---

(15) Schlenk and Herzenstein, *Ann.*, **394**, 199 (1912).

(16) J. Petersen, *Z. Elektrochem.*, **12**, 141 (1906).

only be due to optical instability of the intermediate free radicals, for Just[17] has shown that the reaction of metallic sodium on optically active halides of the type $R_1R_2CHCH_2X$, in which the halogen is separated from the asymmetric carbon by a CH_2 group, leads to the formation of an optically active 1,1,4,4-tetrasubstituted butane of the same sign of rotation as the original alkyl halide.

The asymmetric molecules chosen for these experiments were *l*- and *d*-α-bromobibenzyl, $C_6H_5CHBrCH_2C_6H_5$, and *d*-2-bromobutane, $C_2H_5CHBrCH_3$. In every case the corresponding hydrocarbon, 1,2,3,4-tetraphenylbutane, or 3,4-dimethylhexane, was found to be inactive. The reactions were carried out in ether solution, at 35 and 20°, respectively, and the products subsequently treated under conditions which ordinarily do not cause racemization; yet optical activity invariably resulted.[18]

From these experiments we may infer that free radicals in general, whether they be of the classical triphenylmethyl type, or of the aliphatic or mixed aliphatic–aromatic type, even though they exist but momentarily, cannot maintain the asymmetric configuration of the corresponding quadricovalent compounds from which they are derived. Furthermore, the experiments with aliphatic radicals show conclusively that at least in these compounds the loss of optical activity cannot be explained on the basis of a tautomeric change to a quinonoid form. It must be concluded that either the three substituents and the central carbon atom become coplanar, or, if a non-planar configuration is maintained, an oscillation of the groups around the central carbon atom takes place and their relative positions in space continuously change.

Experimental Part

Preparation of Methylethylphenylmethylthioglycolic Acid.—This compound was prepared in poor yields by the action of thioglycolic acid on methylethylphenylchloromethane, which was synthesized according to the method of Klages.[19] The chloride obtained from 50 g. of methylethylphenylcarbinol was treated with 35 g. of thioglycolic acid in 50 cc. of toluene, and the solution was refluxed until no more hydrogen chloride was evolved. On cooling the solution colorless crystals precipitated out. Recrystallization of this material from hot water gave a product which melted at 137–138°; yield, 11.8 g. Attempts were made to resolve this acid by means of its brucine and strychnine salts. These were unsuccessful.

Anal. Carius method (I) and Messinger method (II). Calcd. for $C_{12}H_{16}O_2S$: S, 14.29. Found: (I) S, 14.17; (II) S, 14.13.

---

(17) Just, *Ann.*, **220**, 155 (1883).

(18) The Grignard reaction could also be studied from this point of view, inasmuch as intermediate free radical formation may be postulated when metallic magnesium reacts with an alkyl halide. A survey of the literature, however, showed that Pickard and Kenyon [*J. Chem. Soc.*, **99**, 65 (1911)] in attempting to prepare 2-methylbutanol in *d*- and *l*-forms studied the reaction of formaldehyde on the Grignard compound produced by the action of magnesium on *l*-2-iodobutane. No difficulty was encountered in preparing the 2-methylbutanol, but all attempts to prepare it in an optically active condition by this method failed. Although their purpose in investigating such a reaction was different from the one discussed above, yet the results obtained are of interest in this connection.

(19) Klages, *Ber.*, **35**, 3507 (1902).

Preparation of 12-Phenyl-12-β-benzoxanthenethioglycolic Acid.—β-Benzoxanthone was prepared by the method of Ullmann.[20] This ketone was caused to react with phenylmagnesium bromide according to Gomberg and Schoepfle.[6] Five times the theoretical amount of phenylmagnesium bromide was used. The mixture was refluxed on the water-bath, with continued stirring, for at least six hours.

12-Phenyl-12-chloro-β-benzoxanthene hydrochloride was prepared from the xanthenol (m. p. 170–171°) according to the directions of Gomberg and Schoepfle.[6] The yields were practically quantitative.

12-Phenyl-12-β-benzoxanthenethioglycolic acid was prepared by refluxing the chloride–hydrochloride in benzene solution with the theoretical quantity of pure thioglycolic acid. After one hour's heating no more hydrogen chloride was evolved. The solution was decolorized with charcoal and the filtrate set aside to cool; colorless crystals, m. p. 187–188°, were obtained; yield, 86%, based on the amount of carbinol taken.

Anal. Carius method. Calcd. for $C_{25}H_{18}O_3S$: S, 8.04. Found: S, 7.99, 8.16. *Mol. wt.*, cryoscopic method in benzene. Calcd.: 398. Found: 402.

Resolution of 12-Phenyl-12-β-benzoxanthenethioglycolic Acid.—Thirty-five and one-half grams of this acid was resolved by fractional crystallization of its brucine salt from acetone. Ten crystallizations gave 6.2 g. of pure material with a constant rotation in acetone $[\alpha]^{20}_{D}$ −38.2°.

This salt was well pulverized and suspended in 150 cc. of ether in a separatory funnel; 5 cc. of 6 *N* sulfuric acid diluted to 100 cc. was then added, and the whole shaken vigorously until no more solid was visible. The ether layer was separated and *immediately* washed with water until the washings were free from sulfate. This solution was dried with anhydrous sodium sulfate, and the ether evaporated under reduced pressure; 2.3 g. of fine colorless crystals was obtained, m. p. 183–184°; $[\alpha]^{20}_{D}$ − 48.5° in acetone (*c*, 0.9892 g./100 cc.).

From the mother liquors of the first and second crystallizations was obtained a sample of brucine salt which was treated as described above, except that the ether was allowed to evaporate spontaneously at room temperature. When half of the ether had evaporated, the white crystals which had precipitated were filtered off and found to be optically inactive.[21] The residue obtained by evaporating the remaining ether from the solution was found to give a product which melted at 179°, $[\alpha]^{20}_{D}$ +28.9° in acetone (*c*, 0.8316 g./100 cc.).

Racemization Experiments on *l*-12-Phenyl-12-β-benzoxanthenethioglycolic Acid.—This acid was found to racemize slowly on standing in acetone solution at 20°. In U. S. P. acetone a sample of the acid was found to lose half of its optical activity in two days; in acetone which had been specially purified the specific rotation fell to half its original value in about five and one-half days.

Long standing in the solid state also causes gradual racemization. One sample of the material decreased in specific rotation from −42.3 to −36.9° in two months, and to −13.9° after fourteen months. This change in rotation was accompanied by a development of a slight orange coloration. Racemization was more rapid when the acid was exposed to light. Heating was found to racemize the acid rather rapidly. When an acetone solution of the compound was refluxed for fifteen minutes the specific rotation decreased from −42.3 to −36.8°. Complete racemization was produced when a sample of the material, dissolved in benzene, was boiled for two hours. This acid is also very sensitive to mineral acids. In one experiment 0.2510 g. was dissolved in 25 cc. of acetone and tested in the polarimeter. Two drops of 6 *N* hydrochloric acid were

---

(20) Ullmann, *Ber.*, **38**, 2116 (1905).

(21) A portion of the racemic form of the acid precipitates out, being less soluble in ether than the optically active modification.

then added to this solution, and its rotation determined at several intervals of time. In six hours optical activity had vanished.

The Action of Sodium on *dl*-12-Phenyl-12-β-benzoxanthenethioglycolic Acid in Liquid Ammonia.—The apparatus used, with some simplifications, was that described by Wooster;[22] 1.23 g. of the *dl*-acid was suspended in about 50 cc. of liquid ammonia in a tube immersed in a bath of the same liquid contained in an unsilvered Dewar flask. A current of ammonia gas was continuously circulated through the mixture to ensure thorough stirring and to displace all air from the reaction vessel; 0.25 g. of sodium in the form of small pellets was added from a side-tube. The blue color which at first developed quickly changed to a deep orange-brown. When no more unreacted acid could be seen in the bottom of the tube, 1.25 g. of dry ammonium bromide was added in small portions through another side-tube. A vigorous reaction ensued which resulted in the decolorization of the solution and the formation of a copious white precipitate. The reaction tube was then removed from the cooling bath and the liquid ammonia allowed to evaporate. The residue was taken up in water and washed until the washings were free from halogen and sodium salts. The amorphous white product was dried in air at room temperature. Tests for sulfur were negative. Crystallization of this material, 12-phenyl-β-benzoxanthene, from petroleum ether (60–75°) gave small colorless needles which melted at 153°. Recrystallization from the same solvent failed to raise the melting point.[23]

Anal. Micro method. Calcd. for $C_{23}H_{16}O$: C, 89.58; H, 5.23. Found: C, 89.63, 89.42; H, 5.25, 5.73. *Mol. wt.* Calcd.: 308. Found: 300.

Essentially the same method was employed with the *l*-acid as that just described. The reaction was repeated many times, and in every case but one the dry sulfur-free product was found to be optically active in the common organic solvents. In the exceptional case (VII) the solution, after the reaction with sodium, was allowed to stand for a much longer time before the ammonium bromide was added. This indicates that the ion racemizes rather easily. A summary of the results of the various experiments is given.

Run	Acid taken, g.	$[\alpha]^{20}_D$ of sample of acid used	Product taken, g.	$[\alpha]^{20}_D$ of product, 2-dm. tube 25 cc. soln.	$[\alpha]^{20}_D$ product	Solvent
I	2.0	−36.9	0.6015	−0.11	− 2.3	Benzene
II	1.0	−36.9	.1337	− .05	− 4.7	Benzene
III	1.25	−38.2	.2036	− .06	− 3.7	C_2H_5OH
IV	1.25	−38.2	.2032	− .05	− 3.1	C_2H_5OH

VI	1.23	−48.5	.1812	− .17	−11.7	Acetone
VII	4.0	−41.6	1.6922	.00	0.0	Benzene

Preparation of the sulfur-free levorotatory trisubstituted methane in a crystalline form was not accomplished. All attempts to crystallize the material gave only an amorphous substance. Experiments showed that this compound was easily racemized. Heating of the material in organic solvents produced either a completely inactive material, or one of lower rotation. Samples of the amorphous active compound after it had been made inactive by the above treatment were found to crystallize as before described. The crystals melted at 153°, and were identical with the product obtained from the *dl*-thioglycolic acid derivative.

---

[22] Wooster, THIS JOURNAL, 51, 1859 (1929).

[23] Kauffmann and Egner [*Ber.*, 46, 3785 (1913)] claim to have prepared this compound by heating 3-hydroxy-β-naphthyldiphenylcarbinol. Their compound melted at 171° and gave a greenish-yellow color with concentrated sulfuric acid, while the compound prepared by us gives the characteristic deep orange coloration observed when all compounds containing the 12-phenyl-β-benzoxanthenyl radical are treated with this reagent. Although their analytical data check with the requirements of the formula, the method of synthesis would indicate that their compound is a derivative of fluorene and not of xanthene.

Preparation of 12-Phenyl-β-Benzoxanthenyl Ethyl Ether.—One gram of the *l*-acid was dissolved in 90 cc. of absolute alcohol, and to the solution was added 1.2 g. of silver nitrate dissolved in 100 cc. of absolute alcohol. A momentary orange coloration was observed. The light yellow precipitate of silver thioglycolate which formed was filtered off, and the alcoholic filtrate allowed to drip into a liter of distilled water. A white curdy precipitate was immediately produced. This was filtered, washed free of silver ion, and dried in the air; yield of dry sulfur-free product, 0.7212 g. or 88%. This amount of material dissolved in 25 cc. of absolute ether gave no appreciable rotation in a 2-dm. tube. Recrystallization from petroleum ether gave colorless crystals which melted at 118°. This experiment was repeated several times under different conditions but the same inactive product was obtained. Crystallization from an aqueous acetone solution gave crystals which melted at the same temperature as those from petroleum ether.

Anal. Calcd. for $C_{25}H_{20}O_2$: C, 85.18; H, 5.72. Found: C, 84.80; H, 6.02. *Mol. wt.* Carlsohn method. Calcd.: 352. Found: 351.

The corresponding methyl ether was also prepared using a methanol solution; colorless needles (acetone) were obtained which melted at 148°.

Anal. Calcd. for $C_{24}H_{18}O_2$: C, 85.21; H, 5.33. Found: C, 85.38; H, 5.64.

Preparation of 12-Phenyl-12-β-benzoxanthenol from the Corresponding Thioglycolic Acid Derivative.—This compound was prepared from the *dl*-acid by a method similar to that above described for the preparation of the ethyl ether, except that acetone and water were used as solvents; yield of crude product, 88%. Crystallization from a mixture of benzene and petroleum ether gave colorless crystals which melted at 170–171°; m. p. by Gomberg and Schoepfle,[6] 171°.

In an entirely similar manner the *l*-acid was converted into the xanthenol. An inactive product was obtained; 0.5706 g. of this compound dissolved in 25 cc. of ether gave no rotation in a 2-dm. tube. Crystallization gave a material which melted at 170–171°.

Preparation of *d*- and *l*-Phenylbiphenyl-α-naphthylcarbinol.—One gram of *d*-phenylbiphenyl-α-naphthylmethylthioglycolic acid[5a] was dissolved in 100 cc. of acetone, and to the solution was added 50 cc. of water. This solution was treated with 1.0 g. of silver nitrate dissolved in 50 cc. of water; yield of product, 0.859 g. Crystallization from aqueous acetone gave colorless crystals which melted at 161–162°, and showed $[\alpha]^{20}_{6563}$ −3.3°; $[\alpha]^{20}_{5893}$ −5.4°; $[\alpha]^{20}_{5463}$ −7.6° (0.1152 g. of substance in 25 cc. of carbon tetrachloride solution, 2-dm. tube; rotation −0.03, −0.05, −0.07°, respectively).

Anal. Calcd. for $C_{29}H_{22}O$: C, 90.13; H, 5.70. Found: C, 90.0; H, 5.9.

In an entirely similar manner 1.0 g. of the *l*-acid was converted into the corresponding carbinol. The product so obtained melted at 160° and showed $[\alpha]^{20}_{5463}$ +7.2° (0.1912 g. in 25 cc. of carbon tetrachloride solution, 2-dm. tube, rotated +0.11°).

Preparation of *d*- and *l*-Phenylbiphenyl-α-naphthylmethyl Ethyl Ether.—One gram of the *d*-acid was dissolved in 50 cc. of absolute alcohol (distilled over calcium) and treated with a solution of 1.0 g. of silver nitrate dissolved in 100 cc. of the same solvent. The solutions were mixed slowly and the product worked up as before described. Crystallization from aqueous alcohol gave a compound which melted at 125–126°, and showed $[\alpha]^{20}_{D}$ +21.7° (0.1495 g. of substance in 25 cc. of ether solution, 2-dm. tube, rotated +0.26°).

These experiments were repeated on the *l*-acid. A crystalline product was obtained which melted at 125.5–126°, and showed $[\alpha]^{20}_{6563}$ −17.4°; $[\alpha]^{20}_{5893}$ −22.7°; $[\alpha]^{20}_{5463}$

−27.0; $[\alpha]^{20}_{4863}$ −34.0° (0.1435 g. in 25 cc. of dry ether solution in a 2-dm. tube, rotated −0.20, −0.26, −0.31, −0.39°, respectively).

Anal. Micro method. Calcd. for $C_{31}H_{26}O$: C, 89.85; H, 6.28. Found: C, 89.79, 89.78; H, 6.19, 6.23.

Action of Bromine on *l*- and *d*-Phenylbiphenyl-α-naphthylmethylthioglycolic Acid.—Two grams of the *l*-acid was dissolved in 50 cc. of dry ether and cooled in a bath of solid carbon dioxide and ether. To this solution was added slowly 100 cc. of dry ether containing an equivalent amount of free bromine. A white crystalline precipitate formed almost immediately. A portion of this dried product, dissolved in benzene, showed no rotation; m. p. of crystallized material (benzene) 191°, with decomposition.

Experiments carried out on the *d*-acid gave the same results.

Anal. Carius method. Calcd. for $C_{29}H_{21}Br$: Br, 17.6. Found: Br, 17.8.

Action of Thionyl Chloride on *d*-and *l*-Phenylbiphenyl-α-naphthylcarbinols and their Ethyl Ethers.—One gram of the *d*-carbinol was dissolved in benzene, and to the solution was added the calculated amount of thionyl chloride. To the mixture was added a small amount of petroleum ether (30–60°) and the solution allowed to stand for twelve hours at −6°. Beautifully formed crystals of the chloride, m. p. 194–195°, precipitated out; m. p. (Schlenk)[24] 194.5°. A saturated benzene solution showed no appreciable rotation. Experiments on the *l*-carbinol and the *d*- and *l*-ethyl ethers gave similar results.

Action of Triphenylmethyl on *l*-Phenylbiphenyl-α-naphthylmethylthioglycolic Acid in the Presence of Mercury.—One gram of triphenylchloromethane was dissolved in specially pure dry ether, and to the solution was added 1.0 g. of the *l*-acid, and the total solution made up to 25 cc. It showed a rotation at 20° in a 2-dm. tube with the 6563 line of −0.98°. This solution was placed in a specially constructed apparatus and shaken with mercury in the absence of oxygen for twenty-four hours. The solution was then allowed to stand in contact with mercury for fourteen days in the dark. After this time had elapsed the rotatory power of the solution was again determined in a specially constructed 2-dm. polarimeter tube. Other readings were taken from time to time: fourteen days −0.59°; nineteen days −0.39°; twenty-three days −0.19°; 27 days −0.02°. During this time the color of the solution changed from yellow to reddish-brown. The solution was removed and allowed to come into contact with air. The brown color quickly disappeared, and the solution became nearly colorless. The precipitated peroxides were filtered and found to be optically inactive. The filtrate also showed no appreciable rotation.

Electrolysis of *l*- and *d*-Methylethylacetic Acid.—Fifty grams of the *l*-acid, previously resolved by the method of Schütz and Marckwald[25] (rotation without solvent at 20°, D line, 2-dm. tube, −12.25°) was converted into its potassium salt and electrolyzed according to the method used by Petersen[16] for the *dl*-acid. After thirty-one hours seven grams of a yellow oily product was obtained. This oil after treatment and purification according to Petersen's method gave a hydrocarbon which was found to be inactive. The experiment was repeated with the *d*-acid. Similar results were obtained. The boiling point of the hydrocarbon produced was 110–116°. The b. p. of 3,4-dimethylhexane recorded in the literature is 116° (Norris and Green).

Preparation of 1,2,3,4-Tetraphenylbutane.—Phenylbenzylcarbinol was resolved into its pure dextro and mixed levo modifications by the method of Gerard and Kenyon;[26] 4 g. of the dextro compound (m. p. 67°, $[\alpha]^{23}_{D}$ +52.0 in alcohol, *c* 1.780 g. per 100 cc.), was dissolved in 50 cc. of benzene. The solution was cooled to 0° and saturated with

(25) Schütz and Marckwald, *Ber.*, **29**, 52 (1896).

(26) Gerard and Kenyon, *J. Chem. Soc.*, 2564 (1928).

pure hydrogen bromide gas. Purification of the product by the usual methods gave a levorotatory bromide which was a viscous yellow oil. This was not distilled because of possible decomposition; d_{21}^{21} 1.316; $[\alpha]_D^{22}$ −27.1° in absolute alcohol (c 1.642 g. per 100 cc.). In a similar manner a *dl*- and a mixed dextrorotatory α-bromobibenzyl were prepared. The mixed *d*-compound showed a rotation at 22° of +2.69° in a 0.5-dm. tube without solvent, D line.

Anal. *l*-Bromide, Parr Bomb and Volhard Titration. Calcd. for $C_{14}H_{13}Br$: Br. 30.62. Found: Br, 29.41.[27]

4.0 g. of *l*-α-bromobibenzyl was dissolved in absolute ether, and to the solution was added 3 g. of sodium in the form of small shot. The mixture was refluxed on the water-bath until the ether solution gave no test for bromine. This required about eight hours. The ether was then filtered off, and the residue treated with alcohol, diluted with water, and extracted with ether. The combined ether solutions were dried with calcium chloride and concentrated to 20 cc. Colorless bromine-free crystals precipitated out; 0.1586 g. of this material in 25 cc. of acetone solution gave no rotation in a 2-dm. tube. Recrystallization of the compound from alcohol gave needles which melted sharply at 178°.

The experiment was repeated with the mixed *d*-α-bromobibenzyl. Similar results were obtained. The crystalline material melted at 178° and was inactive. The *dl*-bromide also gave a product which melted at 178°.[28]

Anal. Calcd. for $C_{28}H_{26}$: C, 92.76; H, 7.24. Found: C, 92.59; H, 7.37. *Mol. wt.* (I) Rast Method, (II) Carlsohn Method. Calcd.: 362. Found: (I) 373, (II) 342.

Preparation of 3,4-Dimethylhexane by the Wurtz Reaction.—*d*-2-Bromobutane was prepared from an incompletely resolved *l*-*sec*-butyl alcohol according to the directions of Levene and Marker.[29] It had a specific rotation $[\alpha]_D^{22}$ +10.70° without solvent. Levene and Marker reported $[\alpha]_D^{25}$ +10.81° for the bromide; 8 g. of this material was dissolved in dry ether and treated at room temperature with metallic sodium according to the method of Norris and Green.[30] After the reaction was complete, the bromine-free ether solution was tested in the polarimeter. It gave no rotation. By fractionation a hydrocarbon was obtained which boiled at 115–117°. Examination of this material in the polarimeter showed that it was completely inactive; b. p. (Norris and Green) 116°.

Summary

12-Phenyl-12-β-benzoxanthenethioglycolic acid (IV) has been synthesized and resolved into pure *levo* and mixed *dextro* modifications. The *levo* form has a specific rotation $[\alpha]_D^{20}$ −48.5°. Evidence is submitted which shows that a carbanion of the type $\left[R_2:\overset{R_1}{\underset{R_3}{\ddot{\underset{..}{C}}}}: \right]^-$ is spatially sufficiently stable to maintain an asymmetric configuration. The three substituents and the central carbon atom, therefore, cannot lie in the same plane.

---

[27] The low value for the bromine in this analysis is undoubtedly due to the presence of small amounts of unchanged carbinol or traces of benzene, since the product was not purified by distillation.

[28] Fromm and Achert [*Ber.*, **36**, 539 (1903)] have prepared a compound, m. p. 255°, by heating benzyl sulfide. To this compound was assigned the structure of 1,2,3,4-tetraphenylbutane. R. Bacon [*Philip. J. Sci.*, **4A**, 166 (1909)] prepared the same compound by heating benzyl chloride with potassium oxalate in a sealed tube. Both these syntheses, however, leave much doubt as to the actual structure of the compound these investigators prepared.

[29] Levene and Marker, *J. Biol. Chem.*, **91**, 405 (1931).

[30] Norris and Green, *Am. Chem. J.*, **26**, 313 (1901). These investigators used the *dl*-bromide.

The stability of the spatial arrangement of the groups in tricovalent carbonium ions,  $\left[R_2:\ddot{C}\,(R_1)(R_3)\right]^+$ has been studied, and evidence has been submitted which indicates that in the absence of a special mechanism which leads to Walden inversion such configurations are optically unstable.

The optical instability of free radicals  $\left[R_2:\ddot{C}\cdot(R_1)(R_3)\right]$ has been demonstrated: by the loss of optical activity when *l*-phenylbiphenyl-α-naphthylmethylthioglycolic acid was allowed to react with triphenylmethyl; by the production of an inactive hydrocarbon in the electrolysis of *l*- and *d*-potassium methylethylacetate; and by the production of an inactive hydrocarbon by the action of metallic sodium on *d*- and *l*-α-bromobibenzyl and *d*-2-bromobutane.

A discussion of these results is given in the light of certain theories which have been proposed for the constitution of these tricovalent compounds.

Radical Interchange on the Part of Certain Alkyl Orthoformates[1]

BY HOWARD W. POST AND EDWIN R. ERICKSON

Early work on aliphatic ortho esters, while outlining their preparation and properties, has mentioned as well their instability. Triethyl orthoformate for example is not as stable as are the orthoformates of the higher aliphatic alcohols, but no further suggestions have been advanced on this point to date. Compounds of this type have been prepared from the corresponding alcoholate[2] and from the alcohol and hydrogen cyanide.[3]

It was our original purpose to test the relative reactivity of some alcoholates of simple aliphatic alcohols by mixing one mole of chloroform with three moles each of two different alcoholates and determining the identities of the products but the problem soon resolved itself into a study of the reaction

$$HC(OR)_3 + HC(OR')_3 \rightleftharpoons HC(OR)_2OR' + HC(OR')_2OR \qquad (1)$$

The Reaction of Chloroform with Alcoholate Mixtures.—One equivalent of chloroform was added to a mixture of 1.5 equivalents each of two aliphatic alcoholates, the system being stirred gently. These proportions gave better yields than 1:3:3. The results are summarized below.

4	C_2H_5-	C_4H_9-	12.6	42.1[a]	35.9[a]	9.4	42.1
5	C_2H_5-	C_3H_7-	2.7	41.9	39.5	16.1	34.0

[a] Identified by boiling point only.

It will be noted that in any reaction such as indicated in Equation 1 using the alcoholates specified in Table I there is a strong tendency for the mixed esters to form at the expense of those whose alkyl radicals are all alike.

The physical constants of these simple and mixed orthoformates may be found in the literature[3] and for purposes of identification we confined ourselves to determinations of boiling points, refractive indices and densities. It was found necessary to determine refractive index and density immediately after distillation to obtain consistent results.

TABLE II

PHYSICAL DATA

Ester	B. p., °C.	n^{20}_D	d^{21}_4	Mol. wt. Calcd.	Mol. wt. Found
$HC(OC_2H_5)_3$	145 (747 mm.) 60 (30 mm.)	1.3915	0.8964	148.13	148.6
$HC(OC_2H_5)_2OC_3H_7$	165 (747 mm.) 81 (30 mm.)	1.3989	.8813	162.1	160.6
$HC(OC_2H_5)_2SC_2H_5$	76–80 (17 mm.)	1.4397	.9451 (20°/4°)	164.2	165.7
$HC(OC_3H_7)_3$	190–191 (745 mm.) 93 (30 mm.)	1.408	.879	190.2	189.9
$HC(OC_3H_7)_2OC_2H_5$	184 (745 mm.) 93 (30 mm.)	1.4031	.8973 (22°/4°)	176.2	175.5
$HC(OC_3H_7)_2OC_5H_{11}$-*i*	124–130 (24 mm.)	1.415	.8647	218.2	216.0
$HC(OC_5H_{11}$-*i*$)_3$	166 (25 mm.)	1.4242	.858	274.3	272.2
$HC(OC_5H_{11}$-*i*$)_2OC_3H_7$	140–147 (30 mm.)	1.4194	.8626	246.2	244.4

Using the formula $N = M(n^2 - 1)/d(n^2 + 2)$.

After standing for thirty days samples of mixed esters when distilled gave fractions which identified by boiling points, refractive indices and densities represented all four possibilities—$HC(OR)_3$, $HC(OR)_2OR'$, $HC(OR')_2OR$ and $HC(OR')_3$. This reaction took place in the case of every mixed ester prepared during the course of this work.

A mixture of pure $HC(OC_3H_7)_3$ and pure $HC(OC_5H_{11}$-*i*$)_3$ in equimolar amounts was set aside to stand for one month at room temperature. At the end of that time fractional distillation at low pressures showed that an interchange of radicals had taken place but that the two middle fractions were not present in as large amount as the first and fourth

$$HC(OC_3H_7)_3 + HC(OC_5H_{11}\text{-}i)_3 \rightleftharpoons HC(OC_3H_7)_2OC_5H_{11}\text{-}i + HC(OC_5H_{11}\text{-}i)_2OC_3H_7 \quad (2)$$

Diethyl propyl orthoformate reacted in the presence of phosphorus pentoxide to give all four possible orthoformates. It may seem at first that the interaction of two molecules of this ester under these conditions may have been catalyzed by hydrogen ion, but this can hardly be so because the pure orthoformates containing like alkyl groups did not hydrolyze when similarly treated. With only a small amount of water present, hydrolysis does take place, however.

Propyl orthoformate reacted with absolute ethyl alcohol to give four possibilities as well as the two alcohols

$$HC(OC_3H_7)_3 + C_2H_5OH \rightleftharpoons C_3H_7OH + HC(OC_3H_7)_2OC_2H_5, \text{ etc.} \quad (3)$$

Yields were: $HC(OC_2H_5)_3$ 2.1%, $HC(OC_2H_5)_2OC_3H_7$ 42.0%, $HC(OC_3H_7)_2$-OC_2H_5 40.0% and $HC(OC_3H_7)_3$ 15.9%. Of course it is probable here that as soon as more than one orthoformate appears it may react with some other orthoformate as well as with one of the alcohols.

Ethyl mercaptan was allowed to stand in contact with triethyl orthoformate in a sealed tube at room temperature for one week. On distillation triethyl orthoformate and monothiotriethyl orthoformate came over. There was a higher boiling fraction but we were not able to isolate anything therefrom

$$HC(OC_2H_5)_3 + C_2H_5SH \rightleftharpoons C_2H_5OH + HC(OC_2H_5)_2SC_2H_5 \quad (4)$$

Experimental Part

Preparation of the Mixed Esters.—The alcohols were purchased from the Eastman Kodak Co. and then dehydrated. To prepare the alcoholates 3 equivalents of clean sodium was dissolved in an excess of the desired alcohol, and the two solutions of alcoholates were mixed. To this system a solution of chloroform in a little mixed alcohols was added dropwise with gentle stirring. All outlets of the system were closed with calcium chloride tubes. Care must be taken lest the temperature rise too high. The reaction was completed in about an hour and a half but it was found that the yield could be increased by allowing the mixture to stand several hours longer. Half a gram of hydroquinone acts as an inhibitor of oxidation here.

Sodium chloride was removed by suction, excess alcohols distilled at atmospheric pressure and the mixture of products fractionated at reduced pressures, generally 30 mm. Refractionations gave pure products.

Reactions of Esters.—The reactions of the mixed esters were brought about simply by allowing them to stand as already described.

Molecular refractions were calculated from the values for the various atoms found in the current literature.[4]

Discussion

We have shown that an equilibrium is immediately set up when two different orthoformates are mixed at room temperatures. This equilibrium reaction consists of the interconversion of the four esters $HC(OR)_3$, HC-

---

[4] Landolt and Börnstein, "Physikalisch-chemische Tabellen," Vol. II, p. 985 (5th ed.).

$(OR')_2OR$, $HC(OR)_2OR'$ and $HC(OR')_3$. Only a small amount of the two mixed esters is obtained when propyl orthoformate and isoamyl orthoformate are mixed, as compared with a larger amount of the two mixed compounds using esters of lower molecular weights. This may be explained by assuming that reaction is preceded by decomposition into fragments, this decomposition being known to be less rapid in the case of the higher homologs. Similar reactions with alcohols and mercaptans seem to involve transfer of OR rather than R.

Summary

1. At room temperatures the mixed orthoformates thus far investigated isomerize to a mixture of all four possible esters, this reaction taking place almost instantaneously over phosphorus pentoxide.

2. At room temperatures two orthoformates react with interchange of radicals, the yield of products varying, as far as observation has gone, inversely as the radical weights involved.

3. Tripropyl orthoformate reacts with absolute ethyl alcohol, giving a mixture of the four possible orthoformates and two alcohols. Ethyl mercaptan reacts with triethyl orthoformate giving the mono thio compound.

Polymerization of Diolefins with Olefins. II. Function of Pentene-2 in the Polymerization of Isoprene

BY CHAS. ALLEN THOMAS AND WM. H. CARMODY

In the previous paper[1] it was reported that when pure isoprene, in which there was no appreciable amount of olefin present, was placed in contact with anhydrous aluminum chloride, there was no temperature rise or any other obvious chemical reaction, even when a considerable proportion of anhydrous aluminum chloride had been added. It was shown that an olefin, such as pentene-2, added to the isoprene–aluminum chloride mix, started the reaction immediately; and that in polymerizing isoprene and pentene-2 by aluminum chloride, there were two solid polymers formed, one insoluble and the other soluble in hydrocarbon solvents. The amount of the soluble polymer formed is proportional to the pentene-2 present, while the amount of the insoluble polymer varies inversely with the amount of pentene-2 present.

The purer the isoprene, the more inert it is toward aluminum chloride. Very pure isoprene can be obtained by converting it into the tetrabromide and regenerating it with zinc dust according to Whitby and Crozier.[2] Several hours of contact of this pure isoprene with anhydrous aluminum chloride causes the formation of small bubbles which are immediately followed by a spongy polymeric growth. A few days later there are masses of this polymer, insoluble in the water-white isoprene. The majority of the isoprene is slowly converted into this gelatinous mass, analysis of which shows it to be $(C_5H_8)_x$, identical with the insoluble polymer previously described.

---

[1] Thomas and Carmody, THIS JOURNAL, 54, 2480 (1932).

Large quantities of dry hydrogen chloride, bubbled through isoprene containing aluminum chloride, cause the reaction to become violent. Fifty cc. of isoprene in 250 cc. of naphtha was stirred rapidly in a cooled vessel while 10 g. of aluminum chloride was added in portions. A slow stream of dry hydrogen chloride gas was led below the surface of the mixture and polymerization was continued for three and one-half hours, after which the polymers were recovered in the manner previously reported. There was obtained 21 g. of soluble polymer and 12.4 g. of insoluble. Hence it can be seen that dry hydrogen chloride gas, beside initiating the polymerization of isoprene, greatly influences the yields of soluble and insoluble polymers.

Isoprene hydrochloride, formed by passing hydrogen chloride into isoprene, reacts with aluminum chloride to form a complex which is soluble in isoprene. This suggested that the soluble polymer is produced in relation to the isoprene hydrochloride present; and when enough is present to dissolve completely the aluminum chloride then only soluble polymer is produced. This point was further substantiated when it was found that only the soluble polymer was formed when isoprene hydrochloride was added to a reaction mixture of isoprene and aluminum chloride.

Other mutual solvents for isoprene and aluminum chloride increase the yield of soluble and decrease the insoluble polymers. When 5 g. of aluminum chloride is dissolved in 45 g. of nitrobenzene and this solution added to isoprene there is obtained soluble polymer only. If a diluent, such as petroleum naphtha, is used with the isoprene, the aluminum chloride is partly thrown out of solution and some insoluble polymer is obtained. Ethyl acetate forms with aluminum chloride, an isoprene soluble complex. By running a series of identical polymerizations with the exception of increasing by small amounts ethyl acetate added to the reaction mixture, it is found that there is an exact relation between yield of soluble polymer and the amount of ethyl acetate added. This relationship is much the same as when pentene-2 is added to isoprene.

It is assumed that the soluble and insoluble polymers differ in molecular weight alone, and it is evident that the more aluminum chloride put into solution, the lower the molecular weight of the polymer obtained. When

---

(2) Whitby and Crozier, *Can. J. Research*, 6, 212 (1932)

no mutual solvent for the isoprene and aluminum chloride is employed the polymerization is initiated on the surface of the catalyst. With solid aluminum chloride, the surface comparable to molecular dispersement, is small when referred to the same mass of aluminum chloride in solution as a complex. Thus, with solid aluminum chloride, not many polymer growths are started, and after prolonged contact the polymers have an opportunity to grow to large size and become insoluble. When the catalyst is in solution, giving molecular contact, many polymer growths are started and these are so numerous that with the available isoprene they do not grow to high molecular weight, thus producing the soluble polymer. This theory of short chain formation has independently been advanced by Houtz and Adkins in their work with styrene.[3]

Previous work showed that in the polymerization of isoprene with pentene-2, the more olefin present the lower the molecular weight of the polymers. This suggests that the pentene-2 is not interreacting with the isoprene, but is present in the role of mutual solvent. Even though pentene-2 and aluminum chloride form a complex, it is immaterial to the theory so long as a solution of the catalyst in the isoprene is obtained. If isoprene was treated with pentene–aluminum chloride complex, and never allowed to be in contact with the solid catalyst, then there should be obtained a minimum of insoluble polymers and a maximum of soluble polymers.

One mole of pentene-2 in 400 cc. of naphtha was stirred violently, while 40 g. of anhydrous aluminum chloride was added portionwise during two and one-half hours, at a temperature between 0 and 5°. Agitation was continued for an additional hour, when most of the aluminum chloride had reacted with the pentene-2; 1 mole of pure isoprene was added over a period of two and one-half hours. Much heat was evolved, and additional cooling was necessary to keep the mixture below 30°. The mixture was neutralized and finished in the usual manner. There was obtained 71.2 g. of soluble polymer and only 1.2 g. of the insoluble polymer.

Summary

1. In polymerization of isoprene by solid aluminum chloride, largely insoluble polymer is formed.

2. When the aluminum chloride is put into solution as a complex in the isoprene, largely a soluble polymer is produced.

3. Pentene-2 acts only as a "solubilizer" for the aluminum chloride when polymerized with isoprene, thus producing a low molecular weight or soluble polymer.

4. A theory for the above is suggested.

The Retropinacolone Rearrangement. I

BY W. E. BACHMANN

Delacre[1] found that *as*-tetraphenylethyl alcohol is converted to tetraphenylethylene when it is heated with acetyl chloride at 200° in a sealed tube. We have now undertaken an investigation of the reaction in order to learn whether the reaction is general for the whole class of tetraarylethanols and also to discover if the rearrangement can be employed to determine the relative migration aptitudes of aryl groups.

An attempt was made to rearrange *as*-tetraphenylethyl alcohol by heating it with acetyl chloride at ordinary pressure; under these conditions tetraphenylethyl acetate was formed. We then tried the action of a solution of iodine in acetic acid, which is an excellent rearranging agent for pinacols;[2] it was found that tetraarylethanols are rapidly and completely rearranged when they are heated with iodine and acetic acid at ordinary pressure.

If a mixed tetraarylethanol of the type $R_1R_1R_2CCH(OH)R_2$ is subjected to rearrangement, two courses are open since either R_1 or R_2 can migrate. From the relative amounts of the two ethylenes that are formed it is possible to determine the extent to which each group migrated in the rearrangement. We have prepared and rearranged three tetraarylethanols of this type; namely, 1,2-diphenyl-2-biphenyleneëthanol (IV), 10,10-diphenylphenanthrol-9 (V) and 10-biphenylenephenanthrol-9 (VI). The results of the rearrangements are presented in Table I.

TABLE I

No.	Ethanol	Group migrated	Yield, %	Products
I	$(C_6H_5)_2CCH(OH)C_6H_5$		100	Tetraphenylethylene
II	$(CH_3C_6H_4)_2CCH(OH)C_6H_4CH_3$		100	Tetra-*p*-tolylethylene
III	$(CH_3OC_6H_4)_2CCH(OH)C_6H_4OCH_3$		100	Tetraanisylethylene
IV	 $\begin{array}{l}(C_6H_4)_2CC_6H_5\\ \quad\quad\;\; \vert \\ C_6H_5CH(OH)\end{array}$	Phenyl Biphenylene	0 100	Diphenylbiphenyleneethylene 9,10-Diphenylphenanthrene
V	 $\begin{array}{l}C_6H_4—C(C_6H_5)_2\\ \vert \quad\quad \vert \\ C_6H_4—CH(OH)\end{array}$	Phenyl Biphenylene	100 0	9,10-Diphenylphenanthrene Diphenylbiphenyleneethylene
VI	 $\begin{array}{l}C_6H_4—C(C_6H_4)_2\\ \vert \quad\quad \vert \\ C_6H_4—CH(OH)\end{array}$	 Biphenylene	0 100	Dibiphenyleneëthylene 9,10-Biphenylenephenanthrene

It is noteworthy that only a single rearrangement product is obtained from the three mixed ethanols. It appears that the formation of the phenanthrene ring is favored, for the same product 9,10-diphenylphen-

anthrene is produced from two different ethanols, 1,2-diphenyl-2-biphenylene-ethanol (IV) and 10,10-diphenylphenanthrol-9 (V). Werner and Grob[3] obtained similar products by the interaction of hydrogen iodide and the pinacolones corresponding to the mixed ethanols; they postulated the intermediate formation of the ethanols in the reaction.

In a future communication will be reported the results obtained with a large number of aryl groups.

Experimental

Preparation of Tetraarylethanols.—We prepared the tetraarylethanols by reduction of pinacolones by isopropylmagnesium iodide[4] and bromide. To a solution of the Grignard reagent prepared from 5 cc. of isopropyl iodide in 20 cc. of ether was added 20 cc. of benzene and then 0.02 g. mole of solid pinacolone in portions; the reaction usually took place at once with evolution of gas. After being refluxed, the mixture was hydrolyzed; all of the compounds were obtained as colorless crystals. The essential data are given in Table II.

[a] The ethanol crystallizes from alcohol with solvent of crystallization.

Rearrangement of Tetraarylethanols.—A solution of 1.0 g. of tetraarylethanol and 0.05 g. of iodine in 10 cc. of acetic acid was refluxed for one hour. In several cases a large proportion of the rearrangement product precipitated from the solution after a few minutes; if the mixture bumped badly more solvent was added. The mixture was cooled slightly and treated with 5 cc. of alcohol saturated with sulfur dioxide. On being chilled the solution deposited the rearrangement product in the form of colorless crystals. The yields of the products were quantitative, showing that no side reactions occurred. The properties of the products with the exception of tetra-*p*-tolylethylene agreed with those described in the literature. Our tetra-*p*-tolylethylene crystallized in colorless needles and melted at 142°; Staudinger and Goldstein[5] reported a melting point of 151°.

Anal. Calcd. for $C_{30}H_{28}$: C, 92.8; H, 7.2. Found: C, 93.3; H, 7.5.

(3) Werner and Grob, *Ber.*, **37**, 2895 (1904).

(4) Gorski, *J. Russ. Phys.-Chem. Soc.*, **45**, 163 (1913).

(5) Staudinger and Goldstein, *Ber.*, **49**, 1925 (1916).

A portion of our tetra-*p*-tolylethylene was reduced to the corresponding ethane by treating a boiling solution of 0.35 g. of the ethylene in 10 cc. of amyl alcohol with 0.5 g. of sodium cut in small pieces. After ten minutes water was added and the product was taken up in benzene; concentration of the solution deposited the *s*-tetra-*p*-tolylethane in colorless prisms; m. p. 278–279°; yield, 95%. The ethane is little soluble in hot alcohol or in cold benzene; it is soluble in hot benzene.

Anal. Calcd. for $C_{30}H_{30}$: C, 92.3; H, 7.7. Found: C, 92.1; H, 7.8.

s-Tetra-*p*-tolylethane was synthesized by heating a mixture of 1.1 g. of di-*p*-tolylbromomethane and 0.05 g. of magnesium ribbon in 5 cc. of ether and 5 cc. of benzene for twenty hours; yield, 50%; m. p. 278–279°; the product so obtained was identical in all respects with the product produced by reduction of the ethylene.

Tetraphenylethyl Acetate, $(C_6H_5)_3CCH(OCOCH_3)C_6H_5$.—A mixture of 1.0 g. of *as*-tetraphenylethyl alcohol, 10 cc. of acetyl chloride and 5 cc. of benzene was refluxed for ten hours. The product obtained by evaporation of the solvents was recrystallized from a mixture of benzene and alcohol; colorless needles; m. p. 151°; yield, 1.11 g. (99%); Delacre[1] reported a m. p. of 131°. Tetraphenylethyl acetate is little soluble in cold alcohol or acetic acid; it is readily soluble in hot benzene and in hot acetic acid.

Anal. Calcd. for $C_{28}H_{24}O_2$: C, 85.7; H, 6.1. Found: C, 85.7; H, 6.3.

A 0.1-g. portion of tetraphenylethyl acetate was warmed for a few minutes with a mixture of 1 cc. of 40% potassium hydroxide and 2 cc. of alcohol; this treatment hydrolyzed the ester to acetic acid and tetraphenylethyl alcohol; the latter was then cleaved into triphenylmethane[1] and benzaldehyde. When the ester was heated with acetic acid and iodine for a few minutes, rearrangement to tetraphenylethylene took place.

Summary

as-Tetraphenylethyl alcohol is dehydrated and rearranged to tetraphenylethylene when it is heated with a solution of iodine in acetic acid. Five new tetraarylethanols have been synthesized and subjected to the retropinacolone rearrangement.

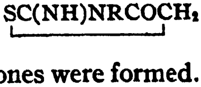
The Alkyl Derivatives of the Mono Substituted Thiazolidones. I

BY F. B. DAINS AND FLOYD EBERLY

Some years ago Beckurts and Frerich[1] published a paper on the ethylation of the monoarylthiazolidones which were prepared by the action of potassium thiocyanate upon the chloracet derivatives of various monoarylamines. Several intermediate products were described, but the ones used in their investigation were regarded as 2-imino-3-aryl-4-thiazolidones. The reason given for this structure was that on hydrolysis 3-aryl-2,4-thiazolediones were formed.



$$\overset{1}{S}\overset{2}{C}(NH)\overset{3}{N}R\overset{4}{C}O\overset{5}{C}H_2$$

Wheeler and Johnson[2] have shown in an exhaustive study that this

---

(1) Beckurts and Frerich, *Arch. Pharm.*, **253**, 233–65 (1915).

(2) Wheeler and Johnson, *Am. Chem. J.*, **28**, 121–128 (1902).

formula of Beckurts and Frerich represented a labile form which rearranged to the stable 2-arylamino(or imino)-thiazolidone. This on hydrolysis gave both the unsubstituted 2,4-thiazoledione and the 3-aryl diketo product obtained by Beckurts and Frerich. They assumed[3] that the two compounds resulted from the hydrolysis of an intermediate aryl thiohydantoic acid, the ring again closing after the loss of aniline or ammonia.

We have found that a benzal group at 5 stabilized the ring and that on hydrolysis a 5-benzal-2,4-thiazoledione resulted and not a 3-aryl diketo compound which would be necessitated by the formula of Beckurts and Frerich.

These authors by the ethylation of the sodium salts of the thiazolidones obtained mono ethyl derivatives which were assumed to be 2-ethylimino-3-aryl-4-thiazolidones, $\underline{\mathrm{SC(NC_2H_5)NRCOCH_2}}$. Wheeler and Johnson[4] had made the observation that the stable phenylthiazolidone in alkaline solution with benzyl chloride gave 2-phenyl-2-benzylaminothiazolidone, a fact not in harmony with the above assumption. The following experimental work has confirmed the Wheeler–Johnson formula for the stable hydantoins (as 2-aryl derivatives). It has also been shown that alkylation of the monoarylthiazolidones gave two isomers: one the 2-aryl-2-alkyl compound and the other a 2-aryl-3-alkylthiazolidone which corresponded to the Beckurts–Frerich idea but with the aryl and alkyl groups reversed in position.

Experimental

2-*p*-Bromophenylaminothiazolidone.—*p*-Bromoaniline (1 mole) was dissolved in acetone (300 cc.) and pyridine (96 g.) in a flask fitted with an air condenser and cooled in ice water. To this mixture was added slowly chloroacetyl chloride (135 g.) with constant agitation. After standing for an hour, water was added and the ω-chloro-*p*-bromoacetanilide was filtered, washed and dried. Crystallization from alcohol gave a pure product (m. p. 178°).[5] The chloroacetyl compound (135 g.) and potassium thiocyanate (60 g.) were dissolved in alcohol (300 cc.) and refluxed for twenty hours. The yield of crude thiazolidone was nearly the theoretical. From glacial acetic acid, the pale yellow needles melted at 224°.

Anal. Calcd. for $C_9H_7BrN_2OS$: N, 10.35. Found: N, 9.96.

The 5-benzal derivative did not melt at 310° (N, 7.80. Found: N, 7.57). The thiazolidone (m. p. 224°) was soluble in hot 5% sodium hydroxide and on cooling the yellow sodium salt crystallized out.

Ethylation of the Sodium Salt.—The dry salt was dissolved in alcohol with a slight molar excess of ethyl iodide and refluxed for ten hours. After removal of the alcohol and excess of ethyl iodide with steam, the residue was dissolved in ether. The ethereal solution was extracted repeatedly with hydrochloric acid (10%). On neutralizing the acid solution there was obtained 2-ethyl-2-*p*-bromophenylamino-4-thiazolidone; the white needles from ligroin melted at 121°.

Anal. Calcd. for $C_{11}H_{11}BrN_2OS$: N, 9.36. Found: N, 9.42.

---

(3) Ref. 2, p. 124.

(4) Ref. 2, p. 146.

(5) Beckurts and Frerich, *Arch. Pharm.*, 241, 212 (1903). The above seems to give better yields than the methods recorded in the literature for the preparation of these chloroacet derivatives.

Proof of Constitution.—The compound (m. p. 121°) was hydrolyzed by boiling with sulfuric acid (50%) for several hours. The mixture was made alkaline with sodium hydroxide and distilled with steam. Ammonia was evolved and an oil, ethyl-*p*-bromoaniline, appeared in the distillate. This oil with phenyl isocyanate gave α-ethyl-α-*p*-bromophenyl-β-phenyl urea; the rhombic crystals from alcohol melted at 108°.

Anal. Calcd. for $C_{15}H_{15}BrN_2O$: N, 8.77. Found: N, 8.62.

For comparison ethyl-*p*-bromophenylamine was made by the action of diethyl sulfate on powdered *p*-bromoaniline at 50°. The fraction of b. p. 146–152° (25 mm.) gave with phenyl isocyanate the same urea (m. p. 108°). Also the same benzoyl-*p*-bromoanilide, m. p. 88°, was obtained from both amines.

Anal. Calcd. for $C_{15}H_{14}BrNO$: N, 4.60. Found: N, 4.66.

***p*-Bromophenyl Ethyl Cyanamide,** $BrC_6H_4N(CN)C_2H_5$.—The residue in the steam distillation flask contained a small amount of the above compound; colorless plates from alcohol which melted at 78°.

Anal. Calcd. for $C_9H_9BrN_2$: N, 12.44. Found: N, 12.42.

It was identical with a synthetic preparation made from ethyl-*p*-bromophenylamine, bromine and potassium cyanide. This cyanamide was also obtained easily by the action of sodium hydroxide (20%) upon the ethyl thiazolidone.

The ethyl thiazolidone (m. p. 121°) condensed with benzaldehyde in hot alcohol solution using piperidine or a few drops of sodium hydroxide and gave a 5-benzal derivative (m. p. 225°).

Anal. Calcd. for $C_{18}H_{15}BrN_2OS$: N, 7.23. Found: N, 7.21.

5-Benzal-2,4-thiazoledione (m. p. 243°).[6]—This was obtained in small amounts by the direct hydrolysis of the 5-benzal-2-aryl-2-alkyl compounds, but was also prepared in an interesting way by the action of an excess of sodium hydroxide (40%) on a mixture in hot alcohol of the ethyl *p*-bromophenylthiazolidone and benzaldehyde and precipitating the product with dilute acid.

2-*p*-Bromophenylimino-3-ethyl-4-thiazolidone, $\overline{SC(NC_6H_4Br)NC_2H_5COCH_2}$.—This was isolated from the original ether solution of the ethylation product, remaining in solution after extraction with dilute acid. It formed about one-sixth of the total product, the needles from alcohol melting at 91°.

Anal. Calcd. for $C_{11}H_{11}BrN_2OS$: N, 9.36. Found: N, 9.44.

The same thiazolidone (m. p. 91°) was made by the action of chloroacetyl chloride upon α-ethyl-β-*p*-bromophenyl thiourea in acetone and pyridine solution,[7] thus showing the separate attachment of the ethyl and phenyl groups (N, found, 9.22).

Hydrolysis of this thiazolidone with sulfuric acid gave *p*-bromoaniline and ethylamine, identified by the carbylamine reaction and analysis of its hydrochloride.

2-*p*-Bromophenyl-3-ethyl-5-benzal-4-thiazolidone was made from benzaldehyde and the 91° product from both sources.

Anal. Calcd. for $C_{18}H_{15}BrN_2OS$: N, 7.23. Found: N, 7.21.

On hydrolysis in acid solution it gave *p*-bromoaniline and 3-ethyl-5-benzal-2,4-thiazoledione, melting at 95.5°.

Anal. Calcd. for $C_{12}H_{11}NO_2S$: N, 6.00. Found: N, 5.97.

The formation of the 3-ethyl derivative gives added proof of the structure of the isomeric thiazolidone. Its synthesis from α-ethyl-β-aryl thiourea shows that these thioureas tend to react with the acid chloride in the enol form $C_2H_5NHC(SH)NR$, thus yielding a 3-alkyl-2-aryl-thiazolidone. a fact that has been noted in other cases.

(6) Andreasch, *Monatsh.*, 10, 75 (1889).

(7) Hunter, *J. Chem. Soc.*, 129, 2956 (1926); Dains, Brewster and Olander, "Organic Syntheses," Vol. VI, p. 72.

The Methylation of the Sodium Salt of *p*-Bromophenylaminothiazolidone.—The same results were obtained both from the use of methyl iodide and of methyl sulfate. The reaction product on extraction with ether left a residue which was soluble in dilute hydrochloric acid and proved to be the 2-methyl-2-*p*-bromophenylaminothiazolidone, prisms from alcohol (m. p. 197°).

Hydrolysis with sulfuric acid (50%) gave ammonia and methyl-*p*-bromophenylamine. This was identified by its reaction with phenyl isocyanate, yielding α-methyl-α-bromophenyl-β-phenyl urea (m. p. 137°) and by the formation of a benzoyl derivative (m. p. 77°). When the 5-benzal compound (m. p. 256° was hydrolyzed it gave the 5-benzal-2,4-thiazoledione (m. p. 242°).

The ether extract from the original methylation product insoluble in dilute acid consisted of the isomeric 2-*p*-bromophenylimino-3-methyl-thiazolidone (m. p. 111°). On hydrolysis methylamine and *p*-bromoaniline were isolated, this proving its constitution. The relative position of the groups was indicated by the hydrolysis of the 5-benzal compound (m. p. 166°) which yielded *p*-bromoaniline and 3-methyl-5-benzal-2,4-thiazoledione (m. p. 133°).

2-Benzyl-2-*p*-bromophenylaminothiazolidone.—This was the only product isolated from the action of benzyl chloride on the sodium salt. It is only slightly soluble in dilute acid. Acid hydrolysis gave ammonia and benzyl-*p*-bromoaniline (m. p. 55°). This was confirmed by a synthetic specimen made from benzyl chloride and *p*-bromoaniline.[8] The fraction of b. p. 237–242° (33 mm.) solidified and melted at 55°.

2-Dibromo-*p*-tolylthiazolidone from 2,6-Dibromo-*p*-toluidine.—This was made by the usual method of refluxing the chloracet derivative with potassium thiocyanate. Methylation of the sodium salt gave nearly equal amounts of the two isomers. The acid soluble 2-methyl-2-dibromo-tolylaminothiazolidone melted at 194°, while the 3-methyl isomer (m. p. 132°) gave a benzal derivative which on hydrolysis yielded the dibromotoluidine, thus proving the structure.

Properties and Analyses

Thiazolidones	Formula	M. p., °C.	Nitrogen, % Calcd.	Nitrogen, % Found

[8] "Organic Syntheses," Vol. VIII, p. 38.

Summary

The aryl thiazolidones studied correspond to the 2-arylamino or stable forms of Wheeler and Johnson.

Their sodium salts with methyl or ethyl iodide yield a mixture of 2-alkyl-2-aryl and of 3-alkyl-2-aryl thiazolidones. With benzyl chloride only the 2-benzyl derivative has been found.

These results have failed to confirm the formulation of Beckurts and Frerich, who assumed that the products they obtained were 2-alkylimino-3-aryl thiazolidones. Further unpublished investigations in this Laboratory support our experimental results.

The Catalytic Hydrogenation of the Halogenomorphides: Dihydrodesoxymorphine-D[1]

BY LYNDON F. SMALL, KECHEE C. YUEN AND LOUIS K. EILERS

In a previous paper from this Laboratory[2] it was shown that catalytic hydrogenation of the halogenocodides yielded, according to the conditions, varying amounts of three hydrogenated desoxycodeine derivatives. By empirical selection of the proper catalyst and solvent, it was possible to direct the hydrogenation in such a way that the non-phenolic dihydrodesoxycodeine-D (IV) was the principal product obtained from any of the four known halogenocodides. Dihydrodesoxycodeine-D,[3] and its unsaturated analog, desoxycodeine-C (II),[4] in both of which the 4,5-ether bridge is still intact, are of particular interest pharmacologically, since they differ structurally from certain codeine derivatives (dihydrocodeine and pseudocodeine, respectively) only in having a hydrogen atom in place of the alcoholic hydroxyl of the codeine series. The demethylated analog of desoxycodeine-C, namely, desoxymorphine-C (I), which may be regarded as a derivative of γ-isomorphine, has already been described,[5] and has been found extraordinarily active in the animal body. With the view of preparing a dihydrodesoxymorphine of the dihydrodesoxycodeine-D type, corresponding in fundamental structure to dihydromorphine (Paramorfan), the catalytic hydrogenation of the halogenomorphides has been investigated.

[5] Small and Morris, *ibid.*, 55, 2874 (1933).

The three known halogenomorphides, on catalytic hydrogenation under identical conditions, yield varying amounts of three different products. α-Chloromorphide, in methyl alcoholic or weakly acid solution, gives largely the desired dihydrodesoxymorphine-D (III), together with some tetrahydrodesoxymorphine and a little non-crystalline material. In the case of β-chloromorphide, the product is almost exclusively dihydrodesoxymorphine-D. Bromomorphide which is believed (without good evidence) to correspond in structure to β-chloromorphide, yields, on the other hand, only small amounts of dihydrodesoxymorphine-D and a large quantity (up to 70%) of an uncrystallizable oil. This oil could not be distilled in high vacuum at any reasonable temperature, which led us to believe that it might correspond in structure to bis-dihydrodesoxycodeine. Decisive chemical evidence on this point could not be obtained, for the product resulting from methylation of the oil gave only one methiodide (amorphous), containing one atom of iodine to one molecule of desoxycodeine base; this does not necessarily exclude a dimolecular structure. An attempt to prepare a bis-dihydrodesoxymorphine for comparison, by demethylation of bis-dihydrodesoxycodeine with hydriodic acid, resulted in a phenolic base containing iodine.

The discrepancy between the hydrogenation of β-chloromorphide and that of bromomorphide has its parallel in a similar observation in the halogenocodide series, but does not permit of any valid conclusion concerning the structure of the two halogenomorphides, since the mechanism of the hydrogenation of these halogeno derivatives is uncertain.[6] The change in reduction conditions, from base in organic solvent to the salt in dilute acid solution, does not produce as great an effect on the course of hydrogenation as was observed in the halogenocodide series. For the halogenomorphides, faintly acid solution increases somewhat the yield of tetrahydrodesoxymorphine, and decreases the amount of oily product formed. In the case of the halogenocodides, good yields of dihydrodesoxycodeine-D could be obtained only by hydrogenation in acid solution, and in alcohol tetrahydro-

(6) Ref. 2, p. 795.

desoxycodeine or bis-dihydrodesoxycodeine resulted almost exclusively. In a repetition of some of the experiments of Mosettig, Cohen and Small, however, we have found that the results of hydrogenation often depend upon unrecognizable slight differences in catalyst or conditions, so that the discrepancy between the morphide and codide series may be largely illusory.

Dihydrodesoxymorphine-D, the principal product from the hydrogenation of α- and β-chloromorphides, is a colorless, well-crystallized base of m. p. 188–189°. It occurs also in a hemihydrated form of lower melting point, which can be converted to the anhydrous form by sublimation in high vacuum. It is not the same as the "dihydrodesoxymorphine" (m. p. 183°) of Knoll and Co.,[7] for the latter is beyond doubt identical with desoxymorphine-C (m. p. 189–190°).[8] The structure of dihydrodesoxymorphine-D is evident from its methylation, which leads to the nonphenolic dihydrodesoxycodeine-D (IV). Furthermore, dihydrodesoxymorphine-D can be obtained as the hydriodide in 93% yield from demethylation of dihydrodesoxycodeine-D. In view of the difficulty of preparation of the halogenomorphides, this constitutes the most practicable preparative method, for dihydrodesoxycodeine-D can be made quantitatively from the easily accessible α-chlorocodide. Dihydrodesoxymorphine-D can also be prepared by "normal" reduction of desoxymorphine-C under the special conditions developed by Lutz and Small[9] for partial hydrogenation of pseudocodeine types.

II. Desoxycodeine-C

III. Dihydrodesoxymorphine-D

IV. Dihydrodesoxycodeine-D

---

[7] Knoll and Co., German Patent 414,598 (1922); *Friedländer*, 15, 1518; *Jahresber. Chem. Tech.*, 71, 123 (1925).

[8] Small and Morris, This Journal, 55, 2876 (1933). Although desoxymorphine-C and dihydrodesoxymorphine-D show the same melting point, an identity of these two substances does not come into question, for they differ in other physical properties, and give a mixed melting point depression of 15°. Moreover, desoxymorphine-C can be hydrogenated with extreme ease, while dihydrodesoxymorphine-D is indifferent to catalytic hydrogenation.

[9] Lutz and Small, *ibid.*, 54, 4715 (1932).

In contrast to its dihydrodesoxycodeine analog, dihydrodesoxymorphine-D is unaffected by prolonged electrolytic reduction. The same unexpected difference in reactivity toward electrolytic reduction has already been noted in the cases of desoxycodeine-C and desoxymorphine-C. It may depend upon imperceptible differences in conditions, and will be the subject of further study.

Because of the differences shown by β-chloromorphide and bromomorphide in catalytic hydrogenation, the electrolytic reduction of bromomorphide was investigated. It proceeds in the same way as that of α-chloromorphide, and yields desoxymorphine-A in 79% of the calculated amount. The reduction of α-chloromorphide with amalgamated zinc and 6-normal hydrochloric acid gives a good yield of a mixture of β-isomorphine (evidently formed by hydrolysis of the α-chloromorphide) and desoxymorphine-A. Bromomorphide yields the same products.

As a result of further attempts to verify the existence of a desoxymorphine which Schryver and Lees[10] prepared by treatment of α-chloromorphide with tin and hot concentrated hydrochloric acid, we have obtained minute quantities of an alkaloid hydrochloride of m. p. 262° and $[\alpha]_D$ $-78°$. The same product results from heating α-chloromorphide with stannous chloride and concentrated hydrochloric acid under pressure at 100°. The new hydrochloride is not the same as that of Schryver and Lees, for which the specific rotation $+140.3°$ was given, nor does it correspond to any of the known desoxymorphine derivatives. It seems to us questionable whether the morphine carbon–nitrogen skeleton would withstand such drastic acid treatment without undergoing fundamental structural changes, since even in the preparation of β-chloromorphide from morphine and hydrochloric acid, a considerable part of the material is converted into apomorphine.

The physiological action of dihydrodesoxymorphine-D has been studied by Dr. N. B. Eddy at the Pharmacological Laboratory of the University of Michigan and will be described in detail in a publication from that Institution. In agreement with the change in physiological action which we have observed to result from replacement of the alcoholic hydroxyl group of the morphine and codeine series by hydrogen, dihydrodesoxymorphine-D is more active than dihydromorphine. Its toxicity is about the same as that of dihydromorphine, but respiratory and analgesic effects are greater. Dihydrodesoxymorphine-D likewise shows more analgesic action than its other hydroxy analog, dihydro-γ-isomorphine.[11]

Experimental

Hydrogenation of α-Chloromorphide.—The α-chloromorphide used in these experi-

---

(10) Schryver and Lees, *J. Chem. Soc.*, **77**, 1024 (1900).

(11) This new derivative of the morphine isomers has been prepared by hydrogenation of γ-isomorphine under special conditions, as well as by demethylation of the non-phenolic dihydropseudocodeine, and will be described in a later paper from this Laboratory.

ments was prepared by treatment of morphine with thionyl chloride,[12] and was purified by dissolving in dilute hydrochloric acid, precipitating with sodium carbonate and extracting the amorphous precipitate rapidly into ether. After several repetitions of this process, the crystalline material from the ether was washed with cold alcohol, which removed a considerable amount of another halogeno compound. The purified material showed $[\alpha]_D$ −363.6° (methanol, c = 0.528). Insufficiently pure chloromorphide leads to very complex hydrogenation mixtures.

Fifteen grams of α-chloromorphide dissolved in 150 cc. of absolute methanol was hydrogenated in the presence of 1.04 g. of palladium–barium sulfate (= 0.05 g. Pd metal). The absorption amounted to 2064 cc. of hydrogen, most of which was taken up in the first three hours, total time, eleven hours. The solution was freed of colloidal palladium by filtering through a layer of Norit, and the methanol removed at 40° in vacuum with a bubble-tube. The colorless resin which resulted was taken up in 100 cc. of water, and the alkaloid precipitated out by slow addition of ammonia, shaking into ether after each addition. Toward the end, the separation of crystalline tetrahydrodesoxymorphine caused troublesome emulsions. The ether was distilled down to 100 cc., and the crystalline tetrahydrodesoxymorphine, with a little dihydrodesoxymorphine-D, was filtered out. After washing with acetone to remove dihydrodesoxymorphine-D (0.6 g.) the tetrahydro product (together with that filtered off during the extraction) weighed 1.5 g. It had the m. p. 228–230°, and was identified by conversion to tetrahydrodesoxycodeine with diazomethane.

The ether solution from which the tetrahydrodesoxymorphine had been separated was distilled down to a yellow oil, which crystallized on rubbing with ethyl acetate. The crystals (3.6 g.) melted at 172–184°, and were purified from ethyl acetate; during this process, 60 mg. of a sparingly soluble base, m. p. 272–276°, was isolated. Analysis of this high-melting base gave the values C, 74.47; H, 7.53. It gave on methylation a colorless oil. The ethyl acetate mother liquors from the main portion gave on further evaporation 5 g. of a base of m. p. 155–170° which proved to be dihydrodesoxymorphine-D hemihydrate. The total yield of dihydrodesoxymorphine-D was 9.2 g.

As an alternative procedure, which is advantageous when much oily material is present, the residue from ether distillation may be extracted with cold acetone, the latter distilled to dryness and the residue treated with absolute alcoholic oxalic acid. Dihydrodesoxymorphine-D acid oxalate crystallizes well even in the presence of large amounts of impurities.

Dihydrodesoxymorphine-D.—Anhydrous dihydrodesoxymorphine-D melts at 188–189°, and has the specific rotation in absolute methanol $[\alpha]_D^{28}$ −76.8° (c = 1.614).

Anal. Calcd. for $C_{17}H_{21}O_2N$: C, 75.23; H, 7.81. Found: C, 74.82, 74.91; H, 7.85, 7.96.

Dihydrodesoxymorphine-D crystallizes best from acetone or ethyl acetate; in alcohol solution it turns red rapidly. It is precipitated by addition of water to its solution in acetone in the form of regular rectangular plates. It sublimes between 140 and 170° at 0.001 mm. pressure. The alkaloid behaves abnormally in camphor: The mixture shows two melting points, 133.5 and 166°, and on cooling, two solidification points, at about the same temperatures.

Two grams of dihydrodesoxymorphine-D in 200 cc. of 20% sulfuric acid was reduced electrolytically at 6 amp. on a 60 sq. cm. electrode for five hours at 10°, and for four more hours at 25°. The starting material, 1.8 g., was regained: m. p. 188–189°, $[\alpha]_D^{27}$ −75.3°.

Dihydrodesoxymorphine-D, 1.3 g., in ethereal solution with a few cc. of methanol was allowed to react with 0.2 g. of diazomethane for twenty-four hours. The yield of

---

(12) Wieland and Kappelmeier, *Ann.*, **382**, 306 (1911).

crude crystalline methylation product was nearly quantitative. After purification from acetone it had the m. p. 106–107° of dihydrodesoxycodeine-D, and showed $[\alpha]_D^{20}$ −81.3° in alcohol.

Demethylation of Dihydrodesoxycodeine-D.—A solution of 15 g. of dihydrodesoxycodeine-D in 45 cc. of hydriodic acid, sp. gr. 1.7, was boiled vigorously for three minutes. To the cooled solution, water (about 150 cc.) was added slowly with scratching until crystals no longer separated. The mixture was warmed nearly to boiling, whereby the crystals became pure white and more granular. The yield of dihydrodesoxymorphine-D hydriodide was 17.3 g. From the mother liquor an additional 1.5 g. of pure dihydrodesoxymorphine-D base was obtained by precipitation with ammonia.

TABLE II

DIHYDRODESOXYMORPHINE-D DERIVATIVES

Derivative	$[\alpha]_D$, solvent, c, t°C	Formula	Analyses, % Calcd.	Found	Calcd.	Found
Hydriodide[a]	−48.4°, water, 1.650,25	$C_{17}H_{21}O_2N\cdot HI$	I, 31.81	32.19	....	....
Hydrochloride[b]	−66.8°, water, 0.898,27	$C_{17}H_{21}O_2N\cdot HCl$	Cl, 11.53	11.54	....	....
Sulfate[c]	−57.9°, water, 1.425,29	$(C_{17}H_{21}O_2N)_2H_2SO_4 + 2H_2O$	H_2O 5.32	5.33	SO_4, 14.99[d]	15.20[d]
Acid oxalate[e]	−57.9°, water, 1.659,28	$C_{19}H_{23}O_6N$	C, 63.12	62.87	H, 6.42	6.43
Salicylate[f]	−42.8°, alc., 0.794,28	$C_{24}H_{27}O_5N$	C, 70.38	69.93	H, 6.64	6.94

[a] Best purified from water; 100 g. satd. aqueous solution at 25° contains 3.86 g. of the salt. [b] Prepd. from base with alcoholic hydrochloric acid, purified from 95% alcohol; exceedingly soluble in water. [c] Prepd. from base with sufficient cold 10% sulfuric acid to turn Congo paper; salt is sparingly soluble in cold water, very soluble in hot water, and is best suited to purification of the alkaloid. Colors slightly at 210°, unmelted at 230°. [d] Anhydrous salt, $(C_{17}H_{21}O_2N)_2H_2SO_4$. [e] Prepd. from base with absol. alcoholic oxalic acid; sparingly sol. in alcohol, very sol. in water, recryst. from 50% alcohol. [f] Prepd. in absolute alcohol with alcoholic salicylic acid, recryst. from 95% alcohol. Different preparations of the salt did not give consistent analyses; under some conditions it apparently crystallizes with a variable amount of water. [g] Prepd. by adding excess methyl iodide to suspension of the alkaloid in hot acetone; the amorphous methiodide becomes cryst. on further heating, and can be recryst. from alcohol.

Dihydrodesoxymorphine-D Hemihydrate.—This derivative was obtained as one of the products from most of the hydrogenations of the halogenomorphides, and usually separated from the ethyl acetate solution which had already yielded a crop of the anhydrous base. The conditions which determine its formation are not known; we were never able to obtain the hemihydrate from the anhydrous base. The hemihydrate does not lose its hydrate water in high vacuum below the temperature at which sublimation occurs, and a direct determination of hydrate water was not possible. The hemihydrate melts at 162–164° with gas evolution, and has $[\alpha]_D^{28}$ −78.6° (ethyl acetate, c = 1.076). It gives the anhydrous base of m. p. 188–189° quantitatively on sublimation. Its salts are identical with those of the anhydrous base, and it gives by methylation dihydrodesoxycodeine-D (70% yield).

Anal. Calcd. for $C_{17}H_{21}O_2N + 0.5H_2O$: C, 72.85; H, 7.93. Found: C, 72.85; H, 8.11.

Dihydrodesoxymorphine-D from Desoxymorphine-C.—A suspension of 2.27 g. of finely powdered desoxymorphine-C hydrochloride (= 2.00 g. of alkaloid) in 15 cc. of glacial acetic acid absorbed 266 cc. (= 1.4 moles) of hydrogen in the presence of 0.05 g. of platinum oxide. The product was precipitated with ammonia, extracted into ether, and the residue from distillation of the ether rubbed up with acetone. The acetone-insoluble tetrahydrodesoxymorphine, 0.75 g., was converted to the salicylate, which melted at 232° and had $[\alpha]^{25}_{D}$ −31.6°. The acetone extract yielded 0.75 g. of dihydrodesoxymorphine-D, which after one crystallization from acetone melted at 185–186° and had $[\alpha]^{25}_{D}$ −84.6°.

Hydrogenation of α-Chloromorphide in Acid Solution.—Five grams of α-chloromorphide suspended in 100 cc. of water was brought into solution by addition of normal hydrochloric acid and hydrogenated in the presence of 1.05 g. of palladium–barium sulfate. The absorption amounted to 2.27 moles of hydrogen most of which was taken up in the first hour. By precipitation with ammonia and extraction with ether, 1.5 g. of dihydrodesoxymorphine-D hemihydrate was obtained, and 1.5 g. of the ether-insoluble tetrahydrodesoxymorphine. The aqueous layer gave a heavy Mayer's test, and yielded on further extraction 1.0 g. of anhydrous dihydrodesoxymorphine-D.

Hydrogenation of β-Chloromorphide.—The β-chloromorphide used was prepared by the action of fuming hydrochloric acid on morphine at 100°[13] and was purified most advantageously as the tartrate, $[\alpha]^{25}_{D}$ +7.4° (water, c = 2.708). The base liberated from the tartrate had $[\alpha]^{25}_{D}$ −4° (methanol, c = 2.115) and melted at about 182°. Hydrogenation of 5.34 g. of β-chloromorphide in 100 cc. of methanol in the presence of Pd–$BaSO_4$ resulted in absorption of 2 moles of hydrogen in about two hours. The product, isolated as described for α-chloromorphide, consisted of 4.5 g. of colorless crystals of dihydrodesoxymorphine-D. By crystallization from ethyl acetate, 3 g. of anhydrous base was obtained, and from the ethyl acetate mother liquors 1.5 g. of the hemihydrate.

When the hydrogenation was carried out in dilute hydrochloric acid solution, the hemihydrate form only, of dihydrodesoxymorphine-D, with about 17% of tetrahydrodesoxymorphine, was obtained.

Hydrogenation of Bromomorphide.—Bromomorphide was prepared by the method of Schryver and Lees[14] and purified from methanol. It sintered and darkened at 164°, and melted above 200°. In methanol it showed $[\alpha]^{28}_{D}$ +73.9° (c = 2.788). When bromomorphide was hydrogenated in methanol, with Pd–$BaSO_4$, 4.85 g. of alkaloid took up 1.86 moles of hydrogen, and yielded 1.0 g. of dihydrodesoxymorphine-D hemihydrate. The remaining material was a viscous oil, containing a trace of the high-melting base mentioned under α-chloromorphide. The oil did not give a crystalline ether on treatment with diazomethane. The methylation product in benzene with methyl iodide gave a methiodide of m. p. 235–238°, which appeared to be amorphous, and could be purified only by washing with acetone. It was not the monomethiodide of a dimolecular base, for analysis showed 29.51% iodine, and its properties were not those of bis-dihydrodesoxycodeine dimethiodide. The hydrogenation of bromomorphide in methanol with platinum oxide gave only a small amount of crystalline product, which proved to be tetrahydrodesoxymorphine.

Hydrogenation of bromomorphide in dilute hydrochloric acid gives more crystalline material than in methanol. From 4.85 g. of bromomorphide, absorption of 1.87 moles of hydrogen, 2.4 g. of dihydrodesoxymorphine-D hemihydrate, 0.2 g. of tetrahydrodesoxymorphine, and 1.2 g. of uncrystallizable oil were obtained.

Electrolytic Reduction of Bromomorphide. Desoxymorphine-A.—Six grams of bromomorphide in 250 cc. of 20% sulfuric acid was reduced at 20° with 12 amp. on a 60 sq. cm. lead cathode, time seven hours. A trace of sodium hydrosulfite was added, the base precipitated out with ammonia, and extracted several times with ether. The calculated amount of salicylic acid was added to the dried ether solution, which was then concentrated to 100 cc. A yield of 4.5 g. (79%) of desoxymorphine-A salicylate was obtained. After purification from alcohol it melted at 248–250° (gas evolution)

---

(13) Ach and Steinbock, *Ber.*, **40**, 4282 (1907).

(14) Schryver and Lees, *J. Chem. Soc.*, **77**, 1032 (1900).

and had $[\alpha]^{25}_D$ +93.6° (methanol, c = 0.801). The base prepared from the salicylate melted at 257–258° with decomp.

Reduction of α-Chloromorphide and Bromomorphide with Zinc.—Fifty grams of α-chloromorphide in 1 liter of 6 N hydrochloric acid was heated at 60° for fourteen hours with 100 g. of amalgamated zinc. After eight days further reaction at room temperature, the solution was treated with excess concd. ammonia, and the precipitated alkaloid extracted into ether. The aqueous layer contained much β-isomorphine, which was isolated by exhaustive extraction with ether, and characterized as the salicylate. The main ether extract was heated with 25 g. of salicylic acid and distilled. Twenty grams of a crystalline salicylate was obtained, m. p. 164–178°, which after repeated crystallizations from alcohol showed the constant m. p. 204–206°, $[\alpha]^{27}_D$ −53° (methanol, c = 0.849). Analysis indicated that this was a mixture of a desoxymorphine salicylate and the salicylate of one or more of the morphine isomers. By converting the mixed salicylate back to the alkaloid, desoxymorphine-A of m. p. 258° could be isolated; it did not depress the m. p. of a known sample.

Anal. Calcd. for $C_{17}H_{19}O_2N$: C, 75.80; H, 7.11. Found: C, 75.92; H, 7.15.

Reduction of bromomorphide in the same way gave the same mixture of salicylates.

Reduction of α-Chloromorphide with Tin.—When α-chloromorphide was reduced with tin and concd. hydrochloric acid as described by Schryver and Lees, 3% yield of a crystalline hydrochloride was obtained by allowing an alcoholic solution of the oily hydrochloride to stand for several weeks. It was difficultly soluble in alcohol and could be recrystallized from water. It melted sharply at 263.5° with decompn. and showed $[\alpha]^{27}_D$ −78.1° in water (c = 1.050). The hydrochloride of Lees had the rotation $[\alpha]_D$ +140.3°. The same hydrochloride (5% yield) was obtained when α-chloromorphide was reduced with stannous chloride and concd. hydrochloric acid under pressure at 100°. It was impossible to purify it to the point where it did not leave a trace of inorganic material on combustion.

Anal. Found: C, 58.73; H, 6.74.

The alkaloid liberated from this hydrochloride could not be obtained crystalline, and gave only a colorless oil on methylation.

Summary

1. Catalytic hydrogenation of the three known halogenomorphides results in varying amounts of dihydrodesoxymorphine-D, tetrahydrodesoxymorphine and an unidentified oil.

2. Dihydrodesoxymorphine-D is obtained in nearly quantitative yield by demethylation of dihydrodesoxycodeine-D. It may likewise be prepared by controlled hydrogenation of desoxymorphine-C.

3. Electrolytic reduction of bromomorphide yields chiefly desoxymorphine-A. Reduction of α-chloromorphide or bromomorphide with zinc and hydrochloric acid gives desoxymorphine-A, β-isomorphine and probably other of the morphine isomers.

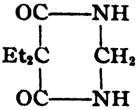
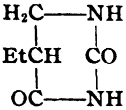
Homodesoxyveronal and Some of its Homologs

BY ARTHUR W. DOX

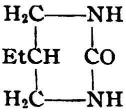
By electrolytic reduction of veronal (barbital) Tafel and Thompson[1] obtained a diethyldiketohexahydropyrimidine (I) which they designated desoxyveronal. Hydrolysis of this product, whereby diethylmalonic acid was obtained, showed that the reduction had occurred in the urea carbonyl. When, however, the corresponding monoethylbarbituric acid was electrolyzed in the same manner, the reduction occurred in one or both of the malonyl carbonyls, depending on temperature and current density, yielding ethylhydrouracil (II) or ethyltrimethyleneurea (III).



I



II



III

Desoxyveronal (I) may be regarded as a cyclic amide of a dibasic acid, the ring closure being effected by substitution of methylene. It should be possible to prepare the substance by direct condensation of diethylmalonyl chloride with methylenediamine. From the high melting point (292°) of desoxyveronal, however, together with the fact that no further study was made, the inference seems warranted that the unrecorded pharmacological tests failed to reveal hypnotic action.[2]

The homologous seven-membered structure, which may be designated homodesoxyveronal (IV), was considered of sufficient interest in this connection to make desirable its preparation and examination. Such a structure should result by condensation of the chloride or ester of diethylmalonic acid with ethylenediamine. Since the esters of malonic acids are more readily available than the chlorides, they were used in the present experiments. The condensations were effected by heating molecular proportions of ester and amine for six to eight hours at 100–110° with absolute alcohol in which two equivalents of sodium had been dissolved. In place of the free base the hydrochloride was also used successfully, with two additional equivalents of sodium ethoxide to liberate the base. Both

(2) Desoxyveronal was also prepared by Einhorn [*Ann.*, **359**, 176 (1908)] by sodium reduction of veronal, but he likewise omits mention of its pharmacological properties.

procedures gave the same condensation products and in practically the same yields. In all, six esters were used, three of dialkyl- and three of monoalkyl-malonic acids. Analyses of the products gave values in satisfactory agreement with those calculated for the seven-membered ring structures.

TABLE I

HOMODESOXYBARBITURIC ACIDS

			Found, %			Calcd., %

Dialkyl-homodesoxybarbituric Acids.—A striking difference was at once apparent between the dialkyl and the monoalkyl derivatives. The former are well-defined crystalline products, but obtained in rather poor yield. They have high, but sharp melting points; on cooling, the melt rapidly solidifies in crystals which show the same melting point as before. Recrystallization is readily effected by cooling or diluting the alcoholic solution. The diethyl derivative has a slightly bitter taste, the two homologs are tasteless. In contrast to desoxyveronal they are insoluble in alkali.

Monoalkyl-homodesoxybarbituric Acids.—These were obtained in much better yields but were invariably amorphous and could not be crystallized from any of the solvents tried. They dissolve in hot glacial acetic acid, but separate as an amorphous slime when the solution is chilled or allowed to evaporate spontaneously. They show a strong tendency to swell to a semi-gelatinous mass in water and for that reason are difficult to filter and purify. Dry powders free from ash were eventually obtained by successive treatments with alcohol and ether. The melting points are high but not sharp and decomposition occurs with darkening in color and evolution of gas. The amorphous character of these products suggests a polymeric structure such as might be represented by Formula V.

The difference in behavior of the esters of dialkyl- and monoalkyl-malonic acids in the condensation with ethylenediamine is not surprising in view of a somewhat similar difference in their reaction with hydrazine.[3] The product there consisted of a single pyrazole ring or the double pyrazopyrazole ring, depending on the absence or presence of an unsubstituted hydrogen in the malonyl grouping. Differences also in reactivity toward ammonia to form amides have long been known.[4]

(4) Fischer and Dilthey, *Ber.*, 35, 884 (1902).

Homodesoxybarbituric Acid.—A reaction between ethyl malonate and ethylenediamine is mentioned in the older literature. Freund[5] obtained an "ethylenemalonamide" by direct condensation without solvent or catalyst. The same substance was again obtained by Ruhemann and Sedzwick[6] as a by-product in the reaction between ethyl dicarboxyglutaconate and ethylenediamine. Aside from the statement that the substance is readily soluble in water, precipitated by alcohol, and melts with decomposition at 280°, nothing is said of its properties.

The writer prepared this ethylenemalonamide (homodesoxybarbituric acid) by the Freund reaction and obtained an amorphous polymeric substance which melted at 280° with decomposition. Its aqueous solution was distinctly colloidal. For example, the warm solution is water clear; on cooling it becomes opaque, but clears up again on warming. In the direct condensation, without solvent or catalyst, between a malonic ester and ethylenediamine, the effect of alkyl substitution in the former is rather striking. Ethyl malonate and the amine react at once with a very considerable rise in temperature, and in a few moments the mixture sets to an opaque gel containing the amorphous condensation product. Ethyl ethylmalonate and the amine form a homogeneous solution but no reaction occurs even after twenty-four hours of standing. When the solution is heated in the steam-bath a white precipitate gradually forms and the mass eventually becomes gelatinous. Ethyl diethylmalonate, on the other hand, does not react with ethylenediamine even after several hours of heating.

As might be expected from the properties of homodesoxyveronal and its higher homologs, these derivatives were found to be pharmacologically inert. Administered orally to rabbits in doses equivalent to the hypnotic dose of barbital no effect whatever was observed.

Summary

Homodesoxyveronal, the seven-membered heterocycle homologous to desoxyveronal, has been synthesized by condensation of ethyl diethylmalonate and ethylenediamine. Its dibutyl and hexylethyl homologs have also been obtained by the same procedure.

Esters of monoalkylmalonic acids also condense with ethylenediamine, yielding products with empirical formulas corresponding to the seven-membered homodesoxybarbituric acids. These products, however, are amorphous and colloidal in character and probably have a polymeric structure.

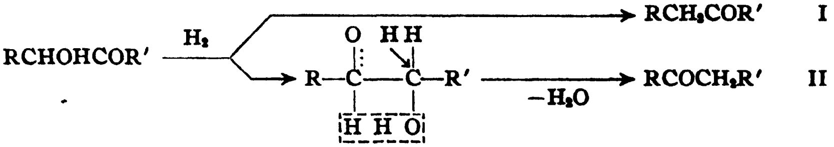
Benzoin Reduction. II. The Mechanism of Ketone Formation. The Case of *m*-Chlorobenzanisoin

BY SANFORD S. JENKINS AND EDWIN M. RICHARDSON

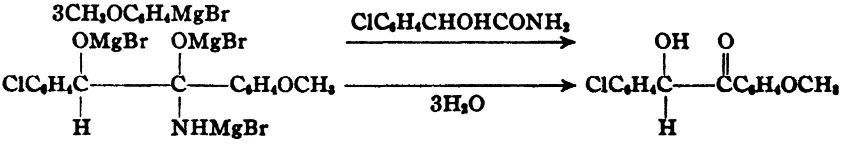
It has been shown previously[1] that certain unsymmetrical benzoins produce *two isomeric* desoxybenzoins when reduced with tin and hydrochloric acid in alcoholic solution and the results obtained were explained by the equations



$$\mathrm{RCHOHCOR'} \xrightarrow{H_2} \begin{cases} \longrightarrow \mathrm{RCH_2COR'} & \mathrm{I} \\ \longrightarrow \mathrm{R{-}\overset{O}{\underset{H}{C}}{-}\overset{H\ H}{\underset{O}{C}}{-}R'} \xrightarrow[-H_2O]{} \mathrm{RCOCH_2R'} & \mathrm{II} \end{cases}$$

This explanation was justified by the fact that the glycol when prepared independently and dehydrated, invariably produced the ketone corresponding to reaction II to the exclusion of I.

The object of the present article is to describe the results which were obtained in the reduction, under similar conditions, of *m*-chlorobenzanisoin in order to test further the validity of the above explanation. This benzoin, which has not been described previously, was prepared in the usual manner by condensing *m*-chlorobenzaldehyde and anisaldehyde in the presence of potassium cyanide. It was shown to be *m*-chloro-α-hydroxybenzyl *p*-methoxyphenyl ketone by comparison with this substance as obtained by reacting *m*-chloromandelamide[2] with *p*-methoxyphenylmagnesium bromide according to the equations



$$3\mathrm{CH_3OC_6H_4MgBr} \xrightarrow{\mathrm{ClC_6H_4CHOHCONH_2}}$$

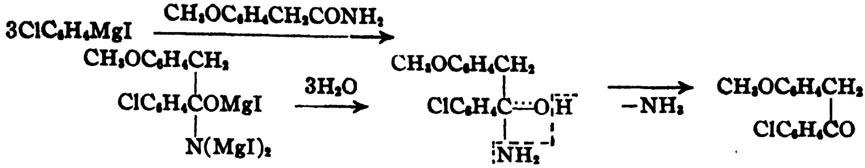
$$\mathrm{ClC_6H_4\overset{OMgBr}{\underset{H}{C}}{-}\overset{OMgBr}{\underset{NHMgBr}{C}}{-}C_6H_4OCH_3} \xrightarrow[3H_2O]{} \mathrm{ClC_6H_4\overset{OH}{\underset{H}{C}}{-}\overset{O}{\overset{\|}{C}}C_6H_4OCH_3}$$

When oxidized with Fehling's solution the benzoin produced the benzil and when reduced with sodium amalgam *sym*-*m*-chloro-*p*′-methoxydiphenylethylene glycol was obtained. The glycol was dehydrated by heating with a solution consisting of 10% concd. sulfuric acid in glacial acetic acid and *p*-methoxybenzyl *m*-chlorophenyl ketone was isolated. The filtrate was carefully examined for the isomeric ketone but only intractable gum could be separated. That the ketone actually has the structure assigned was shown by comparison with the substance as obtained by condensing *p*-methoxyphenylacetamide with *m*-chlorophenylmagnesium iodide according to the reactions

---

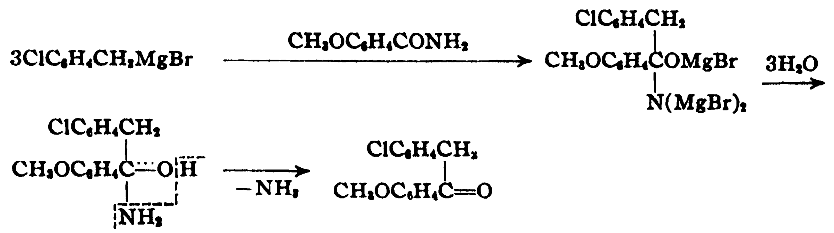
(1) Jenkins, THIS JOURNAL, 54, 1153 (1932).

(2) Jenkins, *ibid.*, 53, 2341 (1931).



$$3ClC_6H_4MgI \xrightarrow{CH_3OC_6H_4CH_2CONH_2} ClC_6H_4\overset{CH_3OC_6H_4CH_2}{\underset{N(MgI)_2}{C}}OMgI \xrightarrow{3H_2O} ClC_6H_4\overset{CH_3OC_6H_4CH_2}{\underset{NH_2}{C}}{-}OH \xrightarrow[-NH_3]{} ClC_6H_4\overset{CH_3OC_6H_4CH_2}{C}O$$

and also by converting it into the oxime, which was rearranged in the Beckmann manner[3] to *p*-methoxyphenylaceto-*m*-chloroanilide the structure of which was established by comparison with an authentic sample (see experimental part). The isomeric ketone, which is *m*-chlorobenzyl *p*-methoxyphenyl ketone, was also prepared independently by condensing *m*-chlorobenzyl bromide[4] with *p*-methoxybenzamide according to the method of synthesizing desoxybenzoins which has been described previously.[5] The reactions may be represented as



$$3ClC_6H_4CH_2MgBr \xrightarrow{CH_3OC_6H_4CONH_2} CH_3OC_6H_4\overset{ClC_6H_4CH_2}{\underset{N(MgBr)_2}{C}}OMgBr \xrightarrow{3H_2O} CH_3OC_6H_4\overset{ClC_6H_4CH_2}{\underset{NH_2}{C}}{-}OH \xrightarrow[-NH_3]{} CH_3OC_6H_4\overset{ClC_6H_4CH_2}{C}{=}O$$

The oxime of this ketone, when rearranged in the Beckmann manner, produced *m*-chlorophenylaceto-*p*-methoxyanilide. Assuming that a *cis* shift takes place between the groups, the oximes have the *anti* benzyl configuration.

The benzoin was reduced with tin and hydrochloric acid in alcoholic solution and both of the above ketones were found to be present in the reduction mixture. By careful fractional crystallization *p*-methoxybenzyl *m*-chlorophenyl ketone was obtained pure in about 10% yield. The major portion of the product, however, melted at 58–60° and proved to be a mixture of the two isomers as was shown by the fact that the melting point was raised when either ketone was added. A portion of the mixture was oximated and *m*-chlorobenzyl *p*-methoxyphenyl ketoxime was obtained by fractional crystallization in a yield of about 20%.

The evidence presented is thus conclusive proof that both isomeric desoxybenzoins are obtained in the reduction of this benzoin under the conditions of the experiment and is a further substantiation of the explanation of the mechanism of these reactions which was previously advanced.

Two other members of the series were prepared. Thus by condensing anisaldehyde with *m*-chlorobenzylmagnesium bromide *m*-chlorobenzyl-*p*-methoxyphenylcarbinol was obtained in a satisfactory yield. This carbinol

(5) Jenkins and Richardson, *ibid.*, 55, 1618 (1933).

could be easily dehydrated to form the corresponding stilbene, *sym-m*-chloro-*p'*-methoxydiphenylethylene.

It is our opinion that most, if not all, of the unsymmetrical benzoins, if reduced in the manner described here and in the preceding article, would be found to produce the two theoretically possible desoxy ketones. Although it is possible that reaction II might be very slow in comparison to I or that the glycol might even lose water to produce I, in every case so far studied both isomeric ketones have been obtained.

Experimental

Preparation of *m*-Chlorobenzanisoin

First Method.—To a solution of 13.60 g. of anisaldehyde, 14.00 g. of *m*-chlorobenzaldehyde and 70 cc. of alcohol was added 6.00 g. of potassium cyanide dissolved in 30 cc. of water. The mixture was refluxed on the water-bath for ninety minutes and placed in the refrigerator. After standing for twenty-four hours the crystalline material was separated, washed with water and recrystallized from slightly diluted alcohol. Yields of 25 to 30% were obtained. Recrystallized from a mixture of benzene and ligroin the substance was obtained as clusters of thick white prisms melting at 85.5° (corr.).

Second Method.—The Grignard reagent from 18.70 g. of *p*-bromoanisole and 2.50 g. of magnesium was prepared in the usual manner. After adding 4.64 g. of *m*-chloromandelamide[3] the solution was refluxed for twenty-five hours and then poured into 200 cc. of ice-cold 10% sulfuric acid. The mixture was stirred occasionally and allowed to stand at room temperature for two hours and then twice extracted with ether. The ether extract was steam distilled and the product was isolated as a yellow gum. After several crystallizations from dilute alcohol and then from benzene–ligroin the substance was obtained in a yield of about 20%, based on the amide used, as thick white prisms which proved to be identical with the compound prepared by method one.

***m*-Chlorobenzanisil.**—To a boiling alcoholic solution of the benzoin (water-bath) strong Fehling's solution was slowly added until an excess was present. After thirty minutes the hot solution was filtered and diluted with water. On standing the benzil separated and was recrystallized from dilute alcohol. The substance was obtained in a yield of about 50% as fine yellow needles which melted at 88° (corr.).

***sym-m*-Chloro-*p'*-methoxydiphenylethyleneglycol.**—This compound was obtained in a yield of about 60% by reducing the benzoin in alcoholic solution with 4% sodium amalgam at room temperature according to the method of preparing glycols which was described in article I.[1] The substance is soluble in alcohol and is best purified by recrystallization from a mixture of benzene and ligroin, from which it is obtained as white prisms melting at 101.5–102.5° (corr.).

Preparation of *p*-Methoxybenzyl *m*-Chlorophenyl Ketone

First Method.—Two grams of the glycol was dissolved in 20 cc. of glacial acetic acid containing 2.0 g. of concentrated sulfuric acid. The solution was refluxed for one hour in an apparatus with ground glass connections and then diluted with about 100 cc. of water. After standing for several hours the yellow solid was separated and recrystallized from dilute alcohol until pure. It consisted of colorless plates melting at 73–74° (corr.) and was obtained in a yield of about 25%. The mother liquors were carefully examined for the isomeric ketone but only gum-like material could be isolated.

Second Method.—A mixture of 5.00 g. of *m*-chlorobenzanisoin, 6.00 g. of mossy tin, 0.30 g. of copper sulfate, 30 cc. of concentrated hydrochloric and 50 cc. of alcohol was refluxed for seven hours and diluted with about 100 cc. of water. After standing for several hours the solid was separated. It weighed about 3.0 g. and melted at 55–65°. After several crystallizations from alcohol a fraction of about 0.60 g. consisting of colorless plates and melting at 73–74° was isolated. This substance proved to be identical with the ketone obtained in the dehydration of the glycol. The filtrates were combined and evaporated to about a third of the original volume and allowed to stand (continued below).

Third Method.—The Grignard reagent from 7.20 g. of *m*-chloroiodobenzene and 0.85 g. of magnesium was prepared in the usual manner. One and two-tenths grams of *p*-methoxyphenylacetamide was then added and the solution refluxed in an atmosphere of hydrogen for twenty-four hours. The ketone was obtained by means of the technique which has been described previously.[5] The yield in this case was not very good—about 20% based on the amide employed. The product proved to be identical in every respect with the substance obtained in methods one and two.

Almost quantitative yields of *p*-methoxyphenylacetamide are obtained by allowing a mixture of the methyl ester and concd. ammonium hydroxide to stand at room temperature for forty-eight hours. Practical purity is obtained by washing with ether; thin plates, m. p. 189–190° (corr.).

Preparation of *p*-Methoxybenzyl *m*-Chlorophenyl Ketoxime.—A mixture of 0.50 g. of the ketone prepared by either method, 0.50 g. of hydroxylamine hydrochloride, 0.80 g. of potassium acetate and 15 cc. alcohol was heated on the water-bath for three hours and diluted with enough hot water to dissolve the potassium chloride formed and cause a cloudiness. After standing in the refrigerator for several hours the solution deposited 0.45 g. of solid which after recrystallization from dilute alcohol consisted of white needles melting at 74–75° (corr.).

Rearrangement of *p*-Methoxybenzyl *m*-Chlorophenyl Ketoxime.—The oxime was rearranged with phosphorus pentachloride in absolute ether employing the technique described in a previous article.[5] The anilide thus obtained was compared (melting point and mixed melting point) with the two theoretically possible anilides, *viz.*, *p*-methoxyphenylacet-*m*-chloroanilide obtained by heating *p*-methoxyphenylacetic acid[6] with *m*-chloroaniline in an oil-bath at 180–190° for three hours and *m*-chlorobenzoyl-*p*-methoxybenzylamine, which was prepared in an analogous manner from *m*-chlorobenzoic acid and anisylamine.[7] The rearranged substance proved to be identical with the first anilide. This evidence thus establishes the structure of the ketone and indicates that the oxime has the *anti* benzyl configuration.

Preparation of *m*-Chlorobenzyl *p*-Methoxyphenol Ketone

First Method.—This ketone was prepared according to the Grignard method of obtaining desoxybenzoins recently described[5] by condensing *m*-chlorobenzylmagnesium bromide with *p*-methoxybenzamide. Four equivalents of the Grignard reagent to one equivalent of the amide were used and the mixture was heated for forty-eight hours. The ketone was obtained in a yield of 60% based on the amide employed. Recrystallized from alcohol it consists of white plates and melts at 70–71° (corr.).

Second Method.—The filtrate obtained in the second method of preparing *p*-methoxybenzyl *m*-chlorophenyl ketone (see above) on standing deposited about 2.0 g. of solid which after recrystallization from alcohol melted at 58–60° and proved to be a mixture of both ketones since when mixed with either the melting point was raised. Although the pure ketone could not be separated from this mixture after oximation the pure oxime was obtained (see below).

Preparation of *m*-Chlorobenzyl *p*-Methoxyphenyl Ketoxime.—This oxime was obtained from the Grignard ketone according to the general method[5] mentioned above in a

---

(6) Mauthner, *Ann.*, **370**, 374 (1909).

(7) Goldschmidt and Polonowska, *Ber.*, **20**, 2407 (1887).

yield of 90% after crystallization from alcohol as white needles melting at 106.5–107.5° (corr.).

One gram of the mixture of ketones obtained in the reduction of the benzoin (see above) was oximated in a similar manner and after careful fractionation 0.22 g. of the pure oxime was obtained.

Rearrangement of *m*-Chlorobenzyl *p*-Methoxyphenyl Ketoxime.—The oxime was rearranged according to the method previously described[3] and the structure of the resulting anilide was established by comparison with the two theoretically possible anilides, *viz.*, *m*-chlorophenylacet-*p*-methoxyanilide obtained by heating *m*-chlorophenylacetic acid[4] and *p*-anisidine in an oil-bath for three hours at 170–190° and *p*-methoxybenzoyl-*m*-chlorobenzylamine prepared similarly from anisic acid and *m*-chlorobenzylamine.[5] The anilide obtained by rearrangement proved to be identical with the first synthetic product. The oxime thus has the *anti* benzyl configuration.

Preparation of *m*-Chlorobenzyl-*p*-methoxyphenylcarbinol.—The Grignard reagent of 0.10 mole of *m*-chlorobenzyl bromide and 2.50 g. of magnesium was prepared in the usual manner. To the solution 12.0 g. of anisaldehyde dissolved in 100 cc. of absolute ether was added. The mixture was heated and mechanically stirred for two hours and then poured into 200 cc. of ice-cold 10% ammonium chloride solution. After extraction with ether, drying with anhydrous sodium sulfate and evaporating the solvent *in vacuo* the carbinol was obtained as a yellow viscous oil in a yield of about 75%. Considerable

(5) This amine was obtained by reducing *m*-chlorobenzaldoxime with zinc and acetic acid according to the method of Franzen [*Ber.*, 38, 1415 (1905)] for preparing the *o*-chloro isomer. The procedure was shortened, however, by steam distilling the crude amine rather than separating it as the carbonate; colorless oil, b. p. 105–110° (13 mm.). See also Braun, Kühn and Weismantel [*Ann.*, 449, 273 (1926)] for a catalytic method of preparation.

difficulty was experienced in inducing the substance to crystallize. Success was attained, however, by dissolving it in a warm mixture of benzene and ligroin and seeding with a few crystals which were obtained by allowing a little of the solution to remain on a watch glass at room temperature for several days. The substance was obtained as thick, white plates melting at 43–44° (corr.).

Preparation of *sym-m*-Chloro-*p*'-methoxydiphenylethylene.—This stilbene was obtained in 60% yield by heating for thirty minutes the above carbinol with twenty parts of a solution consisting of 20% concentrated hydrochloric acid in glacial acetic acid. The crude material was isolated by diluting the solution with water. Recrystallized from alcohol the substance was obtained as cream colored leaves melting at 96° (corr.).

Summary

The explanation of the mechanism of the reduction of unsymmetrical benzoins which was previously advanced has been substantiated in the present work.

m-Chlorobenzanisoin, which has not been described previously, is shown to be *m*-chloro-α-hydroxybenzyl *p*-methoxyphenyl ketone by an independent synthesis.

When reduced under suitable conditions this benzoin was found to produce *m*-chlorobenzyl *p*-methoxyphenyl and *p*-methoxybenzyl *m*-chlorophenyl ketones, the structures of which were established. In the course of this work thirteen new compounds were prepared and characterized.

Some Mono and Dibromo Derivatives of Meta Cresol. II

BY RALPH C. HUSTON AND WALTER J. PETERSON

In a recent report[1] from this Laboratory several new bromo derivatives of *m*-cresol were prepared and their structures conclusively proved. A continuation of this work has resulted in the preparation of several new derivatives. Two new methods for the protection of positions during bromination have been developed.

6-Bromo-*m*-cresols

From 6-Amino-*m*-cresols.—Pure *m*-cresol was nitrated according to the method of Staedel and Kolb,[2] and the isomeric products separated by steam. The volatile 6-nitro product (m. p. 56°) was converted to the 6-amino hydrochloride by reduction in alcohol with stannous chloride and hydrochloric acid.[3] Attempts to change the hydrochloride (m. p. 212°) to the free base were unsuccessful. The free amine (m. p. 157°) may be obtained by reduction of the nitro compound in accordance with the method of Hodgson and Beard.[4] 6-Nitro-*m*-cresol (33 g.) was treated with 400 cc. of water containing

(4) Hodgson and Beard, *J. Chem. Soc.*, **127**, 498 (1925).

60 g. of sodium carbonate. This was treated at the boiling point with 126 g. of solid sodium hydrosulfite. 6-Amino-*m*-cresol[8] was deposited on cooling in almost colorless fine needles melting at 157–159°.

Ten grams of the hydrochloride, dissolved in 16 g. of concd. sulfuric acid and 80 cc. of water, was diazotized below 20° with a solution of 6 g. of sodium nitrite in 125 cc. of water. Replacement of the diazonium group with bromine was effected by dropping the solution into a hydrobromic acid–cuprous bromide solution[6] (from 5 g. of copper sulfate), while a vigorous current of steam was passed through the reaction mixture. The oil in the distillate was extracted with ether and distilled. Four grams of 6-bromo-*m*-cresol came over at 81–82° (4 mm.). The identity with the product formed by direct bromination[1] was proved by boiling point at atmospheric pressure, analysis and bromination[7] to 4,6-dibromo-*m*-cresol[1] (m. p. 65–66°), the benzoyl ester of which melted at 84–85°.

2-Bromo-*m*-cresol

From 2-Nitro-*m*-cresol.—Nitration of *m*-cresol was carried out in fuming sulfuric acid of higher sulfur trioxide content than that used by Gibson,[3] or Hodgson and Beard.[4] A cold solution of 150 g. of *m*-cresol in 100 cc. of fuming sulfuric acid (23% SO_3) was treated with a mixture of 100 cc. of fuming sulfuric acid and 46 cc. nitric acid (1.5) and allowed to stand overnight. The mixture was diluted with 500 cc. of water and heated to 180° on an oil-bath. Decomposition with superheated steam gave 43 g. of 2-nitro-*m*-cresol (m. p. 39°) and 40 g. of *m*-cresol.

Reduction of 33 g. of the nitrocresol by means of sodium hydrosulfite gave 20 g. of 2-amino-*m*-cresol. Eleven grams of this gave, upon diazotization and decomposition with hot hydrobromic acid–cuprous chloride solution (see above), 7.5 g. of an oil which boiled at 83–84° (4 mm.) and solidified on standing. Recrystallization from alcohol gave large monoclinic crystals melting at 58.5–59°.

Anal. Calcd. for C_7H_7OBr: Br, 42.78. Found: Br, 42.62.

A portion of the 2-bromo-*m*-cresol, brominated in cold carbon tetrachloride with one mole of bromine, yielded a portion of uncrystallizable oil (probably 2,6-dibromo-*m*-cresol) and a crystalline fraction which was proved to be 2,4-dibromo-*m*-cresol by melting point (65°) and ester formation.

Methylation of the sodium salt of 2-bromo-*m*-cresol by means of methyl iodide gave a methyl ether melting at 39.5–40°. Hodgson and Beard[4] give 35.5–36.5°.

Anal. Calcd. for C_8H_9OBr: Br, 41.13. Found: Br, 40.98.

By Bromination in Fuming Sulfuric Acid.—To a cold solution of 108 g. of *m*-cresol in 450 cc. of fuming sulfuric acid (23% SO_3), 160 g. of bromine was added very slowly. After 24 hours, the liquid was diluted with 500 cc. of water and heated on an oil-bath to 180°. Steam was passed through the hot solution for about three hours, during which time the temperature was maintained between 180 and 210°. Repeated distillations of the product, using a 20-cm. column and a vacuum of 4 mm., resulted in a large fraction (100.7 g.) boiling at 80–85° and 13.5 g. boiling at 114–116°. The 80–85° fraction, when seeded with a crystal of the 2-bromo-*m*-cresol prepared by diazotization, crystallized immediately. After standing overnight in an ice box, the 2-bromo-*m*-cresol, which made up more than half of the weight of the fraction, was filtered off by suction and recrystallized from alcohol, m. p. 58.5–59°. The uncrystallizable oil came over after refractionation at 80–81° (4 mm.). Preparation of its benzene sulfonyl ester

---

(5) Auwers, Borsche and Weller, *Ber.*, **54**, 1315 (1921).

(6) Bigelow, "Organic Syntheses," Vol. V, p. 21.

(7) Bromination in cold chloroform with 1 mole of bromine gave, in addition to 4,6-dibromo-*m*-cresol, a small amount of oil having the properties of 2,6-dibromo-*m*-cresol.

(8) Claus, *J. prakt. Chem.*, [2] **39**, 61 (1888).

(m. p. 92–93°) proved it to be 6-bromo-*m*-cresol. Ester formation of the fraction boiling at 114–116° proved it to be 2,6-dibromo-*m*-cresol.

By Bromination of the Disulfonic Acid in Alkaline Solutions.—A mixture of one mole (108 g.) of *m*-cresol and 3.5 moles (350 g.) of concentrated sulfuric acid in a three-liter three-necked flask was heated on a steam-bath for three to four hours. At the end of this time the reaction mixture was cooled, the stirring motor attached and the mixture made alkaline with a solution of 7 moles (280 g.) of sodium hydroxide dissolved in 700 cc. of water. The alkaline solution was then cooled to room temperature and brominated slowly with one mole (160 g.) of bromine (during this operation the temperature may be allowed to rise to 40–50°). The mixture was then steam distilled over an oil-bath at 150°. This removed any tribromo-*m*-cresol present. When no more of the tribromo product was observed in the distillate, the distillation was stopped and the mixture, still on the oil-bath, evaporated to a thick pasty mass. This was then allowed to cool and acidified with 800 cc. of concentrated sulfuric acid. (This must be done slowly due to the rapid evolution of hydrogen bromide.) The mixture was again distilled by steam, this time in an oil-bath at 200–210°. The distillate on fractionation gave 37.3 g. boiling at 80–85° (4 mm.) which crystallized on being seeded with 2-bromo-*m*-cresol. From this fraction 13.1 g. of an uncrystallizable oil was separated which boiled at 80–81° (4 mm.) and which was identified as 2-bromo-*m*-cresol. This method of bromination yields a larger portion (43.0 g.) of the 2,6-dibromo-*m*-cresol boiling at 114–116° (4 mm.) than does bromination in fuming sulfuric acid.

2,6-Dibromo-*m*-cresol

From *p*-Nitro-*m*-cresol.—Fifty-eight grams of *p*-nitro-*m*-cresol, when brominated in glacial acetic acid at 15–20° with two moles of bromine, yielded 56.9 g. of 2,6-dibromo-4-nitro-*m*-cresol[8] melting at 134°.

The hydrochloride of 2,6-dibromo-4-amino-*m*-cresol was prepared by reduction in alcohol with stannous chloride and hydrochloric acid according to the method of Raiford.[3b]

For replacement of the amino group with bromine, a modification of the procedure of Bigelow, Johnson and Sandborn[9] for the preparation of *m*-bromotoluene was used. To a cold mixture of 48 cc. of 45% alcohol and 12 cc. of sulfuric acid in one-liter round-bottomed flask provided with a mechanical stirrer was added 20 g. of the hydrochloride of 2,6-dibromo-4-amino-*m*-cresol. The solution was cooled to 10° and a solution of 9 g. of sodium nitrite in 16 cc. of water was added from a separatory funnel. Stirring was continued for a half hour. To the diazotized solution was added 3 g. of reduced copper powder. The stirrer was replaced by a reflux condenser. The flask was warmed cautiously until a vigorous evolution of gas began and was then immersed in ice water. When the reaction had moderated, the flask was heated for ten minutes on a steam-bath. One hundred and twenty cc. of water was added and the mixture was steam distilled. The distillate, after washing and extraction, was fractionated. The bulk of the yellow oil (8.3 g.) came over at 114–116° (4 mm.).

Anal. Calcd. for $C_7H_6OBr_2$: Br, 60.15. Found: Br, 60.32.

A portion of the oil brominated in carbon tetrachloride in the cold yielded 2,4,6-tribromo-*m*-cresol, melting at 80–81°.[10]

By Bromination of the Para Sulfonic Acid in Alkaline Solution.—A mixture of one mole (108 g.) of *m*-cresol and one mole of concentrated sulfuric acid (96 g.) in a two-liter three-necked flask was heated in a water-bath for three hours. The mixture was then cooled and 160 g. of sodium hydroxide in 375 cc. of water was added. The alka-

line solution was cooled to room temperature and brominated (40–50°) with 320 g. of bromine. The rest of the procedure (steam distillation, evaporation and distillation) was carried out as in the preparation of 2-bromo-*m*-cresol by the similar method. The fractionated distillate yielded, besides some tribromo-*m*-cresol, 48 g. of 2,6-dibromo-*m*-cresol. Esters were prepared by the method of Einhorn and Holland.[11]

2,4,6-Tribromo	Small plates	113 –114	48.09	48.17

Summary

1. New bromine derivatives of *m*-cresol were prepared.

2. A new method for the bromination of *m*-cresol in fuming sulfuric acid was developed.

3. Simple diazotization methods have been found applicable for the replacement of amino groups in phenolic compounds with hydrogen and bromine.

Triphenylvinyl Mercaptan

BY C. F. KOELSCH AND GLENN ULLYOT

Thiophenols may be obtained, often in good yields, by the action of sulfur on arylmagnesium halides.[1] Triphenylvinylmagnesium bromide reacts with sulfur in an analogous manner, giving the corresponding thiol, $(C_6H_5)C{=}C(SH)C_6H_5$.

A few thiols have been described in which the sulfhydryl group is attached to an unsaturated aliphatic carbon atom,[2] but the carbonyl group which each of these compounds contains probably influences the behavior of the sulfhydryl group. On alkylation, these substances give S-ethers,[3] and on treatment with phenylhydrazine or with hydroxylamine they evolve hydrogen sulfide with the formation of phenylhydrazones or oximes, indicating that they react in the tautomeric forms C=C—SH and CH—C=S.

In contrast, triphenylvinyl mercaptan appears to react in only the enol form. It dissolves readily in aqueous sodium hydroxide, slowly in boiling aqueous sodium carbonate; carbon dioxide precipitates the mercaptan from these solutions. Methyl sulfate and alkali give a S-methyl ether, and benzoylation by the Schotten–Baumann reaction gives a benzoate. Boiling with alcoholic hydroxylamine acetate gives bis-triphenylvinyl disulfide, which may also be obtained by oxidizing the mercaptan with permanganate. Acid hydrolysis of the mercaptan yields diphenylacetophenone.

Diphenylacetophenone, the O-analog of triphenylvinyl mercaptan, was for a long time considered as triphenylvinyl alcohol, since it could be acetylated and since it supposedly did not form an oxime.[4] At the present time, however, it is given the ketonic formula, Kohler having shown that under the proper conditions it forms an oxime and adds alkylmagnesium halides.[5] Furthermore, diphenylacetophenone is insoluble in alkalies, while the closely related 9-benzoylfluorene is known in a keto and an enol form, the latter of which is readily soluble in aqueous alcoholic alkali, while the former is slowly soluble, solution being accompanied by enolization.[6] The present results indicate that sulfur has little tendency to form a double bond with carbon, a conclusion which may also be drawn from the readiness with which aliphatic thioaldehydes and ketones polymerize, and from the reactivity and color of the aromatic thioketones.

Experimental

Triphenylvinyl Mercaptan.—To a solution of triphenylvinylmagnesium bromide containing two grams of magnesium[7] is added 2.2 g. of sulfur, and the mixture is refluxed for two hours. The magnesium compound is hydrolyzed with iced sulfuric acid, the ether is removed, and the sirupy residue is crystallized from benzene and then from ligroin; yield, 12 g. The compound forms faintly yellow needles that melt at 110–111°.

Anal. Calcd. for $C_{20}H_{16}S$: C, 83.3; H, 5.6. Found: C, 83.5; H, 5.5. *Mol. wt.* Calcd.: 288. Found: (Rast) 275.

Triphenylvinyl mercaptan dissolves in warm aqueous sodium hydroxide, giving a yellow solution which deposits the white difficultly soluble salt on cooling. On boiling with sodium carbonate solution, the mercaptan slowly dissolves; carbon dioxide passed into a warm solution of the sodium salt precipitates the mercaptan.

When a solution of 1 g. of the mercaptan in 30 ml. of acetic acid is acidified with a few drops of sulfuric acid and then boiled, hydrogen sulfide is evolved. On cooling this solution, diphenylacetophenone crystallizes in a nearly theoretical yield. The product melts at 134.5–135° alone or mixed with an authentic sample, and gives the characteristic green color on heating with concd. sulfuric acid.

The methyl ether is obtained by shaking a solution of 1 g. of the mercaptan and 2 g. of sodium hydroxide in 40 ml. of water with 3 ml. of methyl sulfate for twelve hours. The product, crystallized from methanol, forms orange-yellow prisms (0.8 g.) that melt at 109.5–110°. The methyl ether is insoluble in hot sodium hydroxide solution, but very easily soluble in the common organic solvents including petroleum ether; a mixture with triphenylvinyl mercaptan melts at 86–89°. On boiling the methyl ether with acetic acid containing a little sulfuric acid, methyl mercaptan is evolved.

Anal. Calcd. for $C_{21}H_{18}S$: C, 83.4; H, 6.0. Found: C, 83.3; H, 6.0.

The benzoate, prepared by the Schotten–Baumann reaction and crystallized from acetic acid, forms colorless needles that melt at 192–193°. Concordant analytical results were difficult to obtain.

Anal. Calcd. for $C_{27}H_{20}OS$: C, 82.5; H, 5.1. Found: C, 81.6; H, 5.2.

Bis-triphenylvinyl Disulfide.—To a solution of 1 g. of triphenylvinyl mercaptan in hot sodium hydroxide is added 1 g. of potassium permanganate. The mixture is made faintly acid and filtered. The solid is dried and extracted repeatedly with hot ligroin (b. p. 90–110°). The disulfide is obtained by concentrating and cooling the combined extracts. On recrystallization from acetic acid there is obtained about 0.4 g. of yellow prisms that melt at 179.5–180.5° and give a qualitative test for sulfur.

Anal. Calcd. for $C_{40}H_{30}S_2$: C, 83.6; H, 5.3. Found: C, 83.8; H, 5.7. *Mol. wt.* (Rast). Calcd. 574. Found: 585.

The disulfide is obtained when a solution of the mercaptan in alcohol is boiled for four hours with an excess of hydroxylamine hydrochloride and sodium acetate.

Summary

Triphenylvinyl mercaptan, obtained from triphenylvinylmagnesium bromide and sulfur, behaves as an enolic substance, in contrast to its O-analog, diphenylacetophenone.

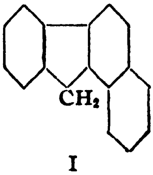
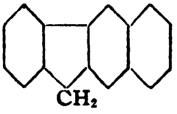
A Synthesis of 2,3-Benzofluorene

BY C. FREDERICK KOELSCH

Since degradation experiments with the hydrocarbon obtained by the action of sodium on 1-diphenylene-3-phenylindene[1] have given results of no value as a structure proof, the problem is being attacked by synthesis. One possible synthesis requires 1,2-benzofluorene (I) as an intermediate. The present paper describes a synthesis which might have led to this hydrocarbon, but which gives its isomer, 2,3-benzofluorene (II), instead.

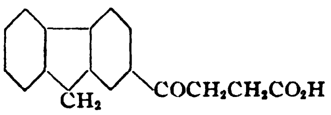


I

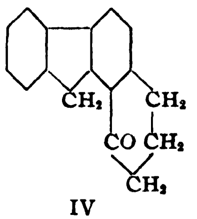


II

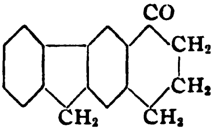
Fluorene and succinic anhydride condense to β-2-fluoroylpropionic acid (III), the orientation of which is shown by oxidation. Reduction of this keto acid gives γ-fluorylbutyric acid. Now although cyclization of this acid by treating its chloride with aluminum chloride may lead to (IV) or (V), actually only one substance is formed.



III



IV



V

The structure of this product is not clearly predictable, since strictly analogous cases have not been investigated previously. γ-2-Naphthylbutyric acid undergoes only angular condensation to form (VI),[2,3] but such a result is occasioned by the known greater reactivity of the α as compared with the β position in the naphthalene nucleus. The more closely related γ-2-tetralylbutyric acid behaves peculiarly, in that it is cyclized by sulfuric acid exclusively to the linear product (VII),[4] while thermal decomposition of its chloride gives a mixture of about equal parts of the linear (VII) and the angular (VIII) products.[5]

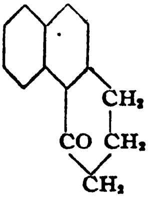
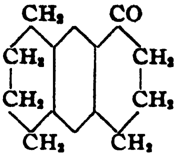
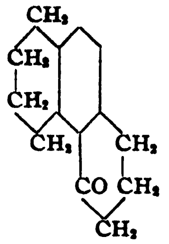
[5] Schroeter, *ibid.*, 57, 2003 (1924).



VI



VII



VIII

The nitration of 2-acetylaminofluorene, which gives the 3-nitro compound[6] and not the 1-nitro compound as was formerly believed,[7] is quite significant as an indication of the greater reactivity of the 3-position in the fluorene nucleus substituted in the 2-position by an *o,p*-directing group.

The further transformations of the cyclization product obtained in the present investigation show it to be the linear (2,3-) compound (V). On reduction it gives tetrahydrobenzofluorene, and this is dehydrogenated to the known 2,3-benzofluorene (II).

Experimental

β-2-Fluoroylpropionic Acid.—To a stirred suspension of 50 g. of succinic anhydride and 85 g. of fluorene in 500 ml. of benzene is added 150 g. of aluminum chloride in portions. The mixture is then heated for one hour on a water-bath with stirring. The reaction mixture is hydrolyzed in the usual way, and the benzene is steam distilled. The solid acid remaining is best purified through its sodium salt, which is easily soluble in hot water and difficultly soluble in cold water. The free acid, obtained in yields of 75–86% after crystallization from acetic acid, forms needles that melt at 210–212°.

Anal. Calcd. for $C_{17}H_{14}O_3$: C, 76.6; H, 5.3. Found: C, 76.5; H, 5.3.

On boiling the keto acid (1 g.) for two hours in acetic acid with 2 g. of sodium dichromate, there is obtained *β-fluorenonoylpropionic acid* which crystallizes from acetic acid in yellow plates that melt at 230–234° with previous darkening.

Anal. Calcd. for $C_{17}H_{12}O_4$: C, 72.8; H, 4.3. Found: C, 72.6; H, 4.6.

Fluoroylpropionic acid dissolved in dilute soda solution is rapidly and completely oxidized on boiling with the calculated amount of potassium permanganate to fluorenone-2-carboxylic acid, yellow needles from acetic acid that do not melt at 295° (literature,[8] >275°). This acid, with thionyl chloride and methanol, gives the methyl ester, yellow needles from methanol that melt at 177–181° (literature,[9] 181°).

Methyl β-2-fluoroylpropionate obtained from the keto acid (5 g.), methanol (75 ml.), and concd. sulfuric acid (5 ml.) by refluxing for four hours, forms white plates from methanol that melt at 111–112°.

Anal. Calcd. for $C_{18}H_{16}O_3$: C, 77.2; H, 5.7. Found: C, 77.2; H, 5.8.

The methyl ester oxime, recrystallized from benzene–ligroin, forms needles that melt at 129–130°.

Anal. Calcd. for $C_{18}H_{17}O_3N$: C, 73.2; H, 5.8. Found: C, 73.5; H, 5.8.

γ-Fluorylbutyric Acid.—The usual Clemmensen method does not affect the keto

---

acid, but by carrying out the reduction in aqueous alcohol, nearly quantitative yields are obtained.

A mixture of 90 g. of fluoroylpropionic acid, 450 ml. of alcohol, 450 ml. of concd. hydrochloric acid and 180 g. of amalgamated zinc is boiled for one hour, an additional 450 ml. of concd. hydrochloric acid is added, and boiling is continued for eight hours. The mixture is cooled, the solid is separated and boiled with one liter of 5% sodium hydroxide until all of the organic matter is dissolved. The solution is filtered and acidified, giving 85 g. of a product that melts at 142–146°. Recrystallization of a portion from acetic acid and then from benzene–ligroin gives white plates that melt at 151–151.5°.

Anal. Calcd. for $C_{17}H_{16}O_2$: C, 80.9; H, 6.4. Found: C, 80.6; H, 6.5.

Ketotetrahydrobenzofluorene.—Distillation of γ-fluorylbutyric acid with phosphorus pentachloride,[3] or heating with 85% sulfuric acid[3] does not cause ring closure. The acid reacts with thionyl chloride to give a black tar which does not have the properties of an acid chloride.

Ring closure is satisfactorily effected as follows: 25 g. of fluorylbutyric acid is refluxed in benzene (250 ml.) with 21 g. of phosphorus pentachloride until the evolution of hydrogen chloride ceases. The solution is cooled and 20 g. of aluminum chloride is added with stirring. After refluxing for thirty minutes, the mixture is poured onto ice and hydrochloric acid, and the benzene is steam distilled. The solid product is dissolved in acetic acid (300 ml.) and boiled with charcoal. The addition of water precipitates 18 g. of light tan colored plates, m. p. 135–140°. Distillation at 20 mm. followed by crystallization from acetic acid is carried out with practically no loss; the ketone forms white plates that melt at 148–149°. It may be distilled without decomposition at atmospheric pressure.

Anal. Calcd. for $C_{17}H_{14}O$: C, 87.2; H, 6.0. Found: C, 86.9; H, 6.1.

The semicarbazone, crystallized from acetic acid, forms needles which become brown at 250°, but do not melt at 290°.

Anal. Calcd. for $C_{18}H_{17}ON_3 + CH_3COOH$: C, 68.3; H, 6.0. Found: C, 68.0; H, 6.1.

Tetrahydrobenzofluorene.—Ketotetrahydrobenzofluorene is reduced readily by the usual Clemmensen procedure, four hours boiling sufficing for complete reduction. The crude solid obtained, which is contaminated with a little dimolecular reduction product, is distilled under reduced pressure and crystallized from acetic acid; yield, 60–70%. The hydrocarbon forms white plates that melt at 129°.

Anal. Calcd. for $C_{17}H_{16}$: C, 92.7; H, 7.3. Found: C, 92.8; H, 7.6.

The picrate forms orange-red needles from absolute alcohol that melt at 123–124°.

2,3-Benzofluorene.—Tetrahydrobenzofluorene (3.2 g.) is heated at 250–275° with sulfur (1.6 g.) until the evolution of hydrogen sulfide ceases (about one hour). The violet melt, from which no crystalline substance can be obtained directly, is distilled under reduced pressure. The deeply colored distillate is crystallized from toluene, giving 0.4 g. of benzofluorene that melts at 204–206° (literature,[10] 208°). On oxidation with sodium dichromate in acetic acid, this hydrocarbon gives 2,3-benzofluorenone, yellow needles that melt at 146–148° (literature,[10] 152°).

The analyses reported in this paper were carried out by Mr. P. O. Tawney.

Summary

A synthesis of 2,3-benzofluorene starting with fluorene has been described.

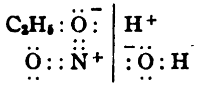
Notes

Explanation of the Formation of Alkyl Nitrites in Dilute Solutions; Butyl and Amyl Nitrites

By William A. Noyes

That nitrous acid is amphoteric, giving both hydrogen and hydroxyl ions in the same manner as hypochlorous acid,[1] is shown by the blue color of nitrous anhydride developed when a dilute acid is added to an ice cold solution of sodium nitrite. Ethyl alcohol is an acid, giving hydrogen ions, as is shown by the action of metallic sodium, by the conductivity of absolute alcohol, which is less than that of pure water, and by the probability of a trifling volatilization of calcium ethylate, $Ca(OC_2H_5)_2$, when absolute alcohol is distilled over calcium oxide.[2] That it is not amphoteric, giving hydroxyl ions, to any appreciable extent is shown by the fact that ethyl ether has never been found in absolute alcohol.

Many years ago Wallach and Otto[3] described a method of preparing ethyl nitrite from dilute alcohol and nitrous acid but they made no remark on the surprising character of this reaction in comparison with those used for the preparation of esters of other weak acids. The explanation is apparent from the considerations given above. The alcohol reacts as an acid and the nitrous acid as a base:



$$\begin{array}{c|l} C_2H_5:\ddot{O}:^{-} & H^{+} \\ \ddot{O}::\ddot{N}^{+} & ^{-}:\ddot{O}:H \end{array}$$

The following method of preparing butyl and amyl nitrites, which is much simpler and quicker than those described in the literature,[4] has been developed by careful experiments on the basis of the principles given.

Dilute 14.5 cc. of concd. sulfuric acid of 96% (one-fourth mole) with 10 cc. of water, cool to 0°, add 39 g. (one-half mole = 37 g.) of normal butyl alcohol or 46 g. of amyl alcohol and cool again. Introduce the resulting homogeneous mixture, during five to ten minutes, beneath the surface of 38 g. of sodium nitrite dissolved in 150 cc. of water. The nitrite solution is cooled in a dish containing ice and water and the contents kept thoroughly mixed by a rapid, whirling motion. Remove the flask from the ice water and allow it to stand for a few minutes until the contents separates in three layers, butyl nitrite above, a saturated solution of sodium sulfate and crystals of sodium sulfate below. Separate sharply in a separatory funnel and wash twice by shaking vigorously with 10 cc. of a solution of 25 g. of salt and 2 g. of acid sodium carbonate in 100 cc. of water.

---

(1) W. A. Noyes and T. A. Wilson, This Journal, **44**, 1630 (1922). S. Goldschmidt, *Ber.*, **52**, 753 (1919), had previously shown the same fact by distilling a solution of hypochlorous acid at a very low temperature but he did not appreciate the theoretical importance of his experiment.

(2) Noyes, This Journal, **45**, 861 (1923).

(3) Wallach and Otto, *Ann.*, **253**, 251 (1889). See also, Noyes, "Organic Chemistry for the Laboratory," fifth edition, p. 285.

(4) R. Adams and O. Kamm, This Journal, **40**, 1285 (1918); last English translation of Gattermann–Wieland, p. 136.

If the nitrite is to be used for a purpose where a little water will do no harm, no further purification is required and the yield is 93 to 95% on the basis of the sulfuric acid used. After standing for a day or two with anhydrous sodium sulfate, the yield is about 90%. The nitrite retains a very small amount of the alcohol used. This is very rarely objectionable but it may be removed by careful distillation with a good column, under diminished pressure. Distillation under atmospheric pressure causes some decomposition.

Aliphatic Hydrocarbons in "Lorol"[1]

BY JOHN R. RUHOFF[2]

Since "Lorol" has recently become available in large quantities, it is one of the best sources of higher aliphatic alcohols. In the course of the distillation of fifty pounds of this material, certain small intermediate fractions were obtained whose presence could not be immediately accounted for. Investigation showed them to be azeotropic mixtures of a paraffin hydrocarbon and an alcohol in the ratio of about 1 to 2.

One of the fractions, boiling at 187–188° (wt. 185 g.), was shaken with benzoyl chloride and sodium hydroxide solution and distilled. Octyl benzoate and a liquid insoluble in concentrated sulfuric acid were recovered. A fraction, boiling at 157–158° (100 mm.) (wt. 105 g.), when treated in a similar manner, yielded decyl benzoate and again an oil insoluble in sulfuric acid. The properties of these two substances, as given in Table I, indicate definitely that they were *n*-undecane and *n*-tridecane.

It seems very probable that, during the high-pressure reduction of the coconut oil, these hydrocarbons were also formed, by the hydrogenolysis

of an alcohol containing one more carbon atom, as described by Wojcik and Adkins.[3] No other hydrocarbon was isolated in quantity sufficient for identification, although there was some evidence that a fraction boiling at 130–50° contained *n*-nonane. However, inasmuch as dodecyl and tetradecyl alcohols are the principal constituents of "Lorol," the amount of hydrocarbon formed from any of the other alcohols present should be small.

COMMUNICATIONS TO THE EDITOR

PHOSPHOROUS FLUOROCHLORIDES

Sir:

We have found that the fluorination of PCl_3 by SbF_3 in the presence of $SbCl_5$[1] yields three gases, PF_3 in large amounts and two new gases, PF_2Cl boiling at approximately −48° and melting at approximately −166°, and small amounts of a $PFCl_2$ boiling a little below room temperature. These new substances are colorless both as gas and liquid, and fume in moist air. Variations of the experimental conditions indicate that the best yields are obtained when 450 parts of PCl_3 and 10 parts of $SbCl_5$ are vigorously stirred while sublimed SbF_3 is slowly added at room temperature.

The low yields by the above method caused us to try converting the PF_3 to the fluorochlorides. It was found that by passing an equimolecular gaseous mixture of PCl_3 and PF_3 through a glass tube filled with broken porcelain heated by an electric furnace so that the temperature of the exit gases was 200°, 50% of the mixture was converted to PF_2Cl and $PFCl_2$ in one pass. We are trying this same general method on mixtures of other non-polar chlorides and fluorides. The complete results of these investigations will be reported later.

AN ATTEMPT TO PREPARE A CHLORIDE OR FLUORIDE OF XENON

Sir:

Frequent attempts have been made to prepare compounds of the noble gases with more electronegative elements, but the results have not been satisfyingly definite. Von Antropoff[1] has described briefly some experiments which indicate that krypton chloride and bromide exist, but no determinations of their composition and physical properties have been published. Both von Antropoff[1] and Pauling[2] have suggested that combination might possibly result with krypton or, more probably, with the heavier xenon. We have carried out experiments in which xenon was mixed with both chlorine and fluorine in an attempt to obtain these halides of xenon.

A mixture of xenon (70 mm.) and chlorine (225 mm.) contained in a quartz tube was irradiated with the light from a mercury arc in Pyrex and in quartz, and from a carbon arc. The source of light in all cases was placed close to the container. The pressure was measured by means of a Pyrex click gage attached through a graded seal to the quartz vessel. In no case was any pressure change observed during or at the end of a twelve-hour exposure. When the gas mixture was condensed by means of liquid air, a small amount of red solid was observed whose color disappeared shortly after removing the liquid air. The mixture was next transferred to a Pyrex bulb equipped with tungsten electrodes. After sparking for varying periods of time and then condensing the contents of the bulb with liquid air, larger amounts of the red solid noted above appeared. A number of tests showed that, in all probability, the red substance was the colored modification of hydrogen chloride described by Giauque.[3] Small amounts of hydrogen chloride are difficult to remove from chlorine and it was doubtless present as an impurity; some may have also been formed by the action of the highly activated chlorine on small amounts of water adsorbed on the walls of the vessel. No definite evidence for the presence of a xenon chloride was found.

It was found that fluorine, carefully freed from hydrogen fluoride, could be kept for an indefinite period in quartz bulbs which had been baked out under vacuum.[4] The small amount of silicon tetrafluoride and oxygen formed as the result of sealing the bulbs at long narrow capillary constrictions did not appear to promote any etching action. By means of quartz "break-offs" a mixture of some 600 mm. of fluorine and 30 mm. of xenon was prepared in an all-quartz apparatus provided with copper electrodes. On condensing the mixture in a side tube at −210° no visual evidence of the existence of anything except liquid fluorine and solid xenon was observed. When the refrigerant was removed the fluorine boiled away rapidly, leaving a volatile white solid with all the properties of xenon. A high voltage (30 k.v.) discharge was then passed through the mixed gases for varying intervals of time. The contents of the apparatus were con-

densed out frequently, but the appearance and properties were no different from those observed before applying the discharge. It was noted that the side tube was appreciably attacked after some time, and this might be due to the action of a reactive xenon fluoride (compare rhenium hexafluoride) or to the presence of a small amount of moisture in the xenon. It cannot be said that definite evidence for compound formation was found. It does not follow, of course, that xenon fluoride is incapable of existing. It is known, for example, that nitrogen and fluorine do not combine in an electrical discharge, but when prepared indirectly nitrogen trifluoride is a very stable compound.

We are greatly indebted to Dr. F. J. Allen, who kindly supplied the xenon used in the experiments.

PREPARATION OF PURE 1-BUTENE AND ISOBUTENE

Sir:

Recently [*Compt. rend.*, **196**, 973 (1933)] Matignon, Moureu and Dode reported that pure aluminum oxide yields only 85% of 1-butene, the remainder being 2-butene.

This is not in agreement with the results previously obtained in our laboratories where it has been found that 1-butene without a trace of 2-butene can be prepared by the dehydration of *n*-butyl alcohol with aluminum oxide. The procedure is as follows: *n*-butyl alcohol is passed with a speed of 75 g. per hour through a glass tube (length, 50 cm.; inner diameter, 2 cm.), filled with 6–8 mesh aluminum oxide and maintained at a temperature of 375–425°. The butenes formed are collected and subjected to distillation in a low-temperature Podbielniak precision distilling apparatus [*Ind. Eng. Chem., Anal. Ed.*, **5**, 172 (1933)].

The aluminum oxide was prepared by the precipitation of aluminum nitrate with ammonium hydroxide; activated alumina received from Alcoa Ore Company, St. Louis, Missouri, gives 1-butene 99.6% pure.

The discrepancy between these results and those of Matignon, Moureu and Dode lies probably in the fact that these authors analyzed the product by converting it into dibromide and subjecting the dibromide to distillation. This method of analysis is not a very reliable one, since isomerization of dibromide can readily take place during the distillation.

V. N. Ipatiev [*Ber.*, **36**, 2011 (1903)] obtained pure isobutene by the dehydration of isobutyl alcohol using aluminum oxide. This work has

been repeated in our laboratories and isobutene 100% pure is obtained by this method.

REMARKS CONCERNING THE PAPER OF G. P. BAXTER AND C. M. ALTER "THE ATOMIC WEIGHT OF LEAD FROM KATANGA PITCHBLENDE"

Sir:

G. P. Baxter and C. M. Alter [THIS JOURNAL, **55**, 2785 (1933)] discuss the theory of the origin of the actinium series [Grosse, *Phys. Rev.*, **42**, 565 (1932)] on the basis of their careful and thorough experimental investigations of the atomic weight of uranium lead from Katanga pitchblende. They find that the lead extracted from the altered yellow portions of the mineral has a lower atomic weight than the lead from the original pitchblende and see in this fact a contradiction to the theory.

We consider that their findings support the theory and think the following the most plausible explanation of the facts.

It is usually considered by mineralogists and geologists [see for instance A. Holmes, "The Age of the Earth," pp. 207–217; G. Kirsch, "Geologie and Radioaktivitat," Chapter III] that lead is leached out from pitchblendes with much greater difficulty than uranium. This is due (1) to its much smaller concentration; (2) to the fact that it forms an insoluble uranate, and generally, because of its chemical nature, lead is much less soluble in acid and alkaline waters than uranium, which easily gives soluble uranyl complex salts. It is, therefore, natural to conclude that the uranium, leached out of the original mineral and redeposited in its veins and crevices, will be, to a great extent, free from U-Pb and being of a younger age, will produce, according to the actino-uranium theory, U-Pb containing less AcD and which therefore will have a lower atomic weight, as was actually found by Baxter and Alter. Furthermore, since this secondary uranium mineral is much more exposed to further leaching, its Pb/U ratio might be easily higher than the true ratio and lead to a wrong estimate of its age.

All of these considerations are only valid in the absence of ordinary lead. A strong indication that such is the case here is given by the low atomic weight figures of Baxter and Alter and is definitely proved by F. W. Aston's mass analysis of Katanga lead [*Nature*, **129**, 649 (1932)].

In conclusion we may state that the actino-uranium theory offers new possibilities for checking geological age determinations and elucidating the phenomena of leaching and other alterations of uranium minerals.

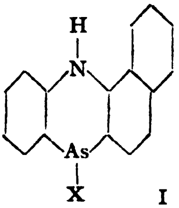
EVIDENCE FOR AN ASYMMETRICAL TRIVALENT ARSENIC ATOM

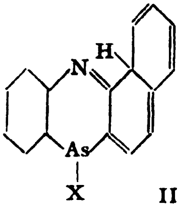
Sir:

The resolution of trivalent nitrogen compounds having three different substituent groups has long baffled organic chemists. Based on certain observations recorded in the literature, it would seem that when a molecule contains a nitrogen atom surrounded by three different groups and a lone pair of electrons, it should be asymmetrical, and capable of resolution if it contains the radicals usually employed for this purpose. Failure to accomplish this has been explained in several ways, one of which is that racemization is so rapid that the optically active molecule has too short a life. Assuming that the presence of additional shells of electrons around the kernel would tend to make a more stable arrangement, a properly constituted trivalent arsenic compound might be capable of resolution, thus showing that such a substance is asymmetrical.

7-Chloro-7,12-dihydro-γ-benzophenarsazine (Formula I, X = Cl) is such a substance. On treatment with silver *d*-bromocamphor sulfonate, dimers (A, B) having different rotations are obtained.



I



II

Subs.	Sp rot	Mol rot	Calcd. half life, min.	Calcd sp rot for As radical
A	+35.11°	+211.4°	70	−24.68°
B	+59.52°	+358.4°	36	+22.65°

Although the arsenic compound has not yet been regenerated from the camphor complex, the formation of these dimers indicates the presence of two asymmetric centers, one of which is in the camphor residue. Both the arsenic and nitrogen atoms are asymmetrical as represented, but since there is yet no recorded case of optical activity of compounds containing trivalent nitrogen, the activity in this instance is probably due to the arsenic. The existence of an asymmetric carbon atom, formed by a 1,3-shift of hydrogen (Formula II), though not excluded seems improbable.

ARSENATED DERIVATIVES OF PHENOBARBITAL

Sir:

An investigation of arsenated derivatives of phenobarbital undertaken several years ago in this Laboratory involves the use of 5-nitrophenyl-5-

ethylbarbituric acid and related compounds described by Bousquet and Adams [THIS JOURNAL, 52, 227 (1930)]. Through the Bart reaction, 5-aminophenyl- and 5-nitroaminophenyl-5-ethylbarbituric acids have been converted into the arsonic acids, 5-arsonophenyl- and 5-nitroarsonophenyl-5-ethylbarbituric acids. By means of hypophosphorous acid the latter were reduced to the corresponding arseno compounds.

During the research it became necessary to establish the position of the nitro group in the starting product and it was shown to be meta. In view of a recent article in this field [Rising, Shroyer and Stieglitz, *ibid.*, 55, 2819, footnote (1933)] in which mention is made of a forthcoming communication by Rising and Pierce concerning the structure of 5-nitrophenyl-5-ethylbarbituric acid, a brief outline is given here of the method of proof used in our work. 5-Nitrophenyl-5-ethylbarbituric acid (m. p. 279–280°) [all melting points are corrected] ⟶ (nitrophenylethylmalonic acid) ⟶ α-nitrophenylbutyric acid (80% yield, m. p. 115.5–116.3°; neutral equivalent 210, calcd. 209.1) ⟶ *m*-nitrobenzoic acid (60% yield, m. p. 141–142°; identity confirmed by mixed m. p.).

5-*m*-Aminophenyl-5-ethylbarbituric acid was converted to a 5-(nitro-*m*-aminophenyl)-5-ethylbarbituric acid (dec. 330–340°) by the method of Bousquet and Adams, and by elimination of the amino group a new isomeric 5-nitrophenyl-5-ethylbarbituric acid (dec. 327–330°) was obtained. In the latter the nitro group may occupy the ortho or para position; the difficulty of hydrolyzing this compound has prevented us from establishing its structure.

THE ACTION OF ELECTROLYTES ON WOOL FIBER

Sir:

During an x-ray investigation of the mordant dyeing of wool, an interesting phenomenon was observed. Using monochromatic radiation (Cu K_α) and mounting the fiber in a box type Laue camera in place of the usual crystal, pure wool fiber gives a very indistinct fiber diagram as contrasted with that obtained from the coarser keratin fibers [W. T. Astbury, *Trans. Faraday Soc.*, **29**, 193 (1933)] such as hair, quills and feathers. However, when this wool has been treated with certain electrolytes, two quite sharp and distinct rings appear. The inner ring is the more intense of the two, corresponding to a spacing of 4.08 Å., while the outer and lighter ring corresponds to a spacing of 3.72 Å. In the case of some of the wool samples, a broad ring quite close to the primary beam was observed corresponding to a spacing of 12.9 Å. Table I is a summary of the results obtained with all of the electrolytes that have been used. The third column indicates in a very approximate manner the visibility of the two lines (4.08 and 3.72 Å.) as observed on diagrams obtained after various treatments, relative to the type of treatment. It is interesting to note that wool which has been dyed as in a regular industrial process shows these two rings. The dye used throughout this work was commercial Orange II furnished through the courtesy of the Dupont Dye Company. NaX signifies the sodium salt of this dye. The wool fiber used was also furnished by the Dupont Dye Company.

It is suggested that the action of electrolytes, particularly those of an acid character, causes the wool protein to become crystalline to some extent and that these crystallites so formed are unoriented along the fiber axis as evidenced by the character of the rings. Table II shows the results of a calculation that would lead one to believe that these three rings are but high orders of a period of 77.8 Å. in length. The data in Table II are averages of all the observations made on many films. The rings on the

FREE PHENYL RADICALS IN THE GAS PHASE

Sir:

In the past few years a number of investigators have demonstrated the existence of active gaseous hydrocarbon molecules in experiments in which various types of substances were thermally decomposed. These have been called free radicals. So far only the methyl and ethyl radicals have been reported. In some experiments which we have been performing we have strong indications of the existence of the free phenyl radical in the gas phase.

The apparatus was made of quartz and consisted of a chamber to contain the lead tetraphenyl, a short region inside an electric furnace inclined slightly from the horizontal, a chamber to retain the liquid and crystalline products formed (chiefly diphenyl) and a chamber in which mercury was kept refluxing. The procedure was similar to that used in our work on the chemical reactions of gaseous methyl and ethyl [THIS JOURNAL, 55, 2696 (1933)]. The lead tetraphenyl was kept just below its melting point (215–220°) and the apparatus run for six hours at an indicated pressure of 0.01 mm.

The deposit formed in the mercury reflux chamber was recrystallized from alcohol. Among the characteristic broad crystals of diphenyl there appeared scattered needle-like crystals. Several were picked out and an attempt made to determine their melting point. This was in the region of 120° as near as could be determined with this small sample. The melting point of mercury diphenyl is 120°. A qualitative analysis showed mercury.

As neither lead tetraphenyl nor diphenyl reacts with mercury vapor, we believe that active phenyl radicals were present. Further work is in progress on this problem.

THE FORMATION OF FREE RADICALS FROM ALIPHATIC AZO COMPOUNDS

Sir:

In view of the publication of a communication on this subject by Leermakers [THIS JOURNAL, 55, 3499 (1933)] it seems desirable to publish an account of some work we performed in this connection in August, 1931. We found that both azomethane and azoisopropane readily remove antimony mirrors when passed through a furnace heated in the range 450–550°; acetone was used as the carrier gas. The temperature of the furnace was far too low to cause any perceptible decomposition of the acetone.

At that time we were more particularly interested in azoisopropane because it seemed to offer the possibility of preparing the free isopropyl group. Paneth and his co-workers [*Ber.*, **62**, 1335 (1929); **64**, 2702, 2708 (1931)] had already prepared free methyl and ethyl but had failed to obtain the *n*-propyl or the isobutyl radicals from the corresponding lead compounds; they concluded that a large proportion of the *n*-propyl and isobutyl radicals must have decomposed into methyl groups since zinc dimethyl was identified among the products. It occurred to us, however, that the isopropyl and tertiary butyl radicals should have about the same stability as the ethyl radical, since in all three cases a C–H bond must break in order for the radical to decompose with production of an olefin hydrocarbon, whereas all other paraffin radicals can undergo this decomposition by rupture of a C–C bond. This may be easily seen from the examples given in a previous paper [Rice, THIS JOURNAL, **55**, 3036 (1933)].

We first made some measurements of the rate of disappearance of the active fragments according to the method described by Rice, Johnston and Evering [THIS JOURNAL, **54**, 3529 (1932)]. The following table gives the results obtained with a 1% solution of azoisopropane in acetone, using a quartz tube 0.4 cm. in diameter and an acetone pressure at the standard mirror of 0.22 mm. of mercury; the fall in pressure down the tube was 0.007 mm. per cm.

d, cm.	15	22	11	30	25	18	13	28	20	30	24
t_m, sec.	51	118	33	225	275	71	42	275	83	305	270

d is the distance from the furnace to the standard mirror and t_m is the time of removal of the standard mirror. These results were plotted and compared with the curve obtained for lead tetramethyl under identical conditions. The first parts of the two curves coincide exactly, but at distances greater than 20 cm. from the furnace the concentration of active fragments does not fall off as rapidly in the case of azoisopropane as in the experiments with lead tetramethyl. This behavior would seem to indicate the formation of a fragment of comparatively long life during the decomposition of azoisopropane. However, at that time we had not yet developed any convenient method of identification and therefore could not determine conclusively whether the isopropyl group was formed, perhaps undergoing partial decomposition into propylene and atomic hydrogen.

INDIUM AND SCANDIUM IN PEGMATITE

Sir:

Indium and scandium have been found in a pegmatite dyke in Western Utah. Analyses of samples taken at random along the dyke indicate 1.0–2.8% indium and 0.5–1.2% scandium.

It is interesting to note that these metals do not occur in connection with zinc. The chief minerals of the deposits are cordierite, actinolite, antigorite, calcite and molybdenite. Apparently the indium occurs as a partial replacement of aluminum in cordierite. The mode of occurrence of the scandium has not yet been determined.

We have succeeded in developing a method for extracting the scandium. This method will be described shortly in detail (as a contribution from the Chemical Laboratory of the University of Utah).

SALT LAKE CITY, UTAH HENDRIK ROMEYN, JR.

RECEIVED AUGUST 24, 1933 PUBLISHED SEPTEMBER 5, 1933

NEW BOOKS

Annual Survey of American Chemistry. Volume VII, 1932. Edited by Clarence J. West, Director, Research Information Service, National Research Council. Published for National Research Council by the Chemical Catalog Company, Inc., 330 West 42d Street, New York, 1933. 346 pp. 13.5 × 21.5 cm. Price, $4.00.

In this volume of the Annual Survey a new policy in regard to the selection of subjects to be considered has been put into effect. The plan followed involves the reduction in the number of fields covered in any year and the treatment of the less important topics once in two or three years. This change was made necessary as the result of the growing size of the volumes from 257 pages in the first year to 543 pages in the sixth year. The number of chapters has been reduced from 37 to 27, which cover 346 pages. Although several topics have been eliminated, the work covered is so extensive that on the average eight references are considered per page, with the result that the discussions are exceedingly brief and limited often to not more than a statement of the titles. Notwithstanding this fact the authors, in general, have produced readable articles which give a clear impression of the recent developments in the subjects treated. The volume is an example of the art of condensation in scientific writing, which is becoming more and more necessary as time goes on and production increases. Since the number of chapters has been reduced it appears to be desirable to list the subjects treated in this volume. They are as follows: theories of solution, kinetics of homogeneous gas reactions, subatomic phenomena, thermodynamics and thermochemistry, colloids, contact catalysis, aliphatic compounds, carbocyclic compounds, heterocyclic compounds, biochemistry, photochemistry, x-ray examination of materials, electrochemical practice, inorganic chemistry 1929–1932, non-ferrous metals, foods, fermentation, water, sewage and trade wastes, soils and fertilizers, coal, petroleum chemistry and technology, textile fibers, dyes and dyeing, rubber, synthetic plastics, chemical engineering. It should be noted that chemical engineering appears for the first time in the Annual Survey. The inclusion of this topic will add to the value of the book.

The Survey has proved of particular value to those who cannot find time to read extensively. It makes it possible for a chemist to learn with little effort something of the developments outside of his own field.

JAMES F. NORRIS

Elementary Quantitative Analysis. Theory and Practice. By Hobart H. Willard, Ph.D., Professor of Analytical Chemistry, University of Michigan, and N. Howell Furman, Ph.D., Associate Professor of Chemistry, Princeton University. D. Van Nostrand Company, Inc., 250 Fourth Ave., New York, 1933. viii + 406 pp. Illustrated. 14.5 × 22.5 cm. Price, $3.25.

This book should be welcomed by all chemists interested in the teaching of quantitative chemistry. It can be characterized as quantitative analysis *per se*, not a pre-professional hurdle nor preliminary practice in technical analysis. The practice determinations are well selected, varied in nature, and in such numbers that flexibility is allowed the teacher in choice of exercises. Recent developments in quantitative methods are introduced through appropriate exercises and combined with the best of well-established, long-standing methods. Directions are written in a simple straightforward style that will impress the student with the essentials of the processes being carried out.

However, the book is more than a collection of conventional directions for carrying on specific determinations designed to familiarize the student with quantitative technique. It is especially characterized by a generous amount of space devoted to the fundamental theory of quantitative chemical processes. In a series of chapters, judiciously distributed among chapters of practical laboratory directions, the modern theoretical basis of analytical chemistry is simply but thoroughly discussed. This material is a natural continuation of the general theory of the introductory course and of quantitative analysis. Many teachers, whose training was secured more than a decade ago, will find interesting information in these theoretical chapters.

Fundamentally sound as the book is, the reviewer cannot but express regret that the authors did not continue to use their original order of treatment; that is, place gravimetric processes before volumetric. This order seems to be the more logical and more in accord with the nature of this text. To be sure, the order of treatment used is well connected and teachable, but it has been the hope of the reviewer that one good quantitative analysis might continue to place first things first, and resist the demand for pre-professional short courses, that is, for the teaching of applications before the fundamentals are thoroughly presented.

With regard to detailed criticisms few objections can be raised. The work is well written and printed throughout, although reading the preface might not seem to promise this, as, in the second paragraph, there is an error in printing and a split infinitive. The authors have included a number of problems and review questions but not too many, and more discussion of methods of solving quantitative problems, the use of reference tables, handbooks, slide rules, etc., might be included. Since some students are familiar with proton chemistry, mention of Brönsted's concepts might have been included in Chapter VI.

The authors have avoided specifying complicated or highly specialized apparatus and only occasionally references are made to specific forms of conventional apparatus or materials. This is commendable since such practical details are administered differently in different laboratories. For example, the reviewer would not agree that the type of buret described and illustrated is the best even for general use, or that a certain excellent rubber paint is the preferred method of lining standard alkali bottles.

There are admittedly other details, described in the book, on which opinions differ, but they are after all mere details. The general impression remains that the authors have produced a thoroughly good textbook of elementary quantitative chemistry, commendable both as to teachability and scope of information presented.

C. R. Hoover

Der Glaszustand. (The Glassy State.) By GUSTAV TAMMANN, Göttingen. Verlag von Leopold Voss, Salomonstrasse 18 B, Leipzig C 1, Germany, 1933. 123 pp. 86 figs. 16 × 23.5 cm. Price, RM. 8.70.

In this monograph there are collected and reviewed the results of numerous researches by Professor Tammann and his students upon substances in the glassy state together with some of the related work of others in the same field. A complete review of the field would be impossible in a book of this size. Consequently the plan is adopted of presenting first in each chapter the author's work upon a phase of the subject and then concluding with a consideration of the parallel work of others, where such work exists. This monograph is unique among books upon glass in that attention is wholly directed to the scientific aspects of the subject with almost no reference to the practical side of glass manufacture.

Because of this point of view, the glasses which were studied were chosen rather because of their suitability for the investigation to be carried out than because of their practical utility. Most of the work was done upon organic glasses softening between 0 and 100°, but the author states that the general results may be carried over into the field of the technically important silicate glasses where the higher temperatures required greatly increase the experimental difficulties encountered.

After a brief review of work upon the formation of crystallization centers and the linear rate of crystallization in supercooled liquids, which will be familiar to most readers, the first half of the book is devoted to a discussion of the changes which occur in all the physical properties of a glass as its temperature is increased through the interval in which it softens. It is shown that for normal glasses the physical properties in general undergo rapid but continuous changes in the interval between the temperature at which the glass ceases to be brittle and that at which it can first be drawn out into threads. In this section is discussed also some most interesting work upon the behavior of glasses under high pressures.

The last half of the book does not possess the unity of the first half but treats a number of more or less unrelated topics. For the most part it is devoted to a further consideration of the phenomena of crystallization or devitrification. There are, however, chapters upon the relation between the properties of the glassy state and the crystalline state, upon the increase in the strength of glass threads with decreasing size, upon the induced birefringence of glass surfaces, upon the molecular constitution of glasses, and upon irreversible changes in the physical properties of glasses. It is perhaps worthy of special mention that condensation and polymerization products such as Bakelite and polyisoprene are found to be distinctly "abnormal" glasses.

While this book contributes nothing directly to the technology of glass it may be recommended highly to those having a scientific interest in this state of matter. It should prove most suggestive to those engaged in the study and development of silicate glasses and should be valuable to the general student as shedding light on what is probably the most obscure realm of physical chemistry.

C. H. GREENE

Phase Rule Studies. An Introduction to the Phase Theory. By J. E. WINFIELD RHODES, Lecturer in Physical Chemistry, Municipal Technical College, Blackburn. With an introduction by E. L. RHEAD, Lecturer in Metallurgy and Assaying in the University and College of Technology, Manchester, England. Oxford University Press, 1933. x + 131 pp. 58 figs. 13 × 19 cm. Price, $2.25.

This is a somewhat elementary though entirely scientific presentation of the whole field of the phase rule, including the treatment of four-component systems. In order to secure such a breadth of field, it has been necessary to make some sacrifices in depth.

The introduction indicates that the book is intended to bridge the gap for students whose knowledge of the subject has come from the brief study usually given it as a part of their physical chemistry, but who find that they need something more extensive upon taking up mineralogical or metallurgical investigations. The book will certainly do something of real value for such students, though it just as certainly leaves much reading to be done. A number of the systems taken for discussion are of mineralogical interest and not previously available in textbooks. The presentation is clear and in good form.

ARTHUR E. HILL

Chemische Grundlagen der Lebensvorgänge. Eine Einführung in biologische Lehrbücher. (The Chemistry of Living Processes. An Introduction to Biological Literature.) By Professor CARL OPPENHEIMER, Dr. Phil. et Med., Berlin. Georg Thieme Verlag, Antonstrasse 15/19, Leipzig C 1, Germany, 1933. vii + 298 pp. 1 fig. 17 × 25 cm. Price, M. 22.50; bound, M. 24.50.

In the preface the author states that this work was originally planned to appear in two parts, "Chemie der Zellvorgänge" and "Energetik der lebenden Substanz" to supplement the recent "Lehrbuch der allgemeinen Physiologie" by Ernst Gellhorn. This plan, however, was later changed because the author wished to appeal to a somewhat wider audience than simply animal physiologists. The present volume is directed not only at zoölogical and medical problems but the author hopes that it will prove of equal value to botanists and bacteriologists.

The book is divided into five parts: (I) Living Substance as a Chemical System, comprising sixteen pages and considering briefly a short introduction in which the composition of protoplasm is considered, followed by a discussion of the elements which occur in living cells.

II. Chemical Compounds in Protoplasm, comprising a short discussion of colloids, association, molecular size, etc., and followed by brief considerations of some of the more important characteristics of the fats and waxes, the carotinoids and the phospholipides, the carbohydrates, the respiratory pyrrole-containing pigments and the proteins.

III. Anabolism and Catabolism, including carbon and nitrogen assimilation and changes which organic compounds undergo in living cells.

IV. The Chemical Mechanism of Cell Activity, in which attention is called to the role of enzymes in biological processes.

V. The Energy Process of Living Substance, in which are considered the general nature of energy transfer and energy cycles, followed by a discussion of living substance as a chemico-dynamical machine.

The volume closes with an adequate subject index.

As might be expected from a knowledge of the field of interest of the author, the major emphasis in this volume is devoted to enzyme chemistry. Almost two-thirds of the book may be regarded as a condensed consideration of enzyme reactions, so that those workers who do not have access to the author's extensive (and expensive) "Die Fermente und ihre Wirkungen" can here find a very excellent, and adequate, résumé of Oppenheimer's views on enzymes, their reaction and the role which they play in vital processes. This is the chief value of the book. The brief introductory discussions of proteins, carbohydrates, fats, etc., are so brief as to contribute little that is new or unique and serve only to introduce the later portions dealing with enzymes and their reactions. Few persons are better qualified than is Oppenheimer to discuss enzym and their reactions and it is this discussion which appeals to the reviewer and which he feels justifies the addition of the present volume to the mass of biochemical texts.

ROSS AIKEN GORTNER

Chemistry of Food and Nutrition. By HENRY C. SHERMAN, Ph.D., Sc.D., Mitchill Professor of Chemistry, Columbia University. Fourth edition, rewritten and enlarged. The Macmillan Company, 60 Fifth Ave., New York, 1932. xiii + 614 pp. 14 × 20.5 cm. Price, $3.00.

The fourth edition of this standard work has been very largely rewritten and somewhat enlarged to include the most recent advances in biochemistry and nutrition. Separate chapters are now devoted to iron, copper and iodine, and to vitamins A, B, G, C, D and E. The chapter on "Dietary Standards" is especially to be commended for the well-balanced treatment it gives this controversial field.

JOURNAL OF THE AMERICAN CHEMICAL SOCIETY

VOLUME 55 OCTOBER, 1933 NUMBER 10

Definitive Report of the Commission on the Reform of the Nomenclature of Organic Chemistry

Translation with

Comments

BY AUSTIN M. PATTERSON

Introduction

It is possible in the domain of organic chemistry to give several names to the same compound. This state of affairs has on the one hand the great advantage of permitting clear expression of thought and of rendering it easier to bring out analogies in structure wherever this is useful. But on the other hand the multiplicity of names for the same substance constitutes a serious obstacle in the preparation of indexes.

Translator's Note.—This report was unanimously adopted by the Commission and by the Council of the International Union of Chemistry at the meeting of the Union, held in Liége, September 14–20, 1930, and the official French text appears in the "Comptes rendus" of that meeting. It seemed likely that some details might be modified at the meeting scheduled to be held in Madrid in April, 1932, but as that meeting was postponed the report may be considered to have reached a certain stage of completion.

The rules are based on those of the Geneva Congress of 1892,[1,2] but include many changes and additions. They are naturally compromises in some cases, but are believed to represent a distinct advance in nomenclature practice.

Many of the provisions are already being observed in the publications of the American Chemical Society. It will be the policy of *Chemical Abstracts*, which was represented on the Working Committee by the translator, to put the rules into practice in its indexing to as great an extent and within as short a time as its long-established system of nomenclature and the requirements of its decennial indexes permit. The *Journal of the American Chemical Society* follows, in general, the usages of *Chemical Abstracts*.

The translator acknowledges his indebtedness to the valuable comments of Professor P. E. Verkade,[3] some of whose examples he has used.

The text of the report is given in ordinary type; comments by the translator are in small type.

---

(1) Pictet, *Arch. sci. phys. nat.*, [3] **27**, 485–520 (1892)

(2) Tiemann, *Ber.*, **26**, 1595–1631 (1893).

(3) Verkade, *Rec. trav. chim.*, **51**, 185–217 (1932).

This difficulty was experienced as long ago as 1892 and the celebrated Congress of Geneva, at which thirty-four of the best qualified chemists from nine countries of Europe created the Geneva nomenclature, attempted to remedy it by laying down as Rule 1 of its report the following: "In addition to the customary methods of nomenclature there shall be established for each organic compound an official name, which will enable it to be found under only one entry in indexes and dictionaries." As is generally known, this intent of the Geneva Congress has not been realized. The Geneva nomenclature has not been sufficiently worked out except for acyclic compounds. Even for many of these, and still more for the rest, its application gives names which are much too complicated. This is probably the reason why the commission of 1892 did not complete its work.

Today, an official nomenclature for indexes, which was desirable forty years ago, has become quite unnecessary for the following reasons: (1) In 1918 a new edition of Beilstein commenced to appear; this admirable work facilitates bibliographic researches in an extraordinary manner.

(2) The problem has been solved by the formula indexes which are now in use in a number of chemical journals, including *Chemical Abstracts* and *Chemisches Zentralblatt.*

Nevertheless, the Geneva nomenclature has been of much value to organic chemistry, for its fundamental ideas are of great importance from the systematic standpoint throughout the entire extent of the science. The classification in Beilstein is based upon it for this reason.

As has just been observed, the Geneva names are inconvenient in the majority of cases and not very practical for ordinary use. The editors of Beilstein as well as of other compilations have rightly employed them, not alone but with the addition of the names in current use.

Now, a revision of these names has become more and more pressing; for the number of compounds has increased incessantly to an extraordinary degree and their discoverers, although following usage as far as possible, have not always made a happy choice of names and have even, in some cases, adopted names manifestly incorrect.

In order to remedy this regrettable state of affairs, in 1922 the International Union of Chemistry, on the proposal of Sir William Pope, named a Working Committee (Comité de Travail) to study the reform of the nomenclature of organic chemistry, composed of delegates from the editorial staffs of important chemical journals. The following were chosen as members: Messrs. Crane, Greenaway and Marquis, representing *Chemical Abstracts*, the *Journal of the Chemical Society* of London and the *Bulletin de la Société Chimique de France.* This Committee was instructed to make a report and submit it to the Commission of the Union, which approved it. The following year this Committee was enlarged by representatives of the *Gazzetta chimica italiana* (Paternò), *Helvetica Chimica*

Acta (Pictet) and *Recueil des travaux chimiques des Pays-Bas* (Holleman). The last-named was chosen chairman, and M. Marquis secretary.

In the course of time this Committee underwent the following changes: Mr. Crane was replaced by Mr. Patterson, Mr. Greenaway (assisted by Mr. Gibson) retired and was replaced by Mr. Barger. M. Paternò was presently replaced by M. Peratoner, but illness prevented him from participating in the sessions. After his death, the Italian Chemical Society named M. Mario Betti, who was unable to take part in editing the report but was present at the Eighth Conference at Warsaw in 1927, the Ninth at The Hague (1928) and the Tenth at Liége (1930) in which the said report was discussed and in part modified. Herr Prager, editor of Beilstein, named by the Verband deutscher chemischer Vereine as its representative on the Committee, was also present at Liége.

During the years 1924–1928 the Committee held several meetings in Paris; the result of its work was a report which was presented at The Hague in 1928 to the Commission of the Union on the reform of the nomenclature of organic chemistry. The latter proposed certain modifications which were examined again by the Working Committee. The report as thus amended was discussed at the meeting of the Commission in 1930 at Liége and was then adopted unanimously.

This report is not intended to interfere with the editing of Beilstein or of *Chemical Abstracts*, publications which have followed for many years their own systems of nomenclature, which moreover are very similar to the rules now adopted.

The object of the Committee in its work has been rather to follow usage as nearly as possible (see rule 1 below), to record it while at the same time proposing certain simplifications and eliminating incorrect names. It hopes that the flexible system of nomenclature thus created will be used more and more by authors of articles and of treatises on organic chemistry as well as in oral instruction and that the editors of journals will recommend its use as far as possible.

Rules

Index: I. General. II. Hydrocarbons: 1. Saturated Hydrocarbons. 2. Unsaturated Hydrocarbons. 3. Cyclic Hydrocarbons. III. Fundamental Heterocyclic Compounds. IV. Simple Functions. V. Complex Functions. VI. Radicals. VII. Numbering.

I. General

1. As few changes as possible will be made in terminology universally adopted.

The Committee members were apparently agreed that any attempt to introduce sweeping changes in terminology, however consistent they might be, would prove impractical and undesirable in the present stage of the science. The purpose of the rules, therefore, is rather to unify existing practice as far as possible by eliminating objectionable names and guiding future naming along desirable lines. The proposal (in Geneva rule 1) of an official name for each organic compound has been abandoned.

2. For the present, only the nomenclature of compounds of known constitution will be dealt with; the question of substances of imperfectly known constitution is postponed.

It is evident that a special technique is required for naming compounds of incompletely known structure so as to denote the presence, or the removal, of certain atoms or groups, or relation to other compounds. Although there might be an advantage in regularizing nomenclature practice in this field, the Committee decided not to consider it for the present. Moreover, the classification and naming of such important natural substances as the proteins and their derivatives, the lipides or lipoids, and the carbohydrates, were already in the hands of the Committee on Biochemical Nomenclature. The wording of this rule is identical with that of Geneva rule 2.

3. The precise form of words, endings, etc., prescribed in the rules should be adapted to the genius of each language by the subcommittees.

The wisdom of this rule seems evident, otherwise chemical word elements might conflict with important grammatical or other usages. As a sample of such difficulties may be cited the fact that in German -e is a case ending and hence -ene is not appropriate as a hydrocarbon suffix; it becomes -en instead. In Spanish the same ending becomes -eno. Most such adaptations will be made readily enough; a few, because of their newness, may require some ingenuity.

II. Hydrocarbons

4. The ending *ane* is adopted for saturated hydrocarbons Open-chain hydrocarbons will have the generic name *alkanes*.

The name "alkane" is better and shorter than "paraffin," especially since the latter term is now so commonly applied to a solid mixture.

5. The present names of the first four normal saturated hydrocarbons (methane, ethane, propane, butane) are retained. Names derived from the Greek or Latin numerals will be used for those having more than four atoms of carbon.

The words "or Latin" have been added to the Geneva rule (no. 4) because *nonane* is almost universally used for C_9H_{20} instead of the Greek derivative *enneane* (as also is *nona-* instead of *ennea-* in combination, as in *nonadecane*); and because *undecane* appears oftener than *hendecane*, although the latter has a respectable standing. For most of the alkanes, however, names of Greek derivation are customary.

6. Branched-chain hydrocarbons are regarded as derivatives of the normal hydrocarbons; their names will be referred to the longest normal chain present in the formula by adding to it the designations of the side chains. In case of ambiguity, or if a simpler name would result, that chain which admits of the maximum of substitutions will be selected as the fundamental chain.

This rule may require further interpretation. The version published by the Journal of the Chemical Society[4] is quite different. It reads: "Branched-chain hydrocarbons

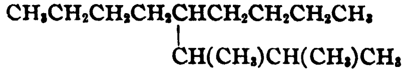
---

(4) *J. Chem. Soc.*, 1607–1616 (1931).

are regarded as derivatives of normal hydrocarbons; their names will be determined by the longest chain containing the maximum number of double or triple linkings (preference being given to the double linking where ambiguity arises), or, in the case of saturated hydrocarbons, by the longest chain in the formula. In cases where there might be doubt as to the choice of the longest chain, that one will be selected which admits of the maximum of substitution." It was the impression of the writer that this version, which he considers preferable, was adopted at Liége, but he has followed the French version of the "Comptes rendus" of the meeting.

If the French version is accepted, then it seems best to interpret it as referring to *saturated* hydrocarbons only, unsaturated hydrocarbons being treated in rules 8–10. The phrase "or if a simpler name would result" ("ou si cela donne un nom plus simple" in the French version) is of doubtful value as there may be differences of opinion as to which name is "simpler." In saturated branched-chain hydrocarbons, in the writer's opinion the longest chain present should be chosen as the fundamental one, and if there are two or more choices for the longest chain, then that one should be chosen in which there is the greatest number of substitutions (the reason being that the substituting radicals, while more numerous, will be of simpler structure).

Example:



$$CH_3CH_2CH_2CH_2\underset{\substack{|\\ CH(CH_3)CH(CH_3)CH_3}}{CH}CH_2CH_2CH_2CH_3$$

By the principle of the "longest chain" the name would be 5-(1,2-dimethylpropyl)-nonane; but according to the rule the name 4-butyl-2,3-dimethyloctane (which avoids a branched side chain) is the one to be chosen if it seems simpler.

7. In case there are several side chains, the order in which such chains are named will correspond to the order of their complexity. The chain having the greatest number of secondary and tertiary atoms will be considered the most complex. The alphabetic order may also be followed in such cases.

The Committee members were divided in their preferences between an order of radical names based on structure (for example, one based on increasing weight, as methyl, ethyl, butyl) and an alphabetic order as used, for example, in *Chemical Abstracts*. The two possibilities were hence left side by side, not only in this rule but also more generally in rule 63.

The advocates of the structural basis for such an order did not formulate any complete rule, and the wording of rule 7 is not very clear. In the writer's opinion it means that the name of the hydrocarbon radical of lowest weight is to be announced first, then that of the next highest weight, and so on, and that as between isomers the normal radical comes first, then the ones of branched structure, *e. g.*, methyl, ethyl, propyl, isopropyl, butyl, isobutyl. The rule does not decide completely between branched isomers, and neither this rule nor rule 63 prescribes any structural order for the host of substituting groups which are not hydrocarbon radicals (such orders have been constructed, however).[5]

The beauty of the alphabetic order is that it furnishes a means of arranging in order, almost instantly, substituents of any kind. Its only difficulty is that a few radical names differ substantially in spelling in certain languages (*e. g.*, ethyl, Äthyl). In such cases a transposition would be necessary in the translation. Fortunately, the exact order of prefixes in an organic name is not of great importance except in indexes. Example of the alphabetic order: butyl, ethyl, isobutyl, isopropyl, methyl, propyl.

---

(5) See for instance Stelzner, *Literatur-Register der organischen Chemie*, 1, xxiv–xxxiii (1913); 2, xxii–xl (1919).

(Or, if *iso-* is italicized, butyl, *iso*-butyl, ethyl, methyl, propyl, *iso*-propyl.) For further illustrations the indexes to *Chemical Abstracts* may be consulted.

8. In the names of open-chain unsaturated hydrocarbons having one double bond the ending *ane* of the corresponding saturated hydrocarbon will be replaced by the ending *ene;* if there are two double bonds, the ending will be *diene,* etc. These hydrocarbons will bear the generic names *alkenes, alkadienes, alkatrienes,* etc. Examples: propene, hexene, etc.

This rule follows the Geneva system and in addition introduces the generic names *alkene,* etc., corresponding to *alkane.* Strictly interpreted, it calls for the replacement of *ethylene* by *ethene.* The writer doubts if this change will ever become general but the higher names, as propene, butene, etc., seem to be slowly supplanting the older propylene, butylene, etc. Examples: $\overset{1}{C}H_2{=}\overset{2}{C}H\overset{3}{C}H_3$, propene; $\overset{1}{C}H_2{=}\overset{2}{C}H\overset{3}{C}H_2\overset{4}{C}H_3$, 1-butene; $\overset{1}{C}H_3\overset{2}{C}H{=}\overset{3}{C}H\overset{4}{C}H{=}\overset{5}{C}H\overset{6}{C}H_3$, 2,4-hexadiene. The double bond receives its number from the lowest-numbered carbon atom to which it is attached. The principle of "lowest numbers" (see rule 64) is always applied; for instance, 1-butene might also be called 3-butene, but the lower number is selected.

For the naming of branched unsaturated hydrocarbons see the comments on rule 10.

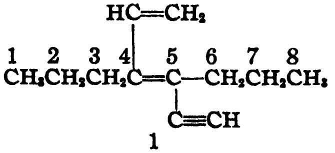
9. The names of triple-bond hydrocarbons will end in *yne, diyne,* etc. They will bear the generic name *alkynes.* Examples: propyne, heptyne, etc.

The Geneva ending *-ine* for these hydrocarbons has been replaced by *-yne* because -ine is reserved for names of organic bases (see rule 33). The English pronunciation of -yne is like that of -ine in "wine." It seems unlikely that the time-honored "acetylene" will be replaced by "ethyne" but the names for the higher members, such as propyne, ($\overset{1}{C}H\equiv\overset{2}{C}-\overset{3}{C}H_3$), 1-butyne ($\overset{1}{C}H\equiv\overset{2}{C}-\overset{3}{C}H_2\overset{4}{C}H_3$) and 2,4-hexadiyne ($\overset{1}{C}H_3\overset{2}{C}\equiv\overset{3}{C}-\overset{4}{C}\equiv\overset{5}{C}\overset{6}{C}H_3$) will probably be increasingly used.

10. If there are both double and triple bonds in the fundamental chain the endings *enyne, dienyne,* etc., will be used. The generic names of these hydrocarbons will be *alkenynes, alkadienynes,* etc.

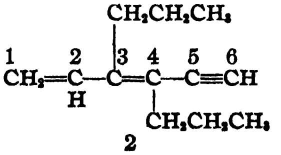
The endings *-enyne* and *-dienyne* given in the rule indicate that the double bonds are always to be expressed first, then the triple bonds. *E. g.,* $\overset{1}{C}H\equiv\overset{2}{C}-\overset{3}{C}H{=}\overset{4}{C}H\overset{5}{C}H{=}\overset{6}{C}H\overset{7}{C}\equiv\overset{8}{C}H$, octa-3,5-diene-1,7-diyne.

If we interpret rule 6 as applying to saturated hydrocarbons only (see the comments on rule 6), then the Committee has made no rule for the naming of *branched unsaturated* hydrocarbons. Two alternatives seem to be open: (1) to follow the Geneva system and choose the longest chain in the molecule as the fundamental one, even if it does not contain the double or triple bonds. (2) To consider the unsaturated linkages as functions (they are so listed in rule 52) and, guided by rule 18, to select as the fundamental chain that one which contains the maximum of double and triple bonds (even if it is not the longest present in the molecule). Example:



$$\overset{1}{C}H_3\overset{2}{C}H_2\overset{3}{C}H_2\overset{4}{C}(\text{HC}{=}\text{CH}_2){=}\overset{5}{C}(\text{C}\equiv\text{CH})-\overset{6}{C}H_2\overset{7}{C}H_2\overset{8}{C}H_3$$

1



$$\overset{1}{C}H_2{=}\overset{2}{C}H-\overset{3}{C}(\text{CH}_2\text{CH}_2\text{CH}_3){=}\overset{4}{C}(\text{CH}_2\text{CH}_2\text{CH}_3)-\overset{5}{C}\equiv\overset{6}{C}H$$

2

By method (1): 4-ethenyl-5-ethynyl-4-octene. By method (2): 3,4-dipropyl-hexa-1,3-dien-5-yne. (As to beginning the numbering with the double instead of the triple bond, see rule 64.) For general use the writer favors method (2) as being in accordance with the treatment of other functions, and also as better expressing the nature of the hydrocarbon in the ending of the name.

11. Saturated monocyclic hydrocarbons will take the names of the corresponding open-chain saturated hydrocarbons, preceded by the prefix *cyclo*. They will bear the generic name *cycloalkanes.*

The Geneva names *cyclopropane, cyclobutane,* etc., have won general acceptance, replacing the older names trimethylene, tetramethylene, etc. The latter names have a better use as applied to bivalent radicals (recognized in rule 57).

12. When they are unsaturated, rules 8–10 will be applied. However, in the case of partially saturated polycyclic aromatic compounds the prefix *hydro,* preceded by *di-*, *tetra-*, etc., will be used. Example: dihydroanthracene.

Further examples: cyclobutadiene, cyclohexene (not tetrahydrobenzene), 1,2-dihydronaphthalene. For completely saturated polycyclic aromatic hydrocarbons it was at one time proposed in the Committee to use the ending -ane; *e. g.*, naphthalane. This provision was later rejected, however. In so doing the Committee no doubt intended that "decahydronaphthalene" be used instead of "naphthalane," and so for other cases. It was therefore probably an oversight that the words "or wholly" were not added after "partially" in revising the rule.

13. Aromatic hydrocarbons will be denoted by the ending *ene* and will otherwise retain their customary names. However, the name *phene* may be used instead of *benzene.*

The best usage in English already conforms to this rule, which will help to hasten the disuse of such names as benzol, toluol and xylol for chemical individuals. "Phene," while logically related to "phenol," is not likely to replace "benzene."

III. Fundamental Heterocyclic Compounds

14. The endings of customary names, endings which do not correspond to the function of the substance, will undergo the following modifications, so far as they are in accord with the genius of each language: (a) The ending *ol* will be changed to *ole.* Example: pyrrole. (b) The ending *ane* will be changed to *an.* Example: pyran.

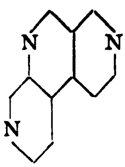
The change from *-ol* to *-ole* is obviously for the purpose of reserving -ol as an ending for the names of alcohols and phenols; similarly, the change from *-ane* to *-an* is made in order to reserve -ane for saturated parent compounds. The rule does not state whether names of fully saturated heterocyclic parent compounds such as  are to be spelled -ane or -an (*Chemical Abstracts* calls the above 1,4-dioxane), or whether -ane is to be used for saturated hydrocarbons only. It is clear, however, that -ane should *not* be used for any substance not completely saturated. The above changes are not possible in German, since *e* is the sign of the plural (*cf.* rule 3).

15. When nitrogenous heterocycles not having the ending *ine* give basic compounds on progressive hydrogenation, such derivation will be indicated by the successive endings *ine*, *idine*. Examples: pyrrole, pyrroline, pyrrolidine; oxazole, oxazoline.

This rule merely recognizes and extends a well-established practice.

16. The ending *a* is adopted for hetero atoms occurring in a ring. Oxygen will accordingly be indicated by *oxa*, sulfur by *thia*, nitrogen by *aza*, etc. The letter *a* may be elided before a vowel. Examples: thiadiazole, oxadiazole, thiazine, oxazine.

While the universally accepted names of heterocyclic compounds are retained, the names of other heterocyclic compounds are derived from that of the corresponding homocyclic compound by adding to it the names of the hetero atoms ending in *a*. Example: 2,7,9-triazaphenanthrene.



The use of *a* in such prefixes as oxa-, thia- and aza- distinguishes these forms clearly from oxy-, thio-, azo-, etc., which have other meanings. The "a" prefixes may be used either (1) to form such names as *thiadiazole*, or (2) to denote the replacement of a carbon atom or hydrocarbon grouping by a hetero atom or grouping, as stated in the second paragraph of the rule. This latter method is a very useful one, especially in naming bridged heterocyclic compounds, but there are objections to making it the sole method for naming new forms. Among these objections are (1) that in certain cases the hetero atom would be given a different numbering in two tautomeric compounds, thus making it appear that the hetero atom has shifted instead of a hydrogen atom;[6] (2) that in some cases the corresponding homocyclic compounds are not known and that the known heterocyclic compound is more readily named from its own component rings; and (3) that in the case of nitrogen bases the method yields names that do not end in -ine.

The writer therefore sought to have this rule modified so as to make it clear that the use of the "a" nomenclature is permissive only. His impression is that it was the intention of the Committee to so modify the rule at Liége, but the modification does not appear in the final version. The Committee surely cannot have intended to abrogate the well-established practice of forming such names as anthrapyrrole and naphthopyridine, in which the prefix denotes a form which is "fused" with the form whose name follows it. Both practices should be permitted, in the writer's opinion. The older practice can be preserved along with the new if, in accordance with rule 1, a broad interpretation is given to the words, "The names of heterocyclic compounds which are universally adopted will be retained." It is interesting to note that the German version reads: "Wo ein solcher Name fehlt, *kann* der Name," etc., and accordingly makes the use of the "a" nomenclature in such cases permissive only.

IV. Simple Functions

17. Substances of simple function are defined as those containing a function of one kind only, which may be repeated several times in the same molecule.

That is to say, a compound which is an acid, an alcohol or an aldehyde and only that, is defined as a substance of simple function, while one which is at the same time an alcohol and an acid, or an acid and an aldehyde, is said to be a substance of complex function.

---

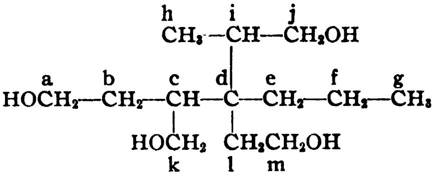
(6) For an example see Patterson, This Journal, 50, 3084 (1928).

(7) *Ber.*, 65A, 11-20 (1932).

18. When there is only one functional group, the fundamental chain will be selected so as to contain this group. When there are several functional groups the fundamental chain will be selected so as to contain the maximum number of these groups.

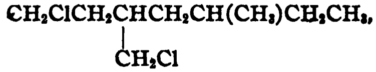
This is an important modification of the Geneva system. The central idea of the latter, so far as aliphatic compounds are concerned, is a fixed carbon skeleton with a fixed numbering, analogous to the fixed scheme for parent cyclic compounds, such as anthracene or quinoline. Hence the longest carbon chain in the molecule and the length and position of the side chains attached to it become of first importance—functional groups such as OH or COOH may come where they will. An example of such a skeleton is  $\overset{1}{C}—\overset{2}{C}—\underset{C}{\overset{3}{C}}—\overset{4}{C}—\overset{5}{C}$ and the saturated hydrocarbon corresponding to it is 3-methylpentane. Suppose carbon atom number 1 and the carbon atom of the side chain in 3-methylpentane to be oxidized to carboxyl groups. According to the Geneva system the original numbering is retained and the compound is called pentanoic-3-methyloic acid. But chemists commonly call this substance ethylsuccinic acid and thereby choose as the fundamental chain the one containing the two carboxyl groups. These groups have a far greater influence upon the properties of the compound than an extra methyl or ethyl group, so it seems natural to treat the compound as a derivative of the corresponding straight-chain diacid rather than as a modified 3-methylpentane. The Committee has recognized this very common principle of nomenclature in rule 18. The functional groups, and not the complete skeleton, are given the place of first importance. By rules 18 and 29 the systematic name of ethylsuccinic acid becomes 2-ethyl-butanedioic acid.

If there are two or more choices for the chain containing the maximum of functional groups, then the principle of rule 6 should be applied (although rule 18 does not so state). That is, the longest chain should be chosen as the fundamental one and if there is still a choice to be made, then the one involving a maximum of substitutions. Example:



In this compound the maximum of functional groups in any straight chain is two. The longest chain in the molecule is abcdefg = 7, but it contains only one OH group. Those containing two OH groups are: abck = 4, kcdlm = 5, jidlm = 5, abcdij = 6 and abcdlm = 6. The choice therefore lies between the two 6-membered chains. Of these, abcdij has one more substitution than the other and therefore becomes the fundamental chain. The compound accordingly receives the name (numbering j = 1, i = 2, d = 3, c = 4, b = 5 and a = 6): 3-(2-hydroxyethyl)-4-(hydroxymethyl)-2-methyl-3-propyl-1,6-hexanediol.

Should rule 18 be applied to halogen substitution products of the hydrocarbons? At first glance one would infer so, since "halogenide" is listed as a function in rule 52. The real purpose for rule 18, however, in the writer's opinion, is to ensure that all, or as many as possible, of the groups of the principal function (see rule 51) may be expressed in the ending of the name. Rule 18, although it occurs under the heading "Simple Functions" is therefore to be regarded as a complement to rule 51; it should be understood to apply to the principal function (and to it only) when other functions are present. Now, according to rules 19 and 52, halogen functions are to be expressed by prefixes only and there is no utility in applying rule 18 to them *or to any other function when it is expressed as a prefix.* The nitro and nitroso functions are other instances of functions which are expressed as prefixes only. It seems better, and more in accord with present usage, to allow chloro, bromo, nitro, etc., derivatives to be named as derivatives of the longest chain present in the molecule. Example:



$$CH_2ClCH_2\underset{\displaystyle CH_2Cl}{\underset{|}{C}}HCH_2CH(CH_3)CH_2CH_3,$$

1-chloro-3-chloromethyl-5-methylheptane and not 1,4-dichloro-2-(2-methylbutyl)-butane.

19. Halogen derivatives will be designated by the name of the hydrocarbon from which they are derived, preceded by a prefix indicating the nature and number of the halogen atoms.

Examination of text-books shows a prevailing use of such names as ethyl chloride, amyl iodide, hexyl bromide. These compounds are usually, however, of very simple structure. A perusal of the journals will show that the more complex halogen derivatives cannot be conveniently named in this manner and as a matter of fact are nearly always named with the use of prefixes. Rule 19 recommends that prefixes be employed in all cases and we have therefore chloromethane instead of methyl chloride, 1-chlorobutane instead of *n*-butyl chloride, 1,2-dichloroethane instead of ethylene chloride, and so on, although by rule 1 the older names may still be used.

20. Alcohols and phenols will be given the name of the hydrocarbon from which they are derived, followed by the suffix *ol.* In accordance with rule 1 names universally adopted will be retained, as: phenol, cresol, naphthol, etc.

This nomenclature may also be applied to heterocycles. Example: quinolinol.

This is the Geneva nomenclature, with an extension to heterocyclic compounds. Examples: CH_3CH_2OH, ethanol; $CH_3CHOHCH_3$, 2-propanol; cyclohexanol; fluorenol (for hydroxyfluorene); quinolinol (for hydroxyquinoline), etc.

By rule 14, names ending in -ol for substances which are not alcohols or phenols are to be spelled -ole. Similarly, trivial names of alcohols and phenols should end in -ol (as, mannitol instead of mannite, resorcinol instead of resorcin).

21. In naming polyhydric alcohols or phenols, one of the forms *di*, *tri*, *tetra*, etc., will be inserted between the name of the parent hydrocarbon and the suffix *ol.*

Examples: CH_2OHCH_2OH, 1,2-ethanediol; $CH_2OHCHOHCH_2OH$, 1,2,3-propanetriol; $C_6H_4(OH)_2$, benzenediol; $C_{10}H_4(OH)_4$, naphthalenetetrol.

22. The name *mercaptan* as a suffix is abandoned; this function will be denoted by the suffix *thiol.*

Examples: CH_3SH, methanethiol; C_6H_5SH, benzenethiol; CH_2SHCH_2SH, 1,2-ethanedithiol.

23. Ethers are considered as hydrocarbons in which one or several hydrogen atoms are replaced by alkoxy groups. However, for symmetrical ethers the present nomenclature may be retained. Examples: $CH_3OC_2H_5$, methoxyethane; CH_3OCH_3, methoxymethane or methyl ether.

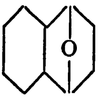
The ether function is treated as a relatively unimportant one, in naming, probably because it is so slightly reactive. Also, like all functions involving a bivalent radical, it causes some difficulties in nomenclature. In this rule the Committee subordinates it to the hydrocarbon and provides that it be expressed in a prefix rather than in the ending of the name. A concession is made to usage in recognizing also the usual names of the simple ethers. In naming by the alkoxy method the larger radical should be chosen for the parent compound. The method is to be extended, presumably, to cyclic compounds. Examples: CH_3OCH_3, methoxymethane or methyl ether; $CH_3OC_2H_5$, methoxyethane; $CH_3OC_4H_3O$, methoxyfuran; $C_6H_5OC_{10}H_7$, phenoxynaphthalene; $CH_3OCH_2CH_2OCH_3$, 1,2-dimethoxyethane.

24. Oxygen linked, in a chain of carbon atoms, to two of these atoms will be denoted by the prefix *epoxy* in all cases where it would be unprofitable to name the substance as a cyclic compound. Examples: ethylene oxide = epoxyethane; epichlorohydrin = 3-chloro-1,2-epoxypropane; tetramethylene oxide = 1,4-epoxybutane.

Rule 24 was no doubt given this position because it refers to a special case of the ether function. The prefix *epoxy* is not intended to supplant the regular cyclic names but to be used only where the latter are inconvenient. It will probably find its most common use in cases where a double bond has been oxidized and it is desired to bring out this relationship. Example:

$CH_2{=}CHCH_2CH_3$	$CH_2OHCHOHCH_2CH_3$	 $\overset{\displaystyle O}{CH{-}CH}CH_2CH_3$
1-butene	1,2-butanediol	1,2-epoxybutane

Another opportunity for its use will be found in bridged compounds; as, 1,4-epoxynaphthalene:



25. Sulfides, disulfides, sulfoxides and sulfones will be named like the ethers, *oxy* being replaced by *thio*, *dithio*, *sulfinyl* and *sulfonyl*, respectively. Examples: $CH_3SO_2C_2H_5$, methylsulfonylethane; $CH_3SC_3H_7$, methylthiopropane; $CH_3CH_2CH_2SOCH_2CH_2CH_2CH_3$, 1-(propylsulfinyl)butane.

Further examples: $CH_3SSC_6H_5$, methyldithiobenzene; $C_6H_5SOC_{10}H_7$, phenylsulfinylnaphthalene; $CH_3SO_2C_4H_3O$, methylsulfonylfuran. Presumably the provision about symmetrical compounds in rule 23 applies here also, according to which CH_3SCH_3 could be called methylthiomethane or methyl sulfide; $C_2H_5SOC_2H_5$, ethylsulfinylethane or ethyl sulfoxide, etc.

26. Aldehydes are characterized by the suffix *al* added to the name of the hydrocarbon from which they are derived; thioaldehydes, by the suffix *thial*. Acetals will be named as 1,1-dialkoxyalkanes.

Aliphatic aldehydes and thioaldehydes are named in the above manner in the Geneva system. Examples: CH_3CHO, ethanal; CHOCHO, ethanedial; CH_3CH_2CHS, propanethial; $CH_3C(OC_2H_5)_2$, 1,1-diethoxyethane. No provision is made in the rules for aldehydes in which the CHO group is attached directly to a ring (compare rule 49). By analogy with the suffixes -carbonamide, -carbonitrile, etc., the suffix for a substituting CHO group would be *-carbonal*, and C_6H_5CHO, for example, would be named benzenecarbonal (naturally, by rule 1, the common name benzaldehyde would also be recognized). Similarly, $C_5H_3N(CHO)_2$ would be named pyridinedicarbonal.

27. Ketones will receive the ending *one*. Diketones, triketones, thioketones will be designated by the suffixes *dione, trione, thione*.

This is a Geneva rule which has justified itself in practice for aliphatic compounds. Examples: CH_3COCH_3, propanone; CH_3CSCH_3, propanethione; $CH_3COCOCH_3$, 2,3-butanedione. So, also, cyclohexanone, 1,4-cyclohexanedione, etc. The rules make no provision for ketone groups in side chains in the cyclic series (compare rule 49).

28. The name *ketene* is retained.

"Ketene" (or, as spelled by some, "keten") is accordingly recognized as a name for the parent compound $CH_2{=}CO$. It was at one time proposed to call this compound "ethenone" or "ketenone" but the Committee finally decided not to disturb already established usage. Example: $(CH_3)_2C{=}CO$, dimethylketene.

29. For acids the rule of the Geneva nomenclature is retained. However, in cases where the use of that nomenclature would not be convenient the carboxyl group will be considered as a substituting group and the name of the acid will be formed by adding to the name of the hydrocarbon the suffix *carbonique* or *carboxylic*, according to the language.

This rule on the naming of acids is a frank compromise between two conflicting ideas, whose advantages and disadvantages led to much discussion both in the Geneva Congress and in the International Committee. By the Geneva rules aliphatic acids are regarded as derived from hydrocarbons of the same number of carbon atoms (CH_3 being replaced by COOH). The acid name is formed from the hydrocarbon name by adding to it *-oic acid, -dioic acid*, etc. Such names are convenient for simple monoacids and diacids, but become less so as the structure grows more complicated. In the latter case most chemists will probably prefer the "carboxylic" nomenclature. Examples of both systems are given below, with their respective numberings. By rule 1, the familiar names of acids, as butyric, succinic, may also be used.

4 3 2 1 $CH_3CH_2CH_2CO_2H$ butanoic acid	3 2 1 $CH_3CH_2CH_2CO_2H$ 1-propanecarboxylic acid
12 3 4 $HO_2CCH_2CH_2CO_2H$ butanedioic acid	1 2 $HO_2CCH_2CH_2CO_2H$ 1,2-ethanedicarboxylic acid
4 3 2 1 $CH_3CH(CH_3)CH_2CO_2H$ 3-methylbutanoic acid	3 2 1 $CH_3CH(CH_3)CH_2CO_2H$ 2-methyl-1-propanecarboxylic acid
1 2 3 4 5 $CH_3CH_2CH(CO_2H)CH_2CH_3$ pentane-3-methyloic acid	1 2 3 4 5 $CH_3CH_2CH(CO_2H)CH_2CH_3$ 3-pentanecarboxylic acid (or 1-ethyl-1-propanecarboxylic acid)
12 3 4 5 $HO_2CCH_2CH(CO_2H)CH_2CO_2H$ pentanedioic-3-methyloic acid	1 2 3 $HO_2CCH_2CH(CO_2H)CH_2CO_2H$ 1,2,3-propanetricarboxylic acid
4 3 2 1 $CH_2{=}CHCH_2CO_2H$ 3-butenoic acid	3 2 1 $CH_2{=}CHCH_2CO_2H$ 2-propene-1-carboxylic acid (*cf.* rule 64)

In the original Geneva system side chains and double bonds take precedence over the carboxyl groups in determining the numbering. Such numberings are contrary to rule 64 and hence in the examples above they have been revised to give carboxyl low numbers. In most of the carboxylic numberings the figures 1, 2, 3 correspond to the familiar α, β, γ. The Geneva rules refer to aliphatic acids only, hence where the carboxyl group is directly attached to a ring the "carboxylic" nomenclature is to be followed. Example: C_6H_5COOH, benzene-carboxylic acid (or benzoic acid).

It will be noted that in the Geneva names of acids a side chain containing a carboxyl group is expressed as "methyloic" (—COOH), "ethyloic" ($—CH_2COOH$), etc. (see examples 4 and 5, above). In the "carboxylic" nomenclature, presumably any carboxyl group which is not attached to the fundamental chain is to be expressed by the prefix "carboxy;" as, $HOOCCH_2C(CH_2COOH)(COOH)CH_2COOH$, pentanedioic-3-methyloic-3-ethyloic acid (Geneva name) or 2-(carboxymethyl)-1,2,3-propanetricarboxylic acid ("carboxylic" name).

30. Acids in which an atom of sulfur replaces an atom of oxygen will be named according to the Geneva nomenclature. Example: ethanethioic, -thiolic, -thionic, -thionothiolic. If the carboxyl is considered as a substituent the compounds will be named *carbothioic* acids. The suffix *carbothiolic* will be used if it is certain that the oxygen of the OH group is replaced by sulfur; the suffix *carbothionic* if it is the oxygen of the CO group; the suffix *carbodithioic* will be used if both oxygen atoms are replaced.

Examples of the two systems of names: CH_3COSH or CH_3CSOH (either one), ethanethioic acid, methanecarbothioic acid; CH_3COSH, ethanethiolic acid, methanecarbothiolic acid; CH_3CSOH, ethanethionic acid, methanecarbothionic acid; CH_3CSSH, ethanethionothiolic acid, methanecarbodithioic acid.

31. The existing conventions will be retained for salts and esters.

Examples: Sodium butanoate or sodium salt of butanoic acid; diethyl 1,2-ethanedicarboxylate or diethyl ester of 1,2-ethanedicarboxylic acid; sodium acetate; methyl succinate.

32. Acid anhydrides will retain their present mode of designation according to the names of the corresponding acids. For names formed in accordance with the Geneva nomenclature, the amides, amidoximes, amidines, imides and nitriles will be named like the acids by adding to the name of the corresponding hydrocarbon the endings *amide*, *amidine*, *amidoxime*, *imide* and *nitrile*, respectively, while the halides will be named by combining *chloride*, etc., with the name of the radical. Examples: C_3H_7COCl, butanoyl chloride; $C_3H_7CONH_2$, butanamide; etc.

If the carboxyl is considered as a substituent the endings *carbonamide*, *carbonamidine*, *carbonamidoxime*, *carbonimide*, *carbonitrile* will be used. Examples: C_3H_7COCl, propanecarbonyl chloride; $C_3H_7CONH_2$, propanecarbonamide; etc.

Further examples: $(CH_3CO)_2O$, ethanoic anhydride or methanecarboxylic anhydride (also acetic anhydride); CH_3CONH_2, ethanamide or methanecarbonamide; $CH_3C({=}NH)NH_2$, ethanamidine or methanecarbonamidine; $CH_3C({=}NOH)NH_2$, ethanamidoxime or methanecarbonamidoxime;  $\begin{matrix} CH_2CO \\ | \\ CH_2CO \end{matrix}\!\!>NH$, butamide or 1,2-ethanedicarbonimide; CH_3CN, ethanenitrile or methanecarbonitrile; CH_3COCl, ethanoyl chloride or methanecarbonyl chloride (*cf.* rule 58).

English-speaking chemists may, if they desire, use *-carboxamide* or *-carboxylamide* instead of -carbonamide, and so on (*cf.* rules 3 and 29) but it is well not to introduce any more such language differences than are necessary.

33. The ending *ine* is reserved exclusively for nitrogenous bases. The present nomenclature of monoamines is retained. For polyamines, the name of the hydrocarbon will be followed by the suffixes *diamine*, *triamine*, etc.

For aliphatic compounds containing quinquevalent nitrogen the ending *ine* will be changed to *onium*. For cyclic substances containing quinquevalent nitrogen in the ring the ending *ine* will be changed to *inium;* for those with the ending *ole*, this will be changed to *olium*. Examples: pyridine, pyridinium; imidazole, imidazolium.

In accordance with the first sentence of this rule the spelling of names of non-bases ending in -ine should be changed; thus glycerine becomes glycerol, dextrine becomes dextrin, propine becomes propyne (see rule 9). Examples of names of amines: CH_3NH_2, methylamine; $(CH_3)_2NH$, dimethylamine; $(CH_3)_3N$, trimethylamine; $H_2NCH_2CH_2NH_2$, 1,2-ethanediamine; $C_6H_4(NH_2)_2$, benzenediamine.

34. The nomenclature of the derivatives of phosphorus, arsenic, antimony and bismuth, being very complicated, will be considered later.

Usage in this field needs systematizing but the Committee could not agree upon a plan. The scheme proposed by the American Committee for the acids of phosphorus, arsenic and antimony was as follows (with "phosph" and "stib" corresponding to "ars"):

Formula	Prefix	Suffix
RR'AsOH	Arsinoso	Arsinous
$RAs(OH)_2$	Arsonoso	Arsonous
RR'AsO.OH	Arsino	Arsinic
$RAsO(OH)_2$	Arsono	Arsonic

35. Compounds derived from hydroxylamine by replacement of the hydrogen of the hydroxyl will be regarded as alkoxy derivatives; those in which an atom of hydrogen of the NH_2 group is replaced, as alkylhydroxylamines. Oximes will be named by adding the suffix *oxime* to the name of the corresponding aldehyde, ketone or quinone. Examples: $C_2H_5ONH_2$, ethoxyamine; C_2H_5NHOH, ethylhydroxylamine.

Further examples: $CH_3CH_2CH{=}NOH$, propanal oxime; $CH_3C({=}NOH)CH_3$, propanone oxime.

36. The generic term *urea* is retained; it will be used as a suffix for the alkyl and acyl derivatives of urea. Examples: butylurea, $C_4H_9NHCONH_2$; butyrylurea, $C_3H_7CONHCONH_2$. The bivalent radical —NHCONH— will be named *ureylene*.

Butyrylurea may also be called butanoylurea or propanecarbonylurea. Nothing is said about polysubstituted ureas.

37. The generic name *guanidine* is retained.

38. The name *carbylamine* is retained.

In earlier drafts the terms *isonitrile* and *isocarbonitrile* were favored and *carbylamine* was rejected. The latter was apparently restored at the instance of Professor Grignard, who believed there should be more of a distinction from nitriles than the prefix "iso" gives. No examples are given but the form favored by custom seems to be: ethylcarbylamine, C_2H_5NC. No objection seems to have been raised to *isocyanide*, a term also in use for these compounds (as, ethyl isocyanide).

39. Isocyanic and isothiocyanic esters (RNCO, RNCS) will be named *isocyanates* and *isothiocyanates*.

Examples: ethyl isocyanate, C_2H_5NCO; ethyl isothiocyanate, C_2H_5NCS.

40. The name *cyanate* is reserved for true esters which on saponification yield cyanic acid or its hydration products. The name *sulfocyanate* will be replaced by *thiocyanate*.

This is Geneva rule 44 with slightly altered wording. Examples: C_2H_5CNO, ethyl cyanate; C_2H_5CNS, ethyl thiocyanate.

41. Nitro derivatives: no change in the present nomenclature.

That is, the group NO_2 is always indicated by the prefix *nitro*, never by a suffix. Nitroso compounds are treated similarly (see rule 52). Examples: nitrosobenzene, 2,4,6-trinitrophenol.

42. Azo derivatives: the forms *azo*, *azoxy* are retained.

This rule is rather non-committal, as it does not state how the azo and azoxy names are to be formed. By rule 1 familiar terms like azobenzene, $C_6H_5N_2C_6H_5$, would be retained. The Geneva name for this substance is benzeneazobenzene. In treating the group $C_6H_5N_2$ as a substituent the Committee does not indicate whether it should be called "benzeneazo" or "phenylazo" (the latter would seem to accord best with rules 23 and 25). The same considerations apply to azoxy compounds. Hydrazo compounds are treated as hydrazine derivatives (rule 44).

43. (a) Diazonium compounds, RN_2X, are named by addition of the suffix *diazonium* to the name of the parent substance (benzenediazonium chloride).

(b) Compounds having the same empirical formula but containing trivalent nitrogen will be named by replacing diazonium with *diazo* (benzenediazohydroxide).

(c) Substances of the type RN_2OM will be named *diazoates*.

(d) Compounds in which the two nitrogen atoms are united to a single carbon atom will be designated by the prefix *diazo* (diazomethane, diazoacetic acid).

(e) The term *diazoamino* is retained; however, these compounds may also be regarded as derivatives of triazene.

(f) Derivatives of the substances $H_2NNHNHNH_2$; $NH{=}NNHNH_2$; $NH{=}NNHN{=}NH$ will be named *tetrazanes*, *tetrazenes*, *pentazdienes*, etc.

Examples: (a) $C_6H_5N({\equiv}N)Cl$, benzenediazonium chloride; (b) $C_6H_5N{=}NOH$, benzenediazohydroxide; (c) $C_6H_5N{=}NONa$, sodium benzenediazoate; (d) N_2CH_2, diazomethane; N_2CH_2COOH, diazoacetic acid, diazoethanoic acid or diazomethanecarboxylic acid; (e) $C_6H_5N{=}NNHC_6H_5$, diazoaminobenzene or 1,3-diphenyltriazene; (f) $C_6H_5NHNHNHNHC_6H_5$, 1,4-diphenyltetrazane; $C_6H_5N{=}NNHNH_2$, 1-phenyl-1-tetrazene. (The numberings are the writer's.)

44. Hydrazines are designated by the name of the alkyl radicals from

which they are derived, followed by the suffix *hydrazine*. In cases where the amino group of carbonamides is replaced by the hydrazino group, the suffix *hydrazide* will be used. Hydrazo derivatives are regarded as derivatives of hydrazine. Examples: CH_3NHNH_2, methylhydrazine; $C_2H_5NHNHC_3H_7$, 1-ethyl-2-propylhydrazine; $C_3H_7CONHNH_2$, butyrohydrazide or propanecarbohydrazide.

The name for $C_3H_7CONHNH_2$ which corresponds to the Geneva name for the acid would probably be butanohydrazide, although neither the Geneva rules nor the present rules say so explicitly. The cases of *poly*substituted hydrazines in which one or more substituents are acid radicals are not covered by the rule. If there is more than one acyl substituent the compound is possibly best named by analogy with rule 36; example: $CH_3CONHNHCOCH_3$, 1,2-diacetylhydrazine, 1,2-diethanoylhydrazine, or 1,2-bis(methanecarbonyl)hydrazine. If there is only one acyl substituent it might be named by analogy with rule 36 (example, $CH_3CONHNHC_2H_5$, 1-acetyl-2-ethylhydrazine) or as a substituted hydrazide (in the latter case, however, the two nitrogen atoms would have to be distinguished in some way). By rule 1, $C_6H_5NHNHC_6H_5$ may still be called hydrazobenzene as well as 1,2-diphenylhydrazine.

45. Hydrazones and semicarbazones are named like the oximes. The term *osazone* is retained.

Examples: $CH_3CH{=}NNHC_6H_5$, ethanal (or acetaldehyde) phenylhydrazone; $(CH_3)_2C{=}NNHCONH_2$, propanone (or acetone) semicarbazone.

46. The name *quinone* is retained.

Examples: *p*-benzoquinone or *p*-quinone, 1,2-naphthoquinone or 1,2-naphthaquinone, phenanthrenequinone or phenanthraquinone.

47. Sulfonic and sulfinic acids will be designated by adding the suffixes *sulfonic* and *sulfinic* to the name of the hydrocarbon.

The analogous acids of selenium and tellurium will bear the names *alkaneselenonic* and *-seleninic* acids; *alkanetelluronic* and *-tellurinic* acids.

Examples: $C_2H_5SO_3H$, ethanesulfonic acid; $C_{10}H_6(SO_2H)_2$, naphthalenedisulfinic acid; CH_3SeO_3H, methaneselenonic acid; $C_6H_5TeO_2H$, benzenetellurinic acid. The radicals of these acids would presumably be named by replacing "ic acid" by *yl;* as CH_3SO_2Cl, methanesulfonyl chloride (but meth*yl*sulfonylethane; *cf.* rule 25). The amides would presumably be named by replacing "ic acid" by *amide* (as, $C_6H_5SO_2NH_2$, benzenesulfonamide), etc. *Cf.* rule 32.

48. Organometallic compounds will be designated by the names of the organic radicals united to the metal which they contain, followed by the name of the metal. Examples: dimethylzinc, tetraethyllead, methylmagnesium chloride.

However, if the metal is united in a complex manner it may be considered as a substituent. Example: $ClHgC_6H_4CO_2H$, chloromercuribenzoic acid.

The rule gives no examples for compounds in which a second metal is present, but the name "methylmagnesium chloride" suggests the principle that organic radicals may be denoted by prefixes attached to one part of a binary inorganic name. Hence, we might risk as a further example: $(C_6H_5)_3SnNa$, sodium triphenylstannide.

49. The nomenclature of cyclic derivatives having side chains will be considered later.

An earlier draft attempted to treat, in two paragraphs, cyclic derivatives with one and with more than one side chain but it became evident that much further study was needed.

50. If it is necessary to avoid ambiguity, the names of complex radicals will be placed in parentheses. Examples: (dimethylphenyl)amine = $(CH_3)_2C_6H_3NH_2$; dimethylphenylamine = $C_6H_5N(CH_3)_2$.

V. Complex Functions

51. For compounds of complex function, that is to say, for compounds possessing different functions, only one kind of function (the principal function) will be expressed by the ending of the name. The other functions will be designated by appropriate prefixes.

This is a definite departure from the Geneva system, since the latter permits functional suffixes to pile up in the names of mixed compounds (as, pentanaloloic acid). The Committee's decision is in accord with usage. The writer, in a study of the names of compounds of complex function in journal and book literature,[8] found 2557 instances in which only one of the functions present was expressed in the ending, as contrasted with 251 names in which two or more were so expressed. In certain cases it seems unavoidable that more than one function be expressed in the ending; as, butenyne, butenol, quinolinesulfonic (*-ene*, *-yne* and *-ine* have no corresponding prefixes).

52. The following prefixes and suffixes will be used for designating the functions.

Function	Prefix	Suffix
Acid and derivatives	carboxy	carboxylic, carbonyl, carbonamide, etc., or oic, oyl, etc.
Alcohol	hydroxy	ol
Aldehyde	oxo, aldo (for aldehyde O) or formyl (for CHO)	al
Amine	amino	amine
Azo derivative	azo	....
Azoxy derivative	azoxy	....
Carbonitrile (nitrile)	cyano	carbonitrile or nitrile
Double bond	....	ene
Ether	alkoxy	....
Ethylene oxide, etc.	epoxy	....
Halide	halogeno [halo]	....
Hydrazine	hydrazino	hydrazine
Ketone	oxo or keto	one
Mercaptan	mercapto	thiol
Nitro derivative	nitro	....

---

(8) Patterson, *Rec. trav. chim.*, **48**, 1016 (1929).

Function	Prefix	Suffix
Nitroso derivative	nitroso	....
Quinquevalent nitrogen	....	onium, inium [olium]
Sulfide	alkylthio	....
Sulfinic derivative	sulfino	sulfinic
Sulfone	sulfonyl	....
Sulfonic derivative	sulfo	sulfonic
Sulfoxide	sulfinyl	....
Triple bond	....	yne
Urea	ureido	urea

The order of functions in the French version is alphabetic and has no significance. The entries have been transposed in the translation in order to give an alphabetic arrangement in English also. The Committee intended at one time to establish an *order of precedence of functions* (to determine which should be the principal function in a compound containing two or more different functions), but later gave up the idea. The study of the writer already referred to under rule 51 indicates that it will be difficult to construct any order that will agree closely with general usage.[9]

As to the choice of the fundamental chain in compounds of complex function, the writer's opinion is, that by analogy with rule 18 (which treats of simple functions) the fundamental chain should be so chosen as to contain as many of the principal functional groups as possible, even if this is not the longest chain in the molecule or the chain which contains the most functional groups of all kinds. A correct name for the compound  $HOCH_2CHOHCH_2\underset{\displaystyle CHO}{\underset{|}{C}H}CH_2CHO$ would therefore be 2-(2,3-dihydroxypropyl)butanedial, rather than 3-formyl-5,6-dihydroxyhexanal. This is in accord with common usage, which would certainly regard the compound as a derivative of succinaldehyde.

53. The names of derivatives of fundamental heterocyclic substances will be formed according to the preceding rules.

Example: Hydroxyquinolinecarbonamide, not quinolinolcarbonamide.

VI. Radicals

54. Univalent radicals derived from saturated aliphatic hydrocarbons by removal of one atom of hydrogen will be named by replacing the ending *ane* of the hydrocarbon by the ending *yl*.

Examples: methyl, ethyl, pentyl (or amyl), etc. Since isopropylidene is recognized (rule 56) it was no doubt the intention of the Committee to recognize isopropyl similarly.

55. The names of univalent radicals derived from unsaturated aliphatic hydrocarbons will have the endings *enyl*, *ynyl*, *dienyl*, etc., the positions of the double or triple bonds being indicated by numerals or letters where necessary

Examples: $CH_2{=}CH{-}$, ethenyl (or vinyl); $CH{\equiv}C{-}$, ethynyl; $CH_3{-}CH{=}CH{-}CH_2{-}$, 2-butenyl; $CH_2{=}CH{-}CH{=}CH{-}$, 1,3-butadienyl.

---

[9] For the order used in the *Chemical Abstracts* indexes, see Patterson and Curran, THIS JOURNAL, 39, 1624 (1917).

56. Bivalent or trivalent radicals derived from saturated hydrocarbons by removal of 2 or 3 hydrogen atoms from the same carbon atom will be named by replacing the ending *ane* of the hydrocarbon by the endings *ylidene* or *ylidyne*. For radicals derived from unsaturated hydrocarbons, these endings will be added to the name of the hydrocarbon. The names isopropylidene and methylene are retained.

Examples: $CH_2<$, methylene; $CH_3CH<$, ethylidene; $CH_3CH_2CH<$, propylidene; $(CH_3)_2C<$, (1-methylethylidene) or isopropylidene; $CH_3C\equiv$, ethylidyne; $CH_2{=}CH{-}CH_2CH<$, 3-butenylidene. In the last example the number must be changed from 1 (in the name of the hydrocarbon, 1-butene) to 3 in order to indicate the position of the double bond correctly. The new ending *ylidyne*, formed by analogy with "ylidene," should prove useful.

57. The names of bivalent radicals derived from aliphatic hydrocarbons by removal of a hydrogen atom from each of the two terminal carbon atoms of the chain will be ethylene, trimethylene, tetramethylene, etc.

Only saturated radicals are provided for: $-CH_2CH_2-$, ethylene; $-CH_2CH_2CH_2-$, trimethylene, etc. (In an earlier draft the ending *ylene* was employed, thus: $-CH_2CH_2CH_2CH_2-$, butylene; $-CH_2CH{=}CHCH_2-$, 2-butenylene)

58. Radicals derived from acids by removal of OH will be named by changing the ending carboxylic to *carbonyl* or, if the Geneva nomenclature is used, oic to *oyl*.

Examples: CH_3CO, ethanoyl or methanecarbonyl (or acetyl).

59. Univalent radicals derived from aromatic hydrocarbons by removal of a hydrogen atom from the ring will in principle be named by changing the ending *ene* to *yl*. However, the radicals C_6H_5 and $C_6H_5CH_2$ will continue provisionally to be named phenyl and benzyl, respectively. Moreover, certain abbreviations sanctioned by usage are authorized, as *naphthyl* instead of *naphthalyl*.

Examples: $CH_3C_6H_4-$, tolyl (instead of toluyl), anthryl (instead of anthracyl), phenanthryl, fluoryl.

60. Univalent radicals derived from heterocyclic compounds by removal of hydrogen from the ring will be named by changing their endings to *yl*. In cases where this would give rise to ambiguity, merely the final *e* will be changed to *yl*. Examples: pyridine, pyridyl; indole, indolyl; pyrroline, pyrrolinyl; triazole, triazolyl; triazine, triazinyl.

In this rule the Committee recognizes such accepted short names as pyridyl, quinolyl and furyl but at the same time recommends the longer forms where confusion could arise; thus, indolyl (instead of indyl, which might suggest indene), pyrrolinyl (instead of pyrrolyl, which might suggest pyrrole), triazolyl (instead of triazyl, which might suggest triazine).

61. Radicals formed by removal of a hydrogen atom from a side chain of a cyclic compound will be regarded as substituted aliphatic radicals.

Examples: $C_6H_5CH_2CH_2-$, (2-phenylethyl); $C_6H_5CH{=}CHCH_2-$, (3-phenyl-2-propenyl).

62. In general, special names will not be given to multivalent radicals derived from cyclic compounds by removal of several hydrogen atoms from the ring. In this case prefixes or suffixes will be used. Examples: triaminobenzene or benzenetriamine; dihydroxypyrrole or pyrrolediol.

Comparison with rules 21, 33 and 51 will show that of the names given as examples, "benzenetriamine" and "pyrrolediol" are the ones ordinarily to be preferred (according to the rule of expressing the principal function in the ending of the name where there is a suffix denoting it.)

63. The order in which prefixes or radicals are stated (alphabetic order or conventional order) remains optional.

See the comments on rule 7. There is no generally accepted "conventional order" for all prefixes

VII. Numbering

64. In aliphatic compounds the carbon atoms of the fundamental chain will be numbered from one end to the other with the use of arabic numerals. In case of ambiguity the lowest numbers will be given (1) to the principal function, (2) to double bonds, (3) to triple bonds, (4) to atoms or radicals designated by prefixes. The expression "lowest numbers" signifies those that include the lowest individual number or numbers. Thus, 1,3,5 is lower than 2,4,6; 1,5,5 lower than 2,6,6; 1,2,5 lower than 1,4,5; 1,1,3,4 lower than 1,2,2,4.

Examples: $CH_2{=}CHCH_2CH_3$, 1-butene (not 3-butene); $CH_2{=}CHC{\equiv}CH$, 1-propen-3-yne (not 3-propen-1-yne); $CH_2{=}CH{-}CH_2OH$, 3-propen-1-ol (not 1-propen-3-ol; the name allyl alcohol may also be used); $CHCl_2CH_2CH{=}CH_2$, 4,4-dichloro-1-butene.

The last example illustrates a difficulty of interpretation which might arise, it might be thought that, the numbers 1,1,3 being lower than 1,4,4, the compound should be named 1,1-dichloro-3-butene This, however, was apparently not the intention of the Committee, for 1-butene is the parent compound. The British version makes this interpretation clearer by translating the French "En cas d'ambiguité" rather freely as "To avoid ambiguity."

The principle of "low numbers" also applies to cyclic compounds, with due regard to their different structure (*e. g*, bridges and hetero atoms are usually given preferred positions). Examples: 1,3-cyclohexadiene; 3-cyclohexen-1-one or simply 3-cyclohexenone; 4,4-dichlorocyclohexene.

Position of Numbers.—Where shall position numbers be placed, *before* or *after* the parts of the name to which they refer? Usage varies; some chemists place them before, some place them after, some use a combination. The Committee has left full latitude on this point. The examples in the French version usually show the numbers placed after; the examples in these comments follow the practice of *Chemical Abstracts* in being placed before. Each method has certain advantages. In Beilstein numbers placed after are in parentheses, those placed before are not, *e. g.*, "2-methyl-butanol-(4)."

65. Positions in a side chain will be designated by numerals or letters, starting from the point of attachment. The numerals or letters will be in parentheses with the name of the chain.

Examples: $(CH_3)_2CH{-}$, (1-methylethyl) or isopropyl; $CH_3CHClCH_2{-}$, (2-chloropropyl). The rule equally permits Greek letters, ordinary letters, primed numbers (1′, 2′), numbers with indices (4^1, 4^2) or other designations. Although the original Geneva nomenclature prescribed numbers with indices for side chains they have not been generally used and the present rules do not mention them. Plain numbers or letters usually suffice. The writer prefers to reserve primed numbers for special cases (as for doubled molecules, or for numbering the branched position in isopropyl).

66. In case of ambiguity in the numbering of atoms or radicals designated by prefixes, the order will be that chosen for the prefixes before the name of the fundamental compound or side chain of which they are substituents.

Example: $CH_2BrCH_2CH_2Cl$, 1-bromo-3-chloropropane (alphabetic order), or 1-chloro-3-bromopropane (order of increasing radical weight). The purpose of the rule is to decide which prefixes shall have which numbers, when the set of numbers (in the above example 1,3) for the prefixes has been determined.

67. The prefixes, *di*, *tri*, *tetra*, etc., will be used before simple expressions (for example, diethylbutanetriol) and the prefixes *bis*, *tris*, *tetrakis*, etc., before complex expressions. Examples: bis(methylamino)propane: $CH_3NH(CH_2)_3NHCH_3$; bis(dimethylamino)ethane, $(CH_3)_2NCH_2CH_2N(CH_3)_2$. The prefix *bi* will be used only to denote the doubling of a radical or compound; for example, biphenyl.

Additional example of the use of *bi:* *p*-$(C_6H_4CO_2H)_2$, 4,4′-bibenzoic acid or biphenyl-4,4′-dicarboxylic acid.

68. A catalog of cyclic systems, with their numberings according both to the existing system and to that of Mr. Patterson, is in preparation under the auspices of the National Research Council of the United States and of the American Chemical Society.

Work on this project is now in abeyance pending better financial conditions for publication.

In order to avoid all confusion the Commission recommends placing a scheme of numbering at the head of each article.

[A CONTRIBUTION FROM THE CHEMICAL LABORATORY OF THE COLORADO SCHOOL OF MINES]

Diffusion as an Aid in the Analysis of Gaseous Paraffin Hydrocarbon Mixtures

BY ROBERT A. BAXTER AND LELAND J. BECKHAM

The purpose of the present investigation is the development of a supplementary procedure to be used in conjunction with the usual combustion analysis on paraffin hydrocarbon gases in order to increase the information attainable. It is a well-known fact that lighter gases will diffuse more rapidly than heavy ones. Thus if a mixture of several gases be allowed to undergo partial diffusion, the residue remaining after part of the gases have diffused away will have a composition which is richer in the heavier constituents. This change in composition can be calculated by means of the kinetic theory.

The present paper describes an apparatus suitable for this determination, together with charts for its application to ordinary analytical practice.

The apparatus (Fig. 3), later described in detail, is operated as follows. The hydrocarbon mixture is introduced into the apparatus, the orifice opened and the gases allowed to diffuse into the air for a certain period of time; the stopper is then replaced, and a sample withdrawn for the usual combustion analysis. From the results of this combustion analysis and from one on the original mixture before diffusion, and by the use of proper equations or charts, considerably more information concerning the nature of the gas sample can be obtained, as is described in this paper.

In the calculation of the composition of gaseous paraffin hydrocarbon mixtures from the results of combustion and absorption data, assumptions are usually made as to the "two most prevalent hydrocarbons" and the analysis is reported in terms of the quantity of these in the mixture.[1] This practice has led to much confusion, particularly when a natural gas is reported as a mixture of ethane and propane before stripping gasoline out of it, and as another mixture of these same two gases after the stripping. The heating value, the air required for combustion, the theoretical flame temperature and the composition of the stack gases resulting from the combustion of any such mixture can be calculated from the analysis reported in this manner. The same results could be obtained from the calculation to any other assumed mixture of paraffin hydrocarbon gases, one of which is lighter, and the other one heavier than the average of the gases actually present. Although several measurable quantities result from the combustion of the gas and the subsequent absorption of the carbon dioxide which is formed, there are only two independent equations, and

(1) "Methods of the Chemists of the U. S. Steel Co. for the Sampling and Analysis of Gases," Carnegie Steel Co., Pittsburgh, 1927, p. 88. Also see Burrell, Seibert and Jones, *Bur. Mines Bull.*, 197, 96 (1926).

consequently only two hydrocarbons can be calculated. Earnshaw[2] developed the equations by means of which the total volume of paraffin hydrocarbons and the average number of carbon atoms per paraffin molecule may be calculated. Similar equations for various combustible gases were set up by de Voldere and de Smet[3] and condensed by Anderson.[4] A further correlation of these equations was made by Baxter.[5] The evidence in these references is very conclusive as to the superiority of reporting these analyses in terms of the amount of paraffin hydrocarbons of a stated average number of carbon atoms per molecule.

The difference in the diffusion characteristics of gases will produce a measurable difference in the value of n (the average number of carbon atoms per molecule of hydrocarbons in the gas) determined before and after diffusion. From the value of Δn (the increase in n which results from the greater rate of diffusion of the smaller molecules) and the value of n in the original mixture, a new equation is obtained by which the calculation may be extended to three hydrocarbons.

However, the use of this equation for the calculation of three component mixtures requires considerable time and effort for solution; therefore, diagrams of the relationship between n and Δn have been prepared for the two ternary mixtures: methane–ethane–propane (Fig. 1) and methane–ethane–butane (Fig. 2). It is obvious that the sides of these diagrams give the five binary relationships.

If a set of charts is determined for any given apparatus these charts can be used completely in place of numerical calculation and the application of the method is extremely simple and rapid. There are three distinct methods whereby any one wishing to use this procedure could obtain charts for an apparatus which he might construct.

1. The charts might be constructed from the fundamental equations given later in the paper. (The charts shown in this paper were obtained in this manner.)

2. One could so choose the length of time of the run that the same total amount of diffusion would take place as in the apparatus which we used. Then the charts in this paper would be applicable. This could be easily calibrated by determining the proper time so that 80% of a sample of pure methane would diffuse out, as our charts were constructed for this amount of diffusion.

3. A sufficient number of experimental determinations upon known mixtures could be run so that the charts could be plotted entirely from experimental data without resorting to the kinetic equations.

The value of n is obtained by the equation: $n = 3y/(2x - y)$, in which

x is volume contraction resulting from combustion and y is volume of carbon dioxide formed by combustion.

For purposes of illustration we will confine our attention to mixtures in which the average value of n as obtained from combustion analysis is 1.60.

The ordinary method of reporting this gas would be as methane and ethane in the ratio of four to six parts by volume in the combustible hydrocarbon mixture. If this happens to be 50% of the original gas sample, the analysis will usually be given as 20% methane and 30% ethane. As pointed out by one of us in an earlier paper to which reference was made above, better information can be obtained by reporting this mixture as 50% total paraffin hydrocarbons of an average value of $n = 1.60$. The volume of the total paraffin in the sample burned is obtained by the equation: $V = (2x - y)/3$. x and y have the meanings given above. This avoids any unwarranted assumptions.

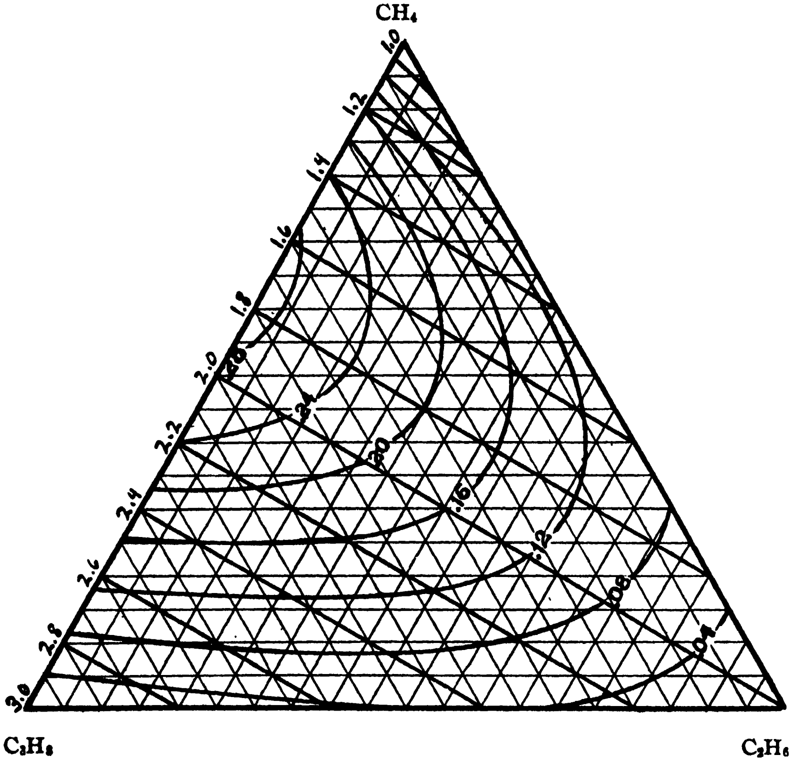

Fig. 1.—Methane–ethane–propane diagram: curved lines are values of Δn.

A glance at the chart or a brief calculation will indicate that one might assume 70% methane and 30% propane, 80% methane and 20% butane, or some corresponding higher ratio of methane to pentane or other hydrocarbons instead of the assumed value of 40% methane and 60% ethane.

In addition, the mixture might be one of methane with two or more higher hydrocarbons. There is just one point which is clear, namely, that in a mixture of paraffin hydrocarbons in which $n = 1.60$, the methane is not less than 40%.

Two gaseous mixtures will be considered. Each has $n = 1.60$. One gives $\Delta n = 0.12$ while the other gives $\Delta n = 0.36$. The intersection of the $\Delta n = 0.12$ curve with the line $n = 1.60$ will first be considered. If the system present is methane–ethane–propane, the propane will be 4% of the entire mixture. If the system present is methane–ethane–butane, the butane will be 2% of the entire mixture. Since still less of any higher paraffin hydrocarbon will be required to have the same effect as the 4% of propane or the 2% of butane, the limits of not less than 96% total methane and ethane mixture, not more than 2% butane, and less than 2% of any higher hydrocarbons are definitely established. The mixture which gives $\Delta n = 0.36$ will now be considered. Since this value is greater than any which appear on the chart for the system methane–ethane–propane, the one first dependable conclusion is that there must be some butane or higher hydrocarbon present. The intersection of the two appropriate

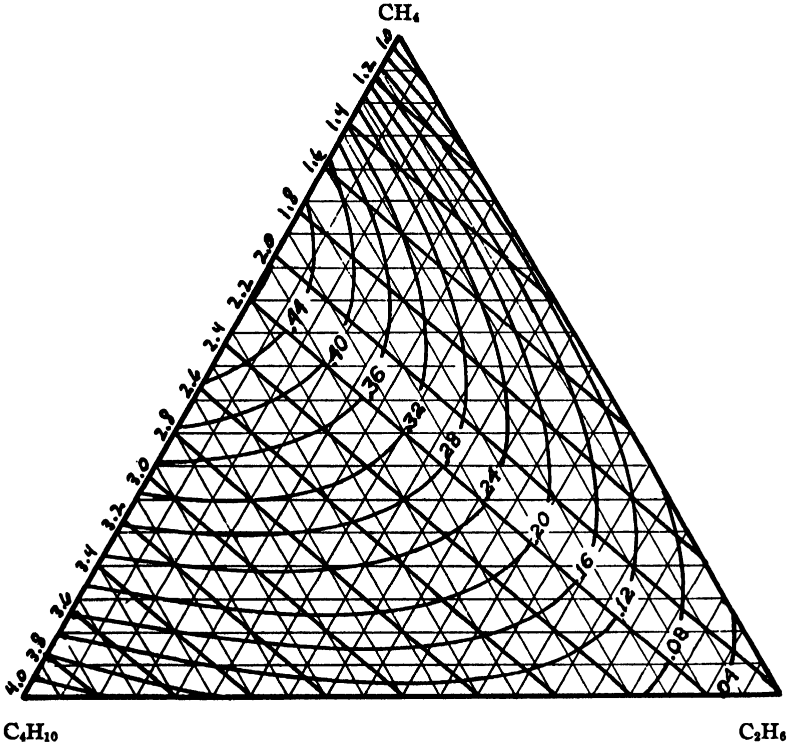

Fig. 2.—Methane–ethane–butane diagram: curved lines are values of Δn.

curves on the methane–ethane–butane diagram indicates that if the system actually happens to consist of these three constituents, the butane must be 17% of the mixture. This is the maximum limit for the butane or heavier hydrocarbons. In case higher ones are present, their amount will be relatively less and the fraction of lighter hydrocarbons relatively more. The minimum amount of methane and ethane cannot be read directly from the methane–ethane–propane diagram as in the former case for the value of Δn does not fall on the chart. However, the minimum can be obtained in this case from a chart constructed for methane–propane–butane. We have constructed only the two charts shown. Similar charts could be constructed for any three assumed hydrocarbons (including hydrogen as a paraffin hydrocarbon in which $n = 0.00$).

The triangular diagrams indicate very definitely the difference between the two gases which would be reported as identical by the conventional method. The gas with $\Delta n = 0.12$ is sufficiently evaluated for most purposes by the diffusion method. The necessity for further work in order to get an accurate evaluation of the one in which $\Delta n = 0.36$ is shown. In general, when the value of Δn is small the analysis as obtained by the combination of diffusion with the combustion and absorption procedures will meet the ordinary analytical requirements, but when the value of Δn is large the presence of higher hydrocarbons is definitely shown. In the latter case the nature of the constituents as well as their concentration is obscure. When Δn is large some type of low-temperature fractional distillation device[6] would probably be the most satisfactory for the separation and identification of the higher boiling constituents. However, this equipment is expensive and more or less complicated, and it requires liquid air or similar material for cooling.

The diffusion method will minimize guessing in the analysis of gaseous mixtures, will itself give sufficient results in many instances, and in the remainder it will give definite indications as to the necessity for using the more complex and expensive methods.

Experimental

Preparation of Materials.—The hydrocarbons used, methane, ethane, propane and butane, were prepared from the corresponding halides by means of the Grignard reaction. The gases were washed with concentrated sulfuric acid and stored over water.

Combustion Analyses.—The combustion and absorption analyses were performed with the laboratory apparatus of the U. S. Steel Corporation[7] using mercury as the confining agent. All samples of gas were analyzed two to eight times, and the average of these values was recorded as the true composition of the gas. The average variation from the mean on the values of n obtained from calculation from the observed data was 0.015.

(7) "Methods of the Chemists of the U. S. Steel Co. for the Sampling and Analysis of Gases," Fig. 3, p. 8.

Description of Diffusion Apparatus.—The device which was used is shown in Fig. 3. It consists of a Shaw filter flask, into which a metal orifice cup has been fitted and held in place by rubber. This is in turn closed by a rubber stopper which fits into the wide opening of the orifice cup, of which the orifice plate is the bottom. The side neck serves as the filling and flushing connection and the bottom serves for the connection to the leveling bottle containing the confining liquid. The stopcock in the bottom is very convenient in handling the device. The diameter of the orifice is 2.44 mm. in a plate 2.15 mm. thick. It is essential that there be no narrow tube leading to or from it, since this sets up extra resistance by providing a region on either side of the orifice in which an appreciable gradient is maintained so that diffusion is hindered.

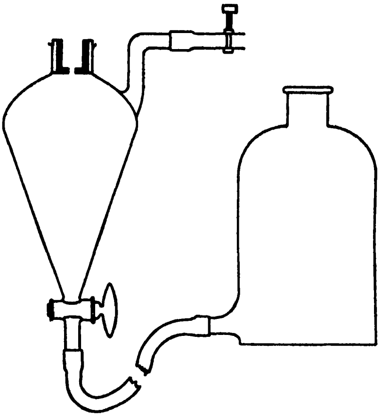

Fig. 3.—Diffusion apparatus.

Operation of Diffusion Equipment.—The diffusion apparatus was operated as follows. The confining liquid used was water. This was saturated with the gas to be used by allowing the apparatus to stand for several hours filled with a sample of the gas. Occasional shaking was employed. A fresh sample of the gas was then placed in the apparatus and the device set in a thermostat at 25° for the duration of the run. The orifice was opened, the gases allowed to diffuse for 195 minutes, the orifice closed and the sample withdrawn for combustion analysis. The volume of sample used was 250 cc. The time of 195 minutes was chosen because in that time approximately 80% of the methane will have diffused. The figure of 80% is a compromise between errors caused by general difficulties in securing complete combustion on small residues from more complete diffusion and normal experimental errors in Δn which have a greater relative value as the magnitude of Δn is decreased. As both the gas inside and the air outside were essentially saturated with water vapor, no correction for humidity was made. Barometric fluctuations were disregarded; the average barometric pressure was 620 mm.

Experimental Data.—Table I shows the experimental data and the data calculated from the diffusion equations for the different mixtures of gases which were employed.

The difference between the calculated and observed values are all within the probable limits of experimental error. A brief comparison of Table I

TABLE I

Composition of the gas						Δn	Δn
CH_4	C_2H_6	C_3H_8	C_4H_{10}	n_0	n	Obs.	Calcd.

..	100	..	..	2.00	2.00	.00	.000

with the charts will show the degree of accuracy of the analyses based upon diffusion much better than any written explanation. Only samples were employed in which the average value of n is less than two for two reasons: first, most samples of natural gas fall in this region; and second, the experimental error is higher for values of n appreciably over two because of the form of the equations for the determination of n.

The equations and diagrams are based on the assumption of a pure paraffin hydrocarbon mixture. Small amounts of other gases will not have any great effect on the value of Δn. In order to minimize the effects of interference of different types of molecules, any gas which does not consist mainly of paraffin hydrocarbons should be treated to remove these other constituents before placing it in the diffusion apparatus. Impurities which consist of air or nitrogen need not be removed. Calculations show that since these gases are already considered in the diffusion equations, even large quantities of them in the original mixture will change the value of Δn by an amount considerably less than the average experimental error.

Theoretical Considerations of the Diffusion Equations and Charts

Derivation of an Equation for the Diffusion Coefficient.—For the coefficient of diffusion D_{12} for two gases diffusing into each other, Maxwell[8] modified the Meyer diffusion formula

$$D_{12} = \frac{1}{3(\nu_1 + \nu_2)} [\bar{C}_1\lambda_1\nu_2 + \bar{C}_2\lambda_2\nu_1] \tag{1}$$

λ_1 and λ_2 are the expressions for the mean free paths of the two species of molecules from which the terms involving collisions between the same species of molecules are neglected because such collisions should not affect diffusion, as the total forward momentum is not changed. $\bar{C}_1$ and $\bar{C}_2$ are the average velocities of the molecules, and ν_1 and ν_2 their respective molecular concentrations. Substituting the values for the mean free path, Maxwell obtained

$$D_{12} = \frac{1}{3\nu_0\pi}\left[\frac{\bar{C}_1}{S_{12}^2\sqrt{1 + M_1/M_2}} + \frac{\bar{C}_2}{S_{12}^2\sqrt{1 + M_2/M_1}}\right] \tag{2}$$

M_1 = mol. wt. of gas 1; M_2 = mol. wt. of gas 2
S_{12} = sum of radii of molecules of gas 1 and 2

We have generalized the above formula to apply to a mixture of s gases, $s - 1$ of which are diffusing in one direction while the other gas is diffusing in the opposite direction.

$$D_{mk} = \frac{1}{3\nu_0\pi}\left[\frac{\bar{C}_m}{\Sigma_1^{s-1} \alpha_s S_{ms}^2\sqrt{1 + M_m/M_s} + \alpha_k S_{mk}^2\sqrt{1 + M_m/M_k}} + \frac{\bar{C}_k}{\Sigma_1^{s-1} \beta_s S_{ks}^2\sqrt{1 + M_k/M_s} + \beta_m S_{km}^2\sqrt{1 + M_k/M_m}}\right] S \neq M \tag{3}$$

The subscript s represents the general gas diffusing in one direction
The subscript k represents the gas diffusing in the opposite direction

---

[8] Maxwell, "Coll. Scientific Papers," Vol. I, p. 392, and Vol. II, pp. 57 and 345; see also Jeans, "Dynamical Theory of Gases," Cambridge University Press, Cambridge, 1921, p. 315.

The subscript m represents the particular one of the s gases for which the diffusion coefficient is to be calculated.

α_s = mole fraction of gas s, calculated by omitting gas m

β_s = mole fraction of gas s, calculated by omitting gas k

α_k = mole fraction of gas k, calculated by omitting gas m

β_m = mole fraction of gas m, calculated by omitting gas k

These mole fractions are the average mole fractions taken over the whole diffusion column.

This equation is obtained by integrating the simultaneous partial second order differential equations as obtained from Meyer's theory[9] of gas diffusion using assumptions similar to those Maxwell used in his equation and also with the additional assumption that there is no net motion of translation of any constituent except the two for which the diffusion constant is to be determined.[10]

M. J. Stefan[11] has developed a theory covering the diffusion of any number of constituents; but it is based on the hydrodynamical rather than the kinetic hypothesis.

Rigorous mathematical analyses for the determination of diffusion coefficients are given by Chapman[12] and by Enskog.[13] They involve the assumption of a definite molecular model (elastic spheres, point centers of force repelling according to an inverse power law, or others). Their formulas are very laborious for numerical computation.

The Diffusion Equation.—The form for the coefficient given in equation (3) is for steady flow. As the apparatus does not employ steady flow, the logarithmic mean of the initial and final concentrations of each constituent is used as the proper concentration for the calculation of the mole fraction. The ordinary diffusion equation

$$\partial A/\partial t = D\partial^2 A/\partial x^2 \tag{4}$$

upon integration gives

$$A = A_0e^{-Dt} \tag{5}$$

provided we assume that the concentration inside the apparatus remains essentially uniform and that the size of the orifice is large in comparison to the mean free path. The second of these statements tends to invalidate the first, but the actual results obtained indicate that the concentration gradient in the body of the diffusion apparatus is small enough to be neglected, since the cross sectional area is large as compared to that of the orifice.

---

(9) Jeans, "Dynamical Theory of Gases," pp. 307 and 312.

(10) It is realized that this equation is complicated for calculation but such simple relations as that of Graham, that rates of diffusion are inversely proportional to the square root of the densities, do not even approximately apply to the interdiffusion of gases; for instance two gases of the same density, ethylene and nitrogen, have coefficients of diffusion into hydrogen of 0.486 and 0.674, respectively. See "Int. Crit. Tables," Vol. V, p. 62. By Graham's law of diffusion these gases would diffuse at the same rate.

Derivation of an Expression for Δn.—The average number of carbon atoms per molecule is

$$n = An_a/V + Bn_b/V + Cn_c/V + \ldots \qquad (6)$$

A, B, C, etc., represent the concentrations of the various hydrocarbons, V being the sum of the concentrations of all the hydrocarbons and n_a, n_b, etc., the average number of carbon atoms per molecule of the corresponding hydrocarbons. We shall hereafter consider constituent A to be methane, B to be ethane, C propane, D n-butane, etc., for the normal paraffin hydrocarbons. We shall indicate initial concentrations and conditions by a subscript 0.

$$n_0 = A_0 + 2B_0 + 3C_0 + \ldots/V_0 \qquad (7)$$

and n at any time t

$$n = A + 2B + 3C + \ldots/V \qquad (8)$$

Then $\Delta n = n - n_0$, the increase in the average value of n during diffusion is given by the difference of equations (8) and (7). From a knowledge of the initial concentrations and the numerical values for the diffusion coefficients, the value of Δn may be calculated. The triangular diagrams are plotted from data of this type.

Numerical Illustration.—A numerical illustration of the calculation is given to make the method entirely clear. For purposes of numerical calculation equation (3) may be rewritten in the form

$$D_{mk} = \frac{\overline{C}}{\sum_1^{s-1} \alpha_s \varphi_{ms} + \alpha_k \varphi_{mk}} + \frac{\overline{C}_k}{\sum_1^{s-1} \beta_s \varphi_{ks} + \beta_m \varphi_{km}} \qquad (9)$$

The numerical values of the terms together with their equivalents in eqn. (3) are given in Table II. The numerical values for $\overline{C}_m$ and $\overline{C}_k$ include the constant factors, those from the equation, those depending on the size of the apparatus, and those depending on the units used. The time of the runs (195) minutes is considered as the unit of time, $t = 1$.

A pure hydrocarbon gas composed of 60% methane, 20% ethane and 20% propane will be considered.

To calculate D_{ak} the appropriate values are substituted in equation (9). All the quantities are given in Table II except the values of the coefficients representing mole fractions. From similar runs we know that only approximately 0.25 of the methane, 0.36 of the ethane and 0.45 of the propane are left at the end of the run. Initial and final concentrations together with the log mean of the concentrations of the gases are as follows.

	Methane	Ethane	Propane
Initial	60.0	20.0	20.0
Final	15.0	7.2	9.0
Log mean	32.3	12.5	13.8

For the calculation of the diffusion coefficient D_{ak} eqn. (9) is used replacing m by a (a represents methane).

$\alpha_b = 12.5/126.3$ $\alpha_c = 13.8/126.3$ $\alpha_k = 100.0/126.3$
$\beta_a = 32.3/58.6$ $\beta_b = 12.5/58.6$ $\beta_c = 13.8/58.6$

The quantities $e^{-D_{ak}t}$, $e^{-D_{bk}t}$, and $e^{-D_{ck}t}$ are found to be 0.252, 0.396 and 0.467, respectively. This means that 25.2% of the methane, 39.6% of the ethane and 46.7% of the propane remain. Now in order to obtain greater accuracy we recalculate the values for the diffusion coefficient using the 25.2, 39.6 and 46.7% instead of the 25, 36 and 45% figures previously used. This gives $D_{ak} = 1.374$. Similarly D_{bk} and D_{ck} are found to be 0.924 and 0.753, respectively. Substitution in equation (7) gives

$$n_0 = (60 \times 1 + 20 \times 2 + 20 \times 3)/100 = 1.6 \qquad (10)$$

and in equation (8)

$$n = \frac{A + 2B + 3C}{V} = \frac{A_0e^{-D_{ak}t} + 2B_0e^{-D_{bk}t} + 3C_0e^{D_{ck}t}}{A_0e^{-D_{ak}t} + B_0e^{-D_{bk}t} + C_0e^{-D_{ck}t}} = 1.823 \qquad (11)$$

$$\text{Therefore: } An = n - n_0 = 0.223 \qquad (12)$$

TABLE II

$\varphi_{AK} = 18.6 = S_{ak}^2 \sqrt{1 + M_a/M_k}$
$\varphi_{AB} = 25.7 = S_{ab}^2 \sqrt{1 + M_a/M_b}$
$\varphi_{AC} = 29.5 = S_{ac}^2 \sqrt{1 + M_a/M_c}$
$\varphi_{AD} = 33.1 = S_{ad}^2 \sqrt{1 + M_a/M_d}$
$\varphi_{BK} = 28.0 = S_{bk}^2 \sqrt{1 + M_b/M_k}$
$\varphi_{BA} = 35.2 = S_{ba}^2 \sqrt{1 + M_b/M_a}$
$\varphi_{BC} = 40.5 = S_{bc}^2 \sqrt{1 + M_b/M_c}$
$\varphi_{BD} = 44.0 = S_{bd}^2 \sqrt{1 + M_b/M_d}$
$\varphi_{CK} = 37.9 = S_{ck}^2 \sqrt{1 + M_c/M_k}$
$\varphi_{CA} = 48.9 = S_{ca}^2 \sqrt{1 + M_c/M_a}$
$\varphi_{CB} = 48.8 = S_{cb}^2 \sqrt{1 + M_c/M_b}$
$\varphi_{CD} = 55.2 = S_{cd}^2 \sqrt{1 + M_c/M_d}$
$\varphi_{DK} = 48.3 = S_{dk}^2 \sqrt{1 + M_d/M_k}$
$\varphi_{DA} = 63.0 = S_{da}^2 \sqrt{1 + M_d/M_a}$
$\varphi_{DB} = 61.3 = S_{db}^2 \sqrt{1 + M_d/M_b}$
$\varphi_{DC} = 63.2 = S_{dc}^2 \sqrt{1 + M_d/M_c}$
$\varphi_{KA} = 25.2 = S_{ka}^2 \sqrt{1 + M_k/M_a}$
$\varphi_{KB} = 27.5 = S_{kb}^2 \sqrt{1 + M_k/M_b}$
$\varphi_{KC} = 30.7 = S_{kc}^2 \sqrt{1 + M_k/M_c}$
$\varphi_{KD} = 34.3 = S_{kd}^2 \sqrt{1 + M_k/M_d}$
$\overline{C}_a = 18.0$
$\overline{C}_b = 13.2$
$\overline{C}_c = 10.9$
$\overline{C}_d = 9.5$
$\overline{C}_k = 13.4$

The molecular radii used in the above calculations are: air, 1.87×10^{-8}, CH_4, 2.00×10^{-8}; C_2H_6, 2.56×10^{-8}; C_3H_8, 3.02×10^{-8}; and C_4H_{10}, 3.42×10^{-8} cm. The value for air was taken from Jeans, "Dynamical Theory of Gases," p. 327. We calculated the others from Trautz's viscosity data [Max Trautz, *Ann. Physik*, [5] **10**, 81–96 (1931)]. Those for methane and ethane agree very closely with diameters calculated from diffusion coefficients for different pairs of gases taken from "Int. Critical Tables," and calculated by means of the Stefan–Maxwell equation (equation (2)).

Summary

1. An extension of the Maxwell diffusion equation has been made to apply to a mixture of gases diffusing out through an orifice, which is large in comparison to the mean free path, against air diffusing in at barometric pressure and constant temperature.

2. An inexpensive device which is simple to operate has been developed.

3. The apparatus and equations have been checked by application to known mixtures of paraffin hydrocarbons.

4. Charts have been developed for the use of this information in gas analysis, whereby a much closer approximation to the actual paraffin hydrocarbons can be obtained by a combination of the diffusion apparatus

with the absorption and slow combustion equipment than can be obtained without the diffusion apparatus.

Dipole Moment and Group Rotation. I. The Moments of the Chloro- and Nitrobenzyl Chlorides and the Effect of Group Separation[1]

BY J. M. A. DE BRUYNE, ROSE M. DAVIS AND PAUL M. GROSS

Discussion of the effect of rotation of component dipoles within molecules on their dipole moments has been confined largely to substituted straight chain hydrocarbons with two identical polar groups at each end. Ethylene chloride is the simplest case. By increasing the length of the hydrocarbon chain, it has been sought to separate the like polar groups at its ends and so study their interactions as a function of the distance separating them.[2]

Unless an extended zigzag chain is assumed with the polar groups rotating about its ends, the number of possible configurations such a molecule can assume by rotation about the various bonds is very great, so that conclusions concerning the interaction of the polar groups as affected by their separation must be drawn with considerable reservation.

The substituted benzyl halides are compounds in which this uncertainty is eliminated, since the benzene ring fixes the position of the second polar group and defines its separation from the rotating halide group in the side chain. This paper gives the results of the determination of the dipole moments of the ortho, meta, and para chlorobenzyl chlorides and the ortho and meta nitrobenzyl chlorides in different solvents. These are the first of a series of measurements designed to extend broadly the experimental background of this field by measuring the dipole moments of molecules containing varying types of rotating groups located at different distances apart in the molecule.

Method.—The dielectric constant ϵ, density d, and refractive index for the sodium D line n_D were determined for dilute solutions of these compounds at 30 ± 0.01°. The molar polarization P_2 of the solute at each concentration was calculated from the equation of Debye[3] in the form

$$P_2 = \frac{\epsilon - 1}{\epsilon + 2}\,\frac{M_2}{d}\,\frac{w_1 + w_2}{w_2} - \frac{w_1}{w_2}\,\frac{M_2}{M_1}\,P_1 \tag{1}$$

---

in which w_1 and w_2 are the weights, and M_1 and M_2 the molecular weights of the solvent and solute, respectively, and P_1 is the molar polarization of the solvent. The molar refraction R_2 of the solute was calculated by substituting for ϵ the square of the refractive index for the sodium D line in equation (1), and for P_1, the molar refraction of the solvent R_1 for the sodium D line. By plotting the values of P_2 against the mole fraction c_2 of the solute and extrapolating to $c_2 = 0$, the molar polarization of the solute P_∞ at infinite dilution was found. The dipole moment μ was then calculated from the equation

$$\mu = 0.0127 \times 10^{-18} \sqrt{(P_\infty - R_2)T} \text{ e. s. u.} \quad (2)$$

Apparatus.—The dielectric constants were determined by the heterodyne beat method employing an arrangement of apparatus similar to that of Williams and Weissberger[4] and others.[5]

A plate-tuned circuit was used in each oscillator so that the various condensers could be grounded, and the entire electrical system was carefully shielded. The beat note was matched with the 1000-cycle note of an electrically excited fork.

The standard condenser was a General Radio Company Precision Condenser, of 500 mmf. capacitance, with a scale of 2500 divisions, and was calibrated by a step method.[6]

Capacitance measurements were made at a frequency of 10^6 cycles/sec.

The measuring condenser was of brass, gold plated, and consisted of three concentric cylinders in an outer brass container. These were mounted by rods on a bakelite lid machined to fit the brass container which was at ground potential. The inner and outer cylinders were connected together. A switch was so arranged that it could connect the middle cylinder either to this pair or to the container, thus providing a minimum or maximum capacitance. The difference between the two values (approximately 100 mmf. air capacitance) measured in corrected scale readings of the standard condenser was used in calculating the dielectric constant. This type of measurement eliminated any uncertainty from lead corrections and also the errors due to changes in the frequency of the oscillators with time.

A correction was necessary for the capacitance of that part of the condenser above the liquid level and due mainly to the rods with the bakelite of the lid as dielectric between them. As this was constant, it was evaluated by obtaining the difference values of the condenser for the standards dry air and benzene. The correction k so found was approximately 6% of the difference value for air. The dielectric constant ϵ of a liquid was then calculated from the equation

$$\epsilon = (\Delta S + k\epsilon')/(\Delta S' + k) \quad (3)$$

in which ΔS and $\Delta S'$ represent the difference values in corrected scale readings for the liquid and for the standard, respectively, and ϵ' the dielectric constant of the standard.

Such difference measurements made on two portions of the standard condenser scale agreed within 1 part in 3000 in every case, and in most instances were within one part in 5000.

Materials

Benzene.—Kahlbaum best grade of benzene was dried over phosphorus pentoxide and fractionated in a Dufton still with a 1.8-m. column. The main fraction distilling within 0.01° range was fractionally crystallized until a fraction of maximum freezing temperature was obtained. Benzene freezing within 0.02° of this temperature was used as the solvent. It was distilled from freshly cut sodium when needed: b. p. 80.05°; $n^{30°}_D$ 1.49486; d^{30}_4 0.86840 (average).

[5] Smyth, "Dielectric Constant and Molecular Structure," The Chemical Catalog Company, New York, 1931, p. 54.

[6] Compare Linton and Maass, THIS JOURNAL, 53, 957 (1931).

Heptane.—Heptane from the Ethyl Gasoline Corporation was shaken with concentrated sulfuric acid, sodium hydroxide, mercury and distilled water, then dried over calcium chloride, over phosphorus pentoxide, and then fractionated. The fraction used had the constants: b. p. 98.47–98.52°; n^{30}_D 1.38292; d^{30}_4 0.67520.

Carbon Tetrachloride.—Eastman best grade was fractionated twice, giving material with the constants: b. p. 76.74°; n^{30}_D 1.45454; d^{30}_4 1.5747.

o-Chlorobenzyl Chloride.—Four hundred and fifty grams from Eastman Kodak Company was repeatedly fractionated at reduced pressure in a Hickman still. Forty-five grams of liquid boiling between 109.0 and 109.2° at 25.6 mm. was obtained. A chlorine analysis of the compound was made by the method described by Vaughn and Nieuwland:[7] chlorine found, 44.02; calcd., 44.05.

m-Chlorobenzyl Chloride.—This was prepared by chlorinating *m*-chlorotoluene. The liquid after shaking with potassium carbonate solution and drying over potassium carbonate and calcium chloride, was fractionated at reduced pressure. The sample used boiled at 111.0–111.2° at 25.4 mm.

p-Chlorobenzyl Chloride.—A sample from Eastman Kodak Company was fractionally crystallized and distilled at reduced pressure. The best fraction obtained after repeated fractionation froze between 28.2–28.4°; b. p. 114.0° at 25 mm.

The total chlorine content was determined by Vaughn and Nieuwland's method: chlorine found, 43.82, 43.91; calcd., 44.05. Side chain chlorine was determined by hydrolysis with alcoholic potassium hydroxide and subsequent analysis of the aqueous solution for chlorine: chlorine found, 22.4; calcd., 22.0. Oxidation of a sample of the compound by refluxing with alkaline permanganate solution gave the anticipated *p*-chlorobenzoic acid. These tests, which seemed desirable because of the results reported by Bergmann and Engel[8] for this substance, conclusively established the identity and purity of our sample of *p*-chlorobenzyl chloride.

o-Nitrobenzyl Chloride.—A sample from the British Drug Houses, Ltd., was recrystallized first from ligroin and then fractionally crystallized. A sample with f. p. 48.0–48.25° was used.

m-Nitrobenzyl Chloride.—A sample similar to the ortho compound was obtained by the same method and had f. p. 45.15–45.35°.

Results

As a check on the apparatus and method the dipole moment of chlorobenzene was determined in benzene as solvent and was found to be $\mu = 1.56D$,[9] a value identical with that found by other recent workers.

The data for the concentrations, dielectric constants and refractive indices of the solutions of the compounds are given in Table I and the polarizations and dipole moments are summarized in Table II. Bergmann and Engel[8] have determined the moment of *p*-chlorobenzyl chloride and find $\mu = 2.11D$. This value is so different from that found here ($\mu = 1.71D$ in benzene) that we are led to conclude that Bergmann and Engel were either dealing with some other substance or that there was some un-

(9) We will designate the values of the moments in terms of the Debye (*D*) as suggested in the "Physikalisch-chemisches Taschenbuch," S. Hirzel, Leipzig, 1932, Vol. I, p. 123, and accepted by others. (Compare Weissberger and Sängewald, *Z. physik. Chem.*, [B] **20**, 145 (1933).) $1D = 1 \times 10^{-18}$ e. s. u.

explained source of error in their measurements on this compound. Our values in the three different solvents agree well and are also practically the same as those for the similar compounds *p*-bromobenzyl chloride (μ = 1.71D) and *p*-chlorobenzyl bromide (μ = 1.72D) measured by Smyth and Walls,[10] as would be expected from the closeness of the values of the C–Cl and C–Br vector moments. The identity and purity of our sample seems well established as previously noted (see. p. 3938).[11] Moreover, a molecular weight determination in benzene solution by the freezing point method gave a value 158.8 as compared to the theoretical value 161.0.

Values for the dipole moments of the other substances have not been reported previously.

Discussion

An exact treatment of the observed moments of the compounds measured here by the method of group moments of Eucken and Meyer[12] should also take into account the moments induced in any one bond by all others following the procedure of Smallwood and Herzfeld.[13] Such an exact treatment has been applied to these compounds but to avoid duplication it will be reserved for presentation in a later paper along with the results of measurements of the moments of bromo and iodo substituted compounds of the benzyl halide type. The induction effects are more important in these cases because of the larger polarizabilities of the C–Br and C–I group moments.

In the present paper we will follow a procedure which gives a good approximation to this more rigorous treatment in the cases of the para and meta substituted benzyl chlorides. Its use is possible because calculation shows that as the —CH_2Cl group assumes various rotational positions, the moment induced in it and the moments induced by it are practically constant in value when the ring substituent is in either para or meta position.

The observed moment of benzyl chloride,[14] μ = 1.85D, which is well established experimentally, may be regarded as representing the resultant of all the inherent bond moments and all the induced moments in the ring and side chain. Similarly the observed moment (μ = 1.56D) of chlorobenzene is the resultant of all the inherent bond moments and the induced moments in the molecule. If the direction of the vector representing the benzyl chloride molecule were known, it would be possible to combine it vectorially with the observed vector for chlorobenzene and obtain the moment of *p*-chlorobenzyl chloride, because the slight difference in induction effects of the chlorine and —CH_2Cl groups, respectively, on the groups

whose magnitude is 1.85*D*. This is in effect an evaluation of the constant contribution that a —CH_2Cl group attached to a phenyl group will make to the observed moment of a compound of which it is a part. This contribution will be constant in compounds with ring substituents para or meta to the —CH_2Cl group provided the moments of such substituent groups are not so large as to induce moments of appreciable magnitude in the —CH_2Cl group. These induced moments will be proportional to the inverse cube of the distance and for the separations involved in the meta and para cases will be small and will not vary greatly with rotation.

Under these assumptions we have calculated the angle as 59°5′ that the vector 1.85 makes with the vertical axis of the ring as shown in Fig. 1(a). The moment of benzyl chloride as calculated from the group moments of Eucken and Meyer is 1.86*D*, disregarding induced effects, and makes an angle of 82°8′ as shown by the dotted line N of Fig. 1(a). The tilt upward by 22° to the angle 59°5′ is a measure of the induced moments in the molecule. It is to be emphasized that this tilting does not necessarily imply any distortion of the normal carbon valence angles but simply determines the direction of the resultant vector of the benzyl chloride molecule relative to the axis of the ring passing through the carbon linked to the —CH_2Cl group.

Since in the para compounds the separation between the dipole of the para group and that of the C–Cl bond of the —CH_2Cl group is constant and independent of rotation, then the angle for this vector calculated for different para substituted benzyl chlorides should remain substantially unchanged. Such is the case. Using the moments of *p*-bromobenzyl chloride ($\mu = 1.70D$) and *p*-nitrobenzyl chloride ($\mu = 3.58D$) and the group moments C–Br = $1.50D$ and C–NO_2 = $3.99D$,[15] values for this angle of 60°19′ and 63°46′, respectively, are found showing that the angle is altered but little by the nature and degree of polarity of the para substituent.

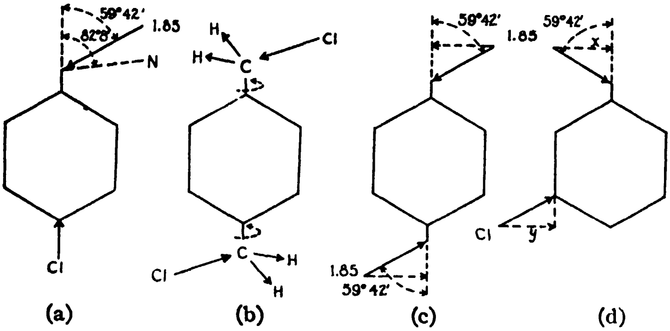

Fig. 1.

This angle, having been shown to be constant, may be used to calculate the moments of compounds containing the rotating —CH_2Cl group of the type shown in Fig. 1(b and d) where the effective component group moments are resolved into their respective vertical vectors and the horizontal rotating vectors x and y. If the effective mean of the latter for all rotational positions can be evaluated, it can be combined with the net vertical component to give the resultant moment of the molecule. For the assumption that all rotational positions are equally probable the effective mean of the two horizontal components is found from

$$\mu_H = \sqrt{\frac{1}{\pi}\int_0^{\pi}(x^2 + y^2 + 2xy\cos\Theta)d\Theta} = \sqrt{x^2 + y^2} \qquad (4)$$

where Θ is the angle between the two considered as rotating independently in the same plane.

In the case of the compound *p*-xylylene dichloride (Fig. 1b and c), the vertical components cancel and the moment can be found directly from equation (4), each horizontal component being equal to 1.85 sin 59°42′. This is the average angle found from the observed moments of *p*-chloro- and *p*-bromobenzyl chloride. The value so calculated is $\mu = 2.26D$, in excellent agreement with the observed value $\mu = 2.23D$.[16]

Calculations similar to these have been applied to those molecules measured here whose moments depend on rotation, the results of which are

---

(15) The average of recent values. See Smyth, Ref. 5, pp. 195 and 203. For the moments of the para compounds see Ref. 10.

(16) Weissberger and Sängewald, *Physik. Z.*, **30**, 792 (1929). A result similar to ours for the calculated moment is given by these authors (see Ref. 11).

given in Table III together with the angles employed. The agreement in the case of the meta chloro- and nitrobenzyl chlorides is good and may, if the validity of the approximate treatment used is granted, be taken as evidence that rotation in these compounds is practically free and unhindered. The large divergence in the case of the ortho compounds between calculated and observed values would on the same basis be attributed to hindrance of free rotation but is probably also due to the failure of the present treatment to weight correctly the induced effects in the ortho cases.

The relation of the separation of the principal dipoles to these results is seen from the last two columns of Table III. These give the maximum and minimum distances in Å. between these dipoles which are assumed to be located at the periphery of the carbon atoms concerned.[17] The table shows that there is practically free rotation when the principal dipoles do not approach each other closer than 4.4 Å. Even with approach of the dipoles to within about 3 Å. of each other in the ortho compounds there is a reduction of moment of only about 15% of that calculated for free rotation with the treatment used here. This small difference is of doubtful significance, however, since this approximate treatment would scarcely be valid for the ortho compounds as previously indicated.

The effect of the solvent on the observed moment and its relation to the freedom of rotation is seen from Table III. In *p*-chlorobenzyl chloride where every rotational position is equally probable, practically identical moments are found in the three solvents. The moments of the meta compounds which are close to those calculated here for free rotation differ but little in the different solvents, whereas fairly large differences are found for both ortho compounds, indicating that freedom of rotation in the case of small dipole separations is significantly affected by the solvent. No systematic regularity of effect of solvent is however apparent, indicating that other factors such as slight deviations from ideality may also cause part of the observed divergences. The indications are that the absence of divergences between values obtained in different solvents may be a valuable criterion for the existence of freedom of rotation.

Summary

The dielectric constants, densities and refractive indices of dilute benzene, carbon tetrachloride and heptane solutions of ortho, meta and para substituted benzyl chlorides have been determined at 30° and also those of dilute benzene and carbon tetrachloride solutions of ortho and meta nitrobenzyl chlorides. The dipole moments of these compounds have been discussed in relation to freedom of rotation as affected by the extent of separation of the groups concerned.

Phenylarsonic Acid as a Reagent for the Determination of Tin

BY J. S. KNAPPER, K. A. CRAIG AND G. C. CHANDLEE

Attention has been called to the possibilities of phenylarsonic acid as an analytical reagent in methods described by Rice, Fogg and James[1] for the determination of zirconium and thorium. The present investigation extends this study to include conditions for the separation and determination of tin.

Phenylarsonic Acid.—Eastman phenylarsonic acid was used without purification. Some samples left no non-volatile residue on ignition; others contained a small amount of sodium salts which did not interfere. A saturated aqueous solution was used as the reagent.

Tin Standards.—For the determination of tin in the absence of other metals Bureau of Standards Sample No. 42B, 99.99% tin, was used. For the determination of tin in the presence of other metallic ions Bureau of Standards Samples No. 37B, sheet brass and No. 52, cast bronze, were used. Other samples were prepared from the pure tin and purified salts of the metals.

Determination of Tin.—Samples of approximately one-tenth of a gram of the pure tin were treated with 10 cc. of 1:1 nitric acid and the mixture heated gently until the metal was completely oxidized. The heating was continued until any excess nitric acid was driven off, care being taken not to dehydrate the metastannic acid. Concentrated hydrochloric acid was then added, dropwise, until the tin was in solution. It was found that phenylarsonic acid would form a precipitate with tin in solutions which contained as much as 50% by volume of hydrochloric or sulfuric acid. However, precipitation was not quantitative when the acid concentration was greater than 5% by volume of hydrochloric acid or 7.5% by volume of sulfuric acid and reasonable amounts of reagent were used. Sufficient acid was added so that the final concentration was within these values upon dilution with water to a volume of 150–200 cc.

The tin was precipitated in hot solution by the addition of 35 cc. of the saturated aqueous solution of phenylarsonic acid. When only enough hydrochloric acid to dissolve the metastannic acid was added, about 1 cc. for this weight of tin, the solution could be filtered immediately. When acid in amounts approaching the limits indicated was added, it was necessary to allow the solution to stand for several hours before filtering. A small amount of paper pulp aided in the filtration. The precipitate was washed with a 4% solution of ammonium nitrate until free of chlorides or sulfates.

All precipitates were ignited to the oxide, no attempt being made to determine composition. The precipitate was ignited gently over a flame until all of the carbon was burned off. It was then heated in an electric furnace at a temperature of 1075–1100° to constant weight. Samples of pure stannic oxide heated under the same conditions showed no loss in weight.

Taking amounts of stannic oxide between one and three tenths of a gram and concentrations of hydrochloric acid or sulfuric acid of 2.5–5.0 and 7.5%, respectively, twelve determinations gave results with an average deviation of 1.1 parts per thousand. The somewhat higher acid concentration permissible in solutions acid with sulfuric acid may possibly be explained on the basis of a complex formed by stannic chloride with hydrochloric acid.[2]

---

(1) Rice, Fogg and James, THIS JOURNAL, 48, 895 (1926).

(2) Dickinson, *ibid.*, 44, 276 (1922).

In general, completeness of precipitation depended upon the relative amounts of acid and reagent present. With acid concentrations above those given, impractical quantities of reagent were required.

Separation from Other Elements.—In aqueous solutions of the chlorides or sulfates most of the elements commonly found in alloys of tin formed precipitates with phenylarsonic acid. With aluminum salts, hydrolysis made the solution sufficiently acid to prevent precipitation. These precipitates were readily soluble in acid and quantitative separations of tin were made in solutions of brass and bronze samples in which as small an amount as one cc. of concentrated hydrochloric acid was added to the 200 cc. volume. None of the elements showed any tendency to be carried down with the tin salt except iron. The difficulty was overcome by one reprecipitation. The precipitate, after washing, was returned to the original beaker, 5 cc. of concentrated hydrochloric acid added and the mixture heated until the precipitate was disintegrated. Water was added to bring the volume to 150–200 cc. and the tin was reprecipitated with 15 cc. of the phenylarsonic acid solution. The determination was then completed in the manner described.

The results obtained for the separation of tin from varying amounts of other elements are given in Table I.

Zirconium.—Conditions satisfactory for a quantitative separation of zirconium and tin by means of phenylarsonic acid could not be obtained. While the acid concentration permissible for complete precipitation of tin is fixed at 5% hydrochloric acid or

7.5% sulfuric acid, the element will precipitate to some extent when as much as 0.2 g. is present, even in solutions containing 50% by volume of either acid.

Thorium.—The determination of thorium with phenylarsonic acid was accomplished by Rice, Fogg and James[1] only in solutions containing acetic acid and ammonium acetate. However, in the present work it was found that part of the thorium was precipitated, when 35 cc. of reagent was used, in a 5% solution of hydrochloric acid. This is the upper limit of acidity permissible for the determination of tin. A satisfactory separation of tin and thorium with this reagent does not seem possible.

Bismuth.—Due to the tendency of bismuth salts to hydrolyze it was necessary to precipitate in solution containing 5% by volume of hydrochloric acid. Results were not satisfactory in sulfuric acid solution. The volume of the solution was kept at approximately 200 cc. Precipitation was done in hot solution by the addition of 40–50 cc. of the reagent and the mixture was allowed to stand several hours before filtering. Reprecipitation was not necessary. The determination was completed in the manner already described. Taking amounts of stannic oxide between one and two tenths of a gram, in the presence of approximately equal amounts of Bi_2O_3, four determinations gave results with an average deviation of two parts per thousand.

Summary

A new gravimetric method for the determination of tin has been described, in which the tin is precipitated with phenylarsonic acid. This method separates tin quantitatively from a number of elements commonly occurring with it in alloys, but not from zirconium or thorium.

The Action of Hydriodic Acid on the Difficultly Soluble Sulfates[1]

BY EARLE R. CALEY

While a number of facts indicate that hydriodic acid is generally more reactive chemically than either hydrochloric acid or hydrobromic acid under like conditions, it has not been recognized that this difference is so great that a number of slightly soluble compounds, quite inert toward the latter acids, react easily with hydriodic acid, a striking example being stannic oxide.[2] In a preliminary note[3] it was stated that a number of other compounds highly resistant to hydrochloric acid, and even such active solvents as nitric acid and aqua regia, are more or less readily decomposed by hydriodic acid. This present paper contains a more detailed account of the action of the latter acid on certain of these compounds.

Materials and General Procedure.—The hydriodic acid used in the experiments was principally the constant boiling acid of specific gravity

1.70, although for certain experiments acids of lower concentration were prepared from this by dilution. The several reactions were tried through repeatedly with a pure acid prepared by the interaction of iodine and hydrogen sulfide, and also with a commercial constant boiling acid stabilized by the addition of 1–2% of hypophosphorous acid. Since the use of the stabilized acid is so much more convenient from a practical manipulative viewpoint, duplicate experiments using this mixture were performed in view of the possible applications of these reactions in chemical analysis. Qualitatively, and to a large extent quantitatively, practically no differences were observed in the behavior of the two acids except in respect to ease of air oxidation and amount of free iodine liberated in the reactions. The several sulfates used in these experiments were prepared by the writer from pure chemicals.

In the following experiments the general procedure was to treat weighed samples of the finely divided solids with definite volumes of acid of known concentration at various temperatures, noting evidences of a reaction or lack of reaction and, in the case of a reaction taking place, collecting and examining the gaseous or solid products by the usual qualitative or quantitative methods, usually both. In cases where pure hydriodic acid was employed the reactions were studied under a carbon dioxide atmosphere, while the corresponding experiments with the stabilized acid were performed in air.

Alkaline Earth Sulfates.—At room temperature the sulfates of barium, strontium and calcium are somewhat less soluble in concentrated solutions of hydriodic acid than in solutions of hydrochloric or hydrobromic acids of like normality, as found by a series of solubility determinations. On the other hand, these compounds have a much higher apparent solubility in hot solutions of concentrated hydriodic acid than in similar solutions of hydrochloric and hydrobromic acids due to an oxidation–reduction reaction progressively occurring between the dissolved salt and the acid, that results in the formation of hydrogen sulfide, iodine, water, and the corresponding metallic iodides. The onset of this reaction is dependent on acid concentration, temperature, and the sulfate-ion concentration as furnished by a particular salt, varying for the salts in the order of their solubility as shown in Table I. The following results are illustrative of the speed with which constant boiling hydriodic acid effects the decomposition of these sulfates at the boiling point in an open vessel. With the quantities given in the footnote to the table, complete decomposition of calcium sulfate occurs in about one minute, that of strontium sulfate in from seven to eight minutes, while barium sulfate decomposes only to the extent of about 60% in twenty minutes. Complete decomposition of the latter cannot be effected under these conditions due principally to the adverse effect of the progressive increase in barium-ion concentration on the solubility of

TABLE I

INFLUENCE OF ACID CONCENTRATION AND TEMPERATURE ON THRESHOLD APPEARANCE OF THE REACTION BETWEEN ALKALINE EARTH SULFATES AND HYDRIODIC ACID[a]

Effect sought	Acid normality	Barium sulfate	Strontium sulfate	Calcium sulfate
Apparent rate of decomposition in boiling acid of medium concentration	1.0	Nil	Nil	Very slow
	2.0	Nil	Very slow	Slow
	3.0	Very slow	Slow	Mod. slow
Apparent rate of decomposition in constant boiling acid at the boiling point	7.6	Slow	Mod.	Rapid
Approximate temperature of beginning reaction in constant boiling acid, °C.	7.6	85	60	50

[a] In each of these experiments a 100-mg. sample of the powdered (100-mesh) sulfate was suspended in 10 cc. of acid in a tube containing a strip of lead acetate paper suspended above the liquid. Evolution of hydrogen sulfide was used as an indication of the start of the reaction and length of paper stained in a given time an indication of the rate of decomposition.

the sulfate and hence on the concentration of dissolved salt available for further reaction. By using successive fresh portions of acid, however, small samples of barium sulfate can be transposed completely. That this decomposition is not due to a direct surface action of the hydriodic acid on these sulfates was indicated by experiments in which a soluble sulfate was first dissolved in cold constant boiling acid in an amount just sufficient to reproduce the initial concentration of sulfate ion furnished by the previously-measured slight solubility of a given alkaline earth sulfate, and then the resulting homogeneous solution was heated. Under these conditions it was observed that the action started at about the same temperature and gave the same reduction products as though the particular alkaline earth sulfate were present. The decomposition of alkaline earth sulfates by hot concentrated hydriodic acid apparently takes place then in two principal stages. First, the salts dissolve to a limited extent in the acid, furnishing the usual ions to the solution, after which the oxidation–reduction reaction takes place between the sulfate ions and the acid. The two stages follow each other progressively and the total rate of decomposition with a given salt depends primarily on the velocity with which sulfate ions are furnished to the solution, which is governed by the specific solubility of the salt, its particle size and the degree of agitation. Second, the rate is determined by the velocity of the oxidation–reduction reaction itself, which is practically imperceptible at room temperature, quite rapid at the boiling point of the acid, and dependent on both sulfate ion and hydrogen iodide concentration, the latter having been found to be of greater influence.

In formulating suitable equations to represent the decomposition of alkaline earth sulfates by hot concentrated hydriodic acid, the following facts must be considered. The essential chemical change consists in the reduction of sulfate ion by the acid with the formation of hydrogen sulfide, iodine, water, and iodide ions as the only discernible products of the primary reaction. To a limited extent secondary reactions also occur between these products, such as that between the hydrogen sulfide and the free iodine to form hydrogen iodide and free sulfur, with some oxidation of the latter, when air is present, to form sulfur dioxide. These latter reactions were found, however, to occur largely in the gas phase above the solution. This reaction has a marked temperature coefficient and a measurable rate of speed, so that it is probably not wholly ionic. Hence it seems most likely that it is largely molecular hydrogen iodide that engages in the reaction with the sulfate ion. On these bases one may write: $SO_4^{=} + 10HI \longrightarrow H_2S + 4H_2O + 4I_2 + 2I^-$. In a given case the total stoichiometric change can be represented by the equation: $SrSO_4 + 10HI \longrightarrow SrI_2 + H_2S + 4H_2O + 4I_2$.

Chromic Dihydroheptasulfate.—The peculiar compound formed by fuming a mixture of chromic hydroxide, or a soluble chromic salt, with an excess of concentrated sulfuric acid for several hours is remarkable for its high resistance to the action of nearly all acids, acid mixtures, and fused salts. Some recent writers have considered this compound to be normal anhydrous chromic sulfate in spite of the considerable evidence existing in the literature respecting its complex nature. By reason of this element of doubt, the compound prepared for use in these experiments from chromium nitrate was checked as to composition and the empirical formula $Cr_4H_2(SO_4)_7$ was again confirmed.

It has been shown by Noyes and Bray[4] that chromic dihydroheptasulfate is attacked slowly by hot concentrated hydrochloric or hydrobromic acid, the latter being more effective. Complete decomposition by these acids requires, however, an excessive number of hours even with small samples. On the other hand, hot concentrated hydriodic acid not only attacks this compound at a higher initial rate, but complete decomposition and solution can be effected in a reasonable time. By using constant boiling acid this substance is decomposed in boiling solution more rapidly than barium sulfate, but not nearly as rapidly as strontium sulfate. Apparently when chromic dihydroheptasulfate is decomposed by the action of hydrochloric or hydrobromic acid, the action involves only the slow initial breakdown of the complex, furnishing chromic and sulfate ions to the solution, and as the concentration of these increases the system tends to reach a state of equilibrium. With hot hydriodic acid, however, equilibrium is not reached due to the continuous destruction of the sulfate ions by the hydrogen iodide with the formation of hydrogen sulfide, iodine, water and iodide ions. This is believed to explain, in some measure, the greater effectiveness of this acid in decomposing the compound.

---

(4) "A System of Qualitative Analysis for the Rare Elements," The Macmillan Co., New York, 1927, pp. 315, 319.

The total stoichiometric change involved in the reaction can be represented by the equation: $Cr_4H_2(SO_4)_7 + 68HI \longrightarrow 4CrI_3 + 7H_2S + 28H_2O + 28I_2$. This equation is admittedly unusual by reason of the large coefficients before some of the quantities, but it is thought to represent the facts. It explains why, in accordance with experiment, such a large proportion of hydriodic acid is required for the complete decomposition of a given quantity of chromic dihydroheptasulfate.

Lead Sulfate.—It has long been known that an iodide solution placed in contact with lead sulfate causes the partial transformation of the latter into lead iodide, but it does not seem to have been previously observed that a comparatively small volume of cold concentrated hydriodic acid completely transforms the salt into the iodide due to the progressive solution of this in the acid with complex formation, leaving free sulfuric acid in the resulting homogeneous golden-yellow liquid. For example, it was found that at 23° only 4.00 cc. of constant boiling acid is required for the solution of 1.000 g. of lead sulfate. This effect falls off rapidly with decrease in acid concentration, so that slight or extended dilution of a solution obtained in this manner results in a copious precipitation of lead iodide.

The nature of the complex formed when hydriodic acid reacts with lead iodide was briefly investigated by Berthelot,[5] who isolated from the solution an unstable compound $PbI_2 \cdot HI \cdot 5H_2O$ which he termed lead hydriodide. This formula, however, rests on a single partial analysis, so by way of confirmation a quantity of the compound was prepared and analyzed with the following results.

Anal. Calcd. for $PbI_2 \cdot HI \cdot 5H_2O$: Pb, 30.51; I, 56.07; H_2O, 13.27. *Found:* Pb, 30.80; I, 55.66; H_2O, 13.40.

In migration experiments performed on concentrated lead iodide–hydriodic acid solutions, movement of lead to the anode was observed, indicating the existence of the metal in the negative ion. For this reason it seems probable that in such solutions the complex is largely iodoplumbous acid with the formula $HPbI_3$, assuming that it exists in solution with the same molecular ratio between constituents as in the above solid compound, which can be considered as being a hydrated form of this acid.

The total change, then, involved in the solution of lead sulfate by cold concentrated hydriodic acid can be represented by the equation: $PbSO_4 + 3HI \longrightarrow HPbI_3 + H_2SO_4$.

When a solution obtained in the above manner is heated, or when lead sulfate is treated with the hot concentrated acid, the oxidation–reduction reaction between sulfate ions and hydrogen iodide then ensues as with the other slightly soluble sulfates, except that in this case the decomposition is very rapid due to the speed with which all the possible sulfate ion becomes available for the reaction.

---

(5) Berthelot, *Compt. rend.*, **91**, 1024 (1880); *Ann. chim. phys.*, [5] **23**, 85 (1881).

Applications.—The above means of decomposing difficultly soluble sulfates has been found to be of considerable practical value in analysis. For example, the presence of such sulfates in the acid insoluble residue obtained in the usual qualitative scheme can be detected readily by heating a sample of the dried residue with stabilized constant boiling acid and testing for the evolution of hydrogen sulfide by means of lead acetate paper. After proper treatment of the resulting solution, the metals can then be detected by the usual reactions. Rapid identification of natural alkaline earth sulfates can be made in this manner as shown by tests on minerals of known character. In quantitative analysis also, hydriodic acid can be used for difficult separations involving these sulfates. As a test of its value in this respect a series of experiments were made on the separation of mixtures of quartz and alkaline earth sulfates. In these analyses each mixture was boiled for a sufficient period with a small volume, or successive small volumes, of the concentrated acid, after which the unattacked silica was transferred to a filtering crucible, washed a few times with water, dried and weighed. Good quantitative separation was obtained. In general, the use of finely-divided samples is essential for the most certain and rapid analytical application of this method of decomposition, especially in dealing with barium sulfate. It is planned to work out in a more detailed manner these uses of hydriodic acid in analytical chemistry.

Summary

All the difficultly soluble sulfates can be decomposed by the action of hot concentrated hydriodic acid. The apparent mechanism involves the reduction by hydrogen iodide of the sulfate ions continuously furnished to the acid solution by these salts with the resulting formation of hydrogen sulfide, iodine, and water, leaving the corresponding metallic iodides in solution. Lead sulfate is also quite soluble in hydriodic acid of high concentration at room temperature. The value of these reactions in chemical analysis has been indicated.

The Effect of Hydrogen-Ion Concentration on the Flocculation Values of Chromic and Aluminum Oxide Sols

BY M. HUME BEDFORD, W. H. KELLER AND J. L. GABBARD

Most of the previous investigations of the variation of flocculation values of hydrous oxide sols with hydrogen-ion concentration have been made in the presence of buffers and other contaminants,[1] or without a direct measure of the hydrogen-ion concentration.[2] But Hazel and Sorum[3] have devised a procedure for investigating the flocculation values of a series of hydrous oxide sols of gradually increasing and directly measured hydrogen-ion concentrations and free from any contaminating ions. This paper reports an application of their method to chromic and aluminum oxide sols.

The hydrogen-ion concentration was controlled by adding equal volumes of very dilute hydrochloric acid of slightly increasing concentrations to equal volumes of stock sols. Hydrogen-ion concentrations were measured by the use of the glass electrode and a vacuum tube voltmeter. Flocculation values were determined by adding equal volumes of the coagulating electrolyte of slightly increasing concentrations to samples of the sol until that concentration of electrolyte was found which, on standing for twenty-four hours, just produced complete coagulation.

Measurements.—Hydrogen-ion concentrations were determined potentiometrically. The glass electrode described by MacInnes and others[4] was used instead of the platinized hydrogen electrode. The glass electrode is greatly superior for this work because it is not poisoned by contaminants, does not tend to coagulate the sol or change its *P*H value during measurements, and allows practically instantaneous readings.

Each glass electrode has a characteristic "asymmetry" potential which is large (as high as several volts) just after the electrode is made, but which gradually decreases to about 0.1 volt while the electrode is "aged" by immersion in dilute hydrochloric acid for several days, and is fairly constant thereafter. This constant was determined for the electrode before and after each set of readings by the use of standard buffer solutions, as described by Hazel and Sorum.[3]

Buffers of KCl–HCl, *P*H 2.2, NaAc–HAc, *P*H 4.63, and KH_2PO_4–Na_2HPO_4, *P*H 5.9 were used. The *P*H values of the buffers were checked with a standard hydrogen electrode. The constant of the electrode checked by the buffers just before and after each set of readings always agreed to within 0.02 of a *P*H unit. The constant is calculated by the equation: $P_H = (E\text{ (cell)} + C)/0.059$ at 25°, where *C* is the desired constant and *E* is the measured e. m. f. of the cell.[5]

(5) Because methods described in the literature for making glass electrodes are both meager and

The hydrogen electrode was coupled with a normal calomel electrode through a salt bridge. The e. m. f. of the completed cell was measured by a vacuum-tube voltmeter of the type described by Partridge.[6] A Leeds and Northrop Student Potentiometer was used in place of the voltmeter in the Partridge circuit.

Precipitating values were determined by adding 3 cc. of the electrolyte to 2 cc. of sol, shaking thoroughly, and permitting the mixture to stand, stoppered, for twenty-four hours. Increasing concentrations of electrolyte were prepared by adding stock electrolyte of convenient concentration (previously determined) by 0.1-cc. increments to a 3-cc. vessel, and diluting to the mark (3 cc.) with distilled water. That concentration which just produced complete coagulation in twenty-four hours was taken as the flocculation value of the sol toward that electrolyte expressed in millimoles of electrolyte per liter of mixture.

This definition of the coagulating value is entirely arbitrary and was used merely as a matter of convenience. The values obtained are only relative, but are of less than 3.33% error with respect to each other. This limit of error is due to the fact that precipitants were added in 3.33% increments of concentration. That the values are valid relatively within this limit was demonstrated experimentally by the failure of 3.33% less electrolyte to produce complete coagulation, even when the sol so treated was left standing for several days.

With univalent and bivalent anions coagulation was usually quite definite. When a perfectly colorless layer of water one millimeter or more in depth was observable above the settling precipitate, coagulation was always found to be complete. This was shown by centrifuging for fifteen minutes at 1500 to 2500 r. p. m. and testing the supernatant liquid qualitatively for the metal. The salts of trivalent cations such as ferric, chromic, and aluminum ions produced a troublesome partial sedimentation very difficult to detect visually, the coagulum even being repeptized on centrifuging. It was necessary to repeat such precipitations until a qualitative test definitely indicated complete coagulation. The aluminum oxide sol particularly produced partial sedimentations which were very difficult to distinguish from complete coagulations because of the practically colorless nature of the sol. In such instances the samples were allowed to stand longer than twenty-four hours to let the coagulum settle further so that a sufficiently large quantity of the supernatant liquid could be drawn off for examination by the aluminon test.

Preparation of Sols.—The chromic oxide sol was prepared by hydrolysis of chromic chloride with boiling distilled water[7] and hot dialysis[8] through cellophane.[9] Dialysis was conducted at 85 to 90° for about twelve to fourteen hours per day for three weeks. At the conclusion of the dialysis, when treated with silver nitrate, distilled water which had stood overnight in contact with the sol through the cellophane failed to show any trace whatever of chloride ion. A sample of the sol dissolved in hot nitric acid showed a very faint cloudiness with silver nitrate due to the chloride ion adsorbed by the micelles. The sol contained 1.35 g. of chromium per liter and its *P*H value at the conclusion of dialysis was found to be 6.4.

---

difficult, a new and ingenious process was devised which produced a stronger electrode and saved much time By careful suction applied by the mouth to a rubber tube attached to the electrode tube, the glass membrane is gently drawn against and fused onto the hot end of the electrode tube held just above it, thus producing an electrode which because its inner surface is convex, is consequently stronger than those with plane surfaces obtained by the methods previously described. MacInnes and Belcher suggest that only one electrode be made from each bubble, but the writers found that by the above procedure a number of electrodes could be made from the pieces of each bubble. Fairly thick (not iridescent) membranes were also found to be quite efficient.

(6) H. M. Partridge, THIS JOURNAL, **51**, 1 (1929).

(9) J. W. McBain and S. S. Kistler, *J. Phys. Chem.*, **35**, 130 (1931).

The aluminum oxide sol was prepared by precipitation and repeptization of aluminum hydroxide from a solution of aluminum chloride[10] and was dialyzed in a Neidle dialyzer using cellophane bags. The dialysis was conducted at 70 to 90° continuously for one week. Distilled water was allowed to flow through the cellophane bag at the rate of about 1 liter per hour. The dialyzed sol did not give a test for the aluminum ion by the aluminon test, and gave only a very slight test for the chloride ion with silver nitrate. The concentration of the sol was 1.652 g. of aluminum per liter and its *PH* value at the conclusion of dialysis was 5.85.

Data and Discussion of Results.—The writers repeated the work of Hazel and Sorum on ferric oxide sols, using two different stock sols each prepared according to the procedure of Hazel and Sorum. The flocculation values obtained were lower than those of Hazel and Sorum but the trends shown by the variations of flocculation values with hydrogen-ion concentration agreed completely with their results and substantiate fully their conclusions.

Tables I and II present the coagulation values of typical electrolytes toward chromic oxide and aluminum oxide sols, respectively.

TABLE I

FLOCCULATION VALUES IN MILLIMOLES PER LITER OF CHROMIC OXIDE SOLS CONTAINING 1.35 G. OF Cr PER LITER

Sols	1	2	3	4	5
PH	5.3	4.9	4.5	4.0	3.5
Electrolyte					
KBr	5.0	8.0	16.0	30.0	...
$^1/_3AlCl_3$	600.0	600.0	600.0	640.0	No ppt.
K_2SO_4	0.136	0.16	0.24	0.32	0.56
$CaSO_4$	.112	.124	.192	.24	.48
$K_3Fe(CN)_6$	.064	.076	.12	.17	.31
$K_4Fe(CN)_6$	.044	.060	.088	.12	.30

TABLE II

FLOCCULATION VALUES IN MILLIMOLES PER LITER OF ALUMINUM OXIDE SOLS CONTAINING 1.22 G. Al PER LITER

Sol	1	2	3	4	5
PH	5.67	5.22	4.74	4.40	3.96
Electrolyte					
KCl	26.0	30.0	34.0	46.0	100.0
K_2SO_4	0.34	0.40	0.44	0.50	0.60
$K_3Fe(CN)_6$	.13	.15	.16	.18	.19
$K_4Fe(CN)_6$	.096	.108	.13	.17	.18
K_2CrO_4	.30	...	.40	..	1.04
$^1/_2BaCl_2$	32.0	...	40.0	..	80.0
$^1/_3AlCl_3$	80.0	...	..	..	100.0

The electrolytes are salts of uni-, bi-, tri-, and quadrivalent anions, since ferric, chromic and aluminum oxide sols are positive, and the anion the component of the solution most active in coagulation.

---

[10] Harry B. Weiser, *J. Phys. Chem.*, **35**, 1368 (1931).

With two exceptions the stability of ferric oxide sol was found to vary directly with its hydrogen-ion concentration; in one case, the stability of ferric oxide sol toward sulfate ion decreased with increase of hydrogen-ion concentration; in the other case the flocculation values of the salts of trivalent metals, such as iron, chromium and aluminum, were constant within certain limits of *P*H values of sol samples. These results were obtained by Hazel and Sorum, and verified by the writers.

Chromic and aluminum oxide sols showed no exceptions whatever to the general rule that sol stability increases with increased hydrogen-ion concentration, within the limits investigated. However, the precipitating value of ferric chloride toward chromic oxide sol was constant from *P*H 5.3 to 4.5 but increased from *P*H 4.5 to 4.0, while at *P*H 3.5 ferric chloride failed entirely to coagulate the sol. This was probably due to the solution of the sol micelles in the quantity of acid from the hydrolysis of the salt added to the already considerable hydrogen-ion content of the sol.

The *P*H values of the sol samples after complete coagulation were also measured, but the trends shown by the results obtained were quite discordant and entirely unpredictable. These changes of *P*H values may have occurred at the time of mixing of electrolyte with the sol since the two systems were not isohydric, as was shown by comparison of the *P*H values of the electrolytes with those of the sols; or, the changes may have occurred during coagulation as a result of the processes accompanying coagulation; or, they may have resulted from both the mixing and the coagulation. Hence the *P*H values assigned to the sols may not represent the *P*H's at which coagulation occurred, but merely the original *P*H values of the sols. However, conclusions based on these data are perfectly valid regarding the stability toward electrolytes of these sols of the given *P*H values. Sufficient data were not collected during this investigation to determine the time of change of the *P*H values of the mixtures, and this problem is now being further investigated in this Laboratory.

Summary

1. The stability of chromic and aluminum oxide sols toward electrolytes has been shown to vary directly with their hydrogen-ion concentration.

2. The stability of ferric oxide sol varies directly with its hydrogen-ion concentration except toward sulfates, in which case the stability varies inversely with the hydrogen-ion concentration.

3. Ferric and aluminum chlorides have been shown to have constant precipitation values toward hydrous oxide sols, within certain limits of *P*H values, probably due to the maintenance of constant hydrogen-ion concentration by buffer action of the hydrolyzed salts.

The Separation and Determination of the Alkali Metals Using Perchloric Acid. V. Perchloric Acid and Chloroplatinic Acid in the Determination of Small Amounts of Potassium in the Presence of Large Amounts of Sodium

BY G. FREDERICK SMITH AND J. L. GRING

Introduction.—In a previous paper[1] the combined use of perchloric acid and chloroplatinic acid in the quantitative separation and determination of mixtures of sodium and potassium was shown to be superior to the customary use of either acid alone. We have now studied the conditions under which this method can be applied to the determination of 0.02 to 0.2% of potassium in sodium chloride.

Very small amounts of potassium in the presence of large amounts of sodium are usually determined by precipitation as potassium-sodium cobaltinitrite and the determination of potassium in the precipitate by the perchloric acid process. The present method involves but a single precipitation and is, therefore, much simpler and more rapid.

Solubility Relationships Governing the Process.—As has been shown previously,[1] the rate of decrease in solubility of potassium perchlorate in alcohol–water solutions with increasing proportions of alcohol is slight by comparison with the decrease in solubility of potassium chloroplatinate under the same conditions. Potassium perchlorate is quantitatively insoluble only in practically absolute alcohol. On the contrary, potassium chloroplatinate is quantitatively insoluble in 85% alcohol and an excess of the chloroplatinate ion. Sodium perchlorate is satisfactorily soluble in either absolute alcohol or any mixture of water and alcohol suitable for the quantitative separation of potassium as perchlorate or chloroplatinate.

For the separation of very small amounts of potassium from large amounts of sodium, conversion of the potassium to chloroplatinate is preferable to the formation of potassium perchlorate for numerous reasons, the most important consisting in the fact that the ratio $K_2PtCl_6/2KCl$ is larger than the ratio $KClO_4/KCl$. This is true notwithstanding the fact that potassium perchlorate can be shown to be less soluble in 97–100% alcohol–water mixtures when a sufficient excess of perchlorate ion is present for its common ion effect than is potassium chloroplatinate with excess of the chloroplatinate ion. In the method under discussion, the perchlorate ion is present in large excess as a result of the high concentrations (0.25–0.30 molal) of sodium perchlorate necessarily present. On the other hand, the process as a whole becomes practicable only in case a small excess of chloroplatinic acid is required as compared to the unmodified Fresenius method.

---

[1] Smith and Shead, THIS JOURNAL, 54, 1722 (1932).

The reaction upon which the method is based is $2KClO_4$ (small amounts) + $NaClO_4$ (large amounts) + $H_2PtCl_6 \rightleftharpoons K_2PtCl_6 + NaClO_4 + 2HClO_4$. The present study consists in the determination of the maximum concentration of sodium perchlorate which may be present to complete the reaction in the sense from left to right. Partial reversal of this reaction would result in the formation of a mixed precipitate of K_2PtCl_6 + $KClO_4$, whereas only potassium chloroplatinate is desired. The reaction is affected by two remaining variables, first, the water concentration in the solvent alcohol, and second, the excess of chloroplatinic acid used as precipitant.

Materials for the Study of the Method.—The reagents used are from the same stock previously described in connection with earlier papers of this series and require therefore no further description. Sodium chloride was used in such quantities that a separate stock perhaps somewhat less pure than that previously described was used. This was prepared by the recrystallization of C. P. sodium chloride from water by the use of gaseous hydrogen chloride. A trace of potassium chloride was a possible contamination but by the application of the method the amount was shown to be barely perceptible.

Determination of Maximum Permissible Perchlorate Ion Concentration and the Influence of Alcohol Strength.—The method employed consisted in preparing solutions of anhydrous sodium perchlorate in 80–100% ethyl alcohol of variable concentrations. Potassium was added to these various solutions in small amount either by the suspension of 100–200 mg. of potassium chloroplatinate or by the addition of potassium perchlorate and a slight excess of chloroplatinic acid. The solutions and precipitates thus formed were sealed in glass tubes and rotated in a thermostat at 25° until an equilibrium was established. The tubes were then opened and the precipitates filtered, dried, and examined for any potassium perchlorate partially precipitated together with potassium chloroplatinate. The study of the precipitates was carried out in a number of ways as follows: (a) microscopic examination. Suitable for extensive contamination of potassium chloroplatinate by potassium perchlorate. (b) Determination of platinum in the potassium chloroplatinate to prove the presence or absence of potassium perchlorate. (c) By the color of the solutions produced by the addition of potassium chloroplatinate to the alcoholic sodium perchlorate after equilibrium. Precipitation of potassium perchlorate resulted in the formation of chloroplatinic acid in solution, identified by its color. (d) By adding weighed amounts of potassium chloroplatinate and testing for quantitative recovery.

The data thus obtained defined the maximum concentration of sodium perchlorate which may be present without the formation of potassium perchlorate. The data are presented graphically in the accompanying Fig. 1. But a slight excess of chloroplatinic acid was employed in these experiments since in actual practice larger excesses would make the results more selective in the proper sense due to the decreased solubilities of potassium chloroplatinate.

Analytical Interpretation of the Experimental Results.—The study of the data of Fig. 1 leads to the following conclusions. (1) The maximum concentration of sodium perchlorate which may be present is 0.28 molal using 95% alcohol. (2) 80–90% alcohol permits the presence of a constant concentration of sodium perchlorate, 0.20 molal. (3) Using 95–100% alcohol, the precipitation of potassium perchlorate takes place to the exclusion of potassium chloroplatinate with rapidly decreasing concentrations of sodium perchlorate. (4) For each 100 cc. of 95% alcohol, 1.63 g. of sodium chloride can be used as sample for analysis. (5) Since potassium perchlorate is known to become increasingly less soluble in more concentrated alcohol, these data show that 95% ethyl alcohol causes the least dissociation of sodium perchlorate. Since 95% ethyl alcohol is the most commonly occurring strength, this fact is a fortunate circumstance operating to simplify the process.

Outline of Procedure.—1.48 to 1.63 g. of sodium chloride (containing potassium chloride) sufficient to give a sodium concentration of 0.25–0.28 normal is dissolved in water in a 150-cc. beaker and converted to sodium and potassium perchlorate using twice the perchloric acid required. The residue thus obtained is freed from excess perchloric acid by heating, the last part of the operation being carried out on a wire gauze over a free flame, the beaker being rotated with the cover glass supported on glass hooks and the beaker walls brushed carefully by the flame to remove perchloric acid condensed on the inside walls of the beaker and under side of the cover glass. If evaporation of the sodium perchlorate solution has been carried out above 35°, the residue is anhydrous upon deposition from the water–perchloric acid solution.

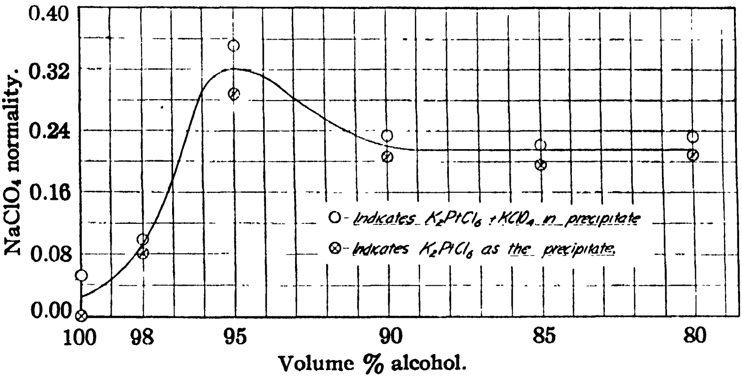

Fig. 1.—Selective precipitation of K_2PtCl_6 from $KClO_4$ and $NaClO_4$ solutions: influence of alcohol strength.

The beaker is cooled, the inside rinsed with a few ml. of water, and the evaporation and heating repeated for the second time. By this operation the perchloric acid occluded in the first obtained anhydrous sodium perchlorate is freed and the residue is acid free. Dissolve the salts by adding 95 ml. of 95% ethyl alcohol and heating if desired up to near the boiling point on the hot-plate. (The heating of such solutions is perfectly safe since free acid is not present.) Chloroplatinic acid, 0.2 g. in 5 ml. of 95% ethyl alcohol, is added to this solution, preferably hot, and after a few minutes' digestion and vigorous stirring the mixture is cooled to 0° and allowed to stand with frequent stirring at this temperature for an hour or longer.

The precipitated solution is filtered through a sintered glass or quartz filtering crucible, the potassium chloroplatinate washed once with 95% alcohol and finally with cold absolute alcohol until free from sodium perchlorate (9–10 portions of 1 ml. each) and finally dried and weighed. The potassium chloroplatinate is stable at 350° and its weight may be checked by solution in hot water and precipitation of the platinum by acidification with hydrochloric acid and decomposition with a few milligrams of magnesium ribbon. The precipitated platinum is then filtered on a small ashless filter which is dried, ignited and weighed, from which value the amount of potassium chloride originally present is calculated using the theoretical factor.

Experimental Analyses.—The first variable requiring study was the determination of the required excess of chloroplatinate ion. Weighed amounts of sodium chloride were treated with weighed amounts of potassium chloride in the form of a dilute solution in water using a weight buret to increase the accuracy of obtaining the small amounts of potassium chloride. Solutions were prepared for analysis as above described and various weights of chloroplatinic acid were added and the effects determined. The results of these analyses are given in Table I. Precipitations were carried out in 100 cc. of 95% alcohol.

Table I

The Influence of Excess Chloroplatinic Acid on the Separation of Small Amounts of Potassium in the Presence of Large Amounts of Sodium

KCl, g.	NaCl, g.	Excess $H_2PtCl_6 \cdot 6H_2O$, g.	$NaClO_4$, normality	K_2PtCl_6 found, g.	KCl calcd., %	KCl found, %	Error KCl unpptd., %
0.0010	1.4705	0.0025	0.25	0.0003	0.068	0.006	90
.0020	1.4600	.0038	.25	.0011	.137	.019	83
.0039	1.4225	.0096	.24	.0061	.266	.131	58
.0012	1.4281	.0680	.24	.0028	.084	.052	38
.0024	1.4724	.1000	.25	.0071	.163	.148	9

Results from Table I indicate that an excess of somewhat greater than 100 mg. of $H_2PtCl_6 \cdot 6H_2O$ in 100 ml. of solution should provide a sufficient excess of precipitant; 200 mg. of precipitant per 100 ml. of solution was therefore chosen as a safe working basis. Results obtained in final tests of the new method of analysis are given in Table II.

From an examination of Table II it is seen that 0.15% of potassium chloride in sodium chloride can be determined readily by one precipitation with an accuracy of 5% if the blank correction for the determination of the trace of potassium in the sodium chloride used to test the results is disregarded. Applying the blank correction, the results obtained are as accurate as are those obtained in analyses of the ordinary rather than the semi-micro type. While the analyses of Table II deal with comparatively large amounts of potassium chloride, the method has been applied with equal success to much smaller amounts of potassium approaching that of the blank determination given above. The method has already been shown to apply admirably to large amounts of potassium[1] and by examination of the last table of results in that paper, it will be seen that in the cases in which the method did not apply for small amounts the cause is found in either the use of too high concentrations of sodium salts or the incorrect strength of solvent alcohol. If the directions are properly followed, no free perchloric acid is left, and so there is no danger in heating the alcoholic solutions.

Summary

1. The method of Smith and Shead[1] has been extended to include the determination of small quantities of potassium in the presence of large amounts of sodium.

2. The salts of sodium and potassium, in the modified procedure, are converted to the neutral anhydrous perchlorates, dissolved in 95% alcohol, and treated with a moderate excess of chloroplatinic acid. The precipitate of potassium chloroplatinate can be weighed as such, or converted to platinum and the potassium calculated from this.

3. The method involves the direct precipitation of potassium (one operation) and no previous concentration to isolate the potassium for subsequent purification is required.

4. The method involves the use of but 0.20 g. of chloroplatinic acid ($H_2PtCl_6 \cdot 6H_2O$) per determination. The demand for, and cost of recovery of, platinum is therefore a small factor.

5. In analyses of samples of sodium chloride containing no more than 0.15% of potassium chloride, results obtained by the method should not be in error by more than 0.01%.

The Systems (a) Ammonium *d*-Tartrate–Lithium *d*-Tartrate–Water, and (b) Ammonium Lithium *d*-Tartrate–Ammonium Lithium *l*-Tartrate–Water

BY ALAN NEWTON CAMPBELL AND LOUIS SLOTIN

Pasteur's first method of resolution of optically active substances has so far only been found applicable to a relatively few cases, the reason being that most inactive forms at room temperature are true racemates and not conglomerates. A study of the mixed solubilities will always tell whether or not the transition point lies in an attainable region. Such studies have been carried out by van't Hoff and by Findlay. So far as is known to the present authors, the only racemic salts whose transition points are known are sodium ammonium racemate,[1] sodium potassium racemate,[2] and rubidium racemate.[3]

It was thought therefore that it would be of interest to investigate the effect on the transition temperature of the substitution of lithium for so-

[1] Van't Hoff and van Deventer, *Z. physik. Chem.*, 1, 165 (1887).

dium in sodium ammonium racemate. Such a study as this should, for completeness, comprise five systems, namely

NH_4 *d*-tartrate–Li *d*-tartrate–H_2O (1)
NH_4 *d*-tartrate–NH_4 *l*-tartrate–H_2O (2)
Li *d*-tartrate–Li *l*-tartrate–H_2O (3)
NH_4 *r*-tartrate–Li *r*-tartrate–H_2O (4)
NH_4Li *d*-tartrate–NH_4Li *l*-tartrate–H_2O (5)

Only with this complete knowledge can one be certain that system 5, on which interest centers, is really a three-component system. Only systems 1 and 5 were investigated by us, but it will be seen from an examination of the isotherms that we were justified in assuming that none of the components of system 5 broke into single constituents at the temperature of investigation.

Experimental

All the salts used in this investigation had previously been prepared. The information attainable in the literature is summarized in the table.

Salt	Prepared by	Formula assigned	Solubility in H_2O
NH_4 *d*-tartrate	Scacchi[a]	$(NH_4)_2C_4H_4O_6$	Unknown
Li *d*-tartrate	Dulk[b]	......	Readily soluble
NH_4Li *d*-tartrate	Scacchi[a]	$Li(NH_4)C_4H_4O_6 \cdot 0.5$ or $1H_2O$	14.186 g. per 100 g. soln. at 20°
NH_4Li *r*-tartrate	Scacchi[c]	$Li(NH_4)C_4H_4O_6 \cdot 0.5$ or $1H_2O$	13.104 g. per 100 g. soln. at 20°

[a] *Atti accad. Sci. Fis. Mat. (Napoli)*, 3, No. 5 (1866); 6, No. 25 (1867); No. 29, pp. 29, 33 and 38.

[b] *Ann. chim. phys.*, [3] 5, 370.

[c] Scacchi, *Atti accad. Sci. Fis. Mat. (Napoli)*, No. 5, 3 (1866), and No. 25, 29 (1867).

Ammonium *d*-tartrate was prepared by the complete neutralization of Mallinckrodt C. P. tartaric acid with ammonia. The evaporation must be conducted in the presence of excess ammonia to prevent formation of the acid salt. The salt was recrystallized twice from water. A solution of the final preparation was neutral to litmus and had $[\alpha]^{30}_D$ +34.320°. Landolt[4] gives $[\alpha]^{20}_D$ 34.260°. NH_4 found by the distillation method, 19.58%; formula requires 19.59%.

Lithium *d*-tartrate was prepared by neutralizing C. P. tartaric acid with C. P. lithium carbonate until the solution was just alkaline to phenolphthalein. The crystallized salt was purified twice by recrystallization from water. It had $[\alpha]^{30}_D$ 35.87°. Landolt[4] gives $[\alpha]^{20}_D$ 35.84°. The lithium content was determined by ignition and conversion of the residual carbonate to sulfate.[5] Li found, 9.36%; formula requires 9.38%. This method of analysis was checked, since it was the method used throughout the solubility work, by precipitation of silver tartrate. In this way, for example, the following figures were obtained: weight of lithium tartrate, 1.3423 g.; weight of lithium tartrate calculated from weight of silver, 1.3425 g. Hence the above method is satisfactory for determining lithium.

Ammonium lithium *d*-tartrate was prepared by evaporation of an equimolar solution of ammonium and lithium tartrates and was purified by recrystallization from water.

---

(4) Landolt, *Ber.*, 6, 1676.

(5) Scott, "Standard Methods of Chemical Analysis," p. 414.

The purity of the salt was checked by analyzing weighed amounts and calculating from the formula the corresponding weight of double salt; thus, for example, (a) weight double salt, 3.421 g.; weight double salt from NH_4 determination, 3.4213 g.; (b) weight double salt, 1.6731 g.; weight double salt from Li determination, 1.6735 g.

For the inactive double salt, racemic acid was prepared by a method given elsewhere.[6] From this the double salt was prepared in the same way as the active double salt. The analytical figures were: (a) weight double salt, 1.6431 g.; weight double salt calculated from NH_4 determination, 1.6436 g.; (b) weight double salt, 2.0033 g.; weight double salt calculated from Li determination, 2.0029 g. The formula of the anhydrous double salt is therefore $(NH_4)_2C_4H_4O_6 \cdot Li_2C_4H_4O_6$.

All solubilities at temperatures higher than room temperature were determined by analyzing solutions obtained by stirring for a minimum of ten hours in contact with the appropriate solid phase, in an electrically heated and controlled thermostat. For this thermostat the temperature variations did not exceed 0.01°. At 0° the temperature was maintained constant by the use of ice and here the temperature variations amounted to 0.1°. For temperatures between 0° and room temperature, the arrangement of Walton and Judd[7] was adopted. It was found advantageous to couple this arrangement with an electrical heating unit, so that the bath was alternately heated by the heater or cooled by an entering stream of water. All thermometers were compared with a standard thermometer.

For accurate solubility work, especially where the wet solid phase is being analyzed, it is indispensable that filtration should be carried out actually in the thermostat. Accordingly, the following filtration apparatus, a modification of the previous one,[8] was used. Its construction is shown in the diagram.

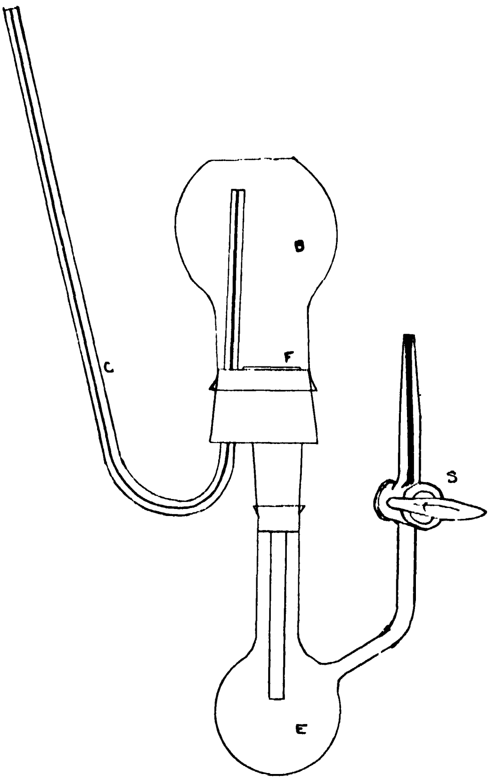

Fig. 1.

B is the bottle in which the saturated solution is prepared, F a sintered glass filter, C a capillary tube communicating with the atmosphere to equalize the pressure, E the receiver; the side-arm is for the purpose of applying suction. To operate the apparatus, the stirring apparatus is removed from the solubility bottle and the filtration apparatus and receiver inserted in its place. The whole unit is then inverted in the thermostat and the flask E slightly evacuated with a water pump. The stopcock S is then closed. The difference in pressure in the two flasks is sufficient to cause a rapid filtration of the saturated solution, the solid phase remaining on the surface of the stopper. The

amount of evaporation from the solution during the evacuation of the lower flask is negligible, since the greater part of the liquid is in the upper part of the apparatus, and the evacuation is only carried on for a few seconds before the stopcock is closed. This method has the further advantage that no volumetric apparatus is required, both solutions and solid phase being weighed.

Solutions and solid phase were analyzed for ammonia by the distillation method, and for lithium by the method previously described. The polarimetric method was found to be insufficiently accurate for system 1, probably because of the high concentration of active material. Its use was unavoidable in system 5, where both active and inactive double salts were present, and here it seems to have been fairly accurate, possibly because no interaction is possible between the active and inactive material.

These results are expressed graphically on rectangular coördinates in Fig. 2.

98.392	10.244	47.16	4.91	69.08	13.12

From these diagrams it appears that the transition temperature below which the active double salt cannot exist lies below room temperature. An anomaly is caused, however, by the lithium tartrate curve changing direction, an anomaly due to lithium tartrate changing its hydration, and this renders the interpretation of the curve by mere inspection difficult.

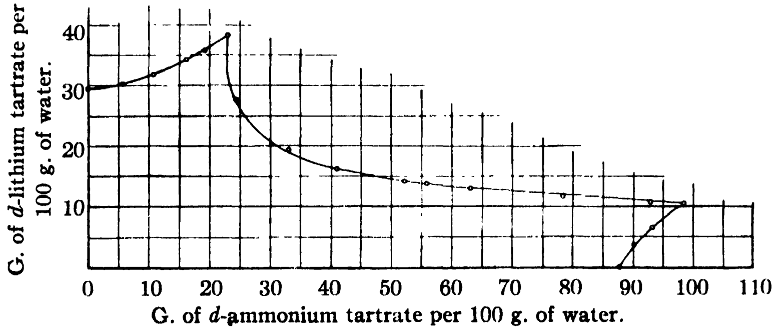

Fig. 2.—60°.

The complete triangular diagrams are given in Fig. 3.

The triangular diagram shows that the double salt has the formula $Li_2C_4H_4O_6 \cdot (NH_4)_2C_4H_4O_6$, and that it is anhydrous at all temperatures studied, although Schlossberg[9] gives to the doubled molecule 1 or $2H_2O$. The 0° triangular diagram shows that the solid phase along the lithium tartrate branch is $Li_2C_4H_4O_6 \cdot 2H_2O$, while at the higher temperatures this

---

(9) Schlossberg, *Ber.*, **33**, 1084 (1900).

salt is anhydrous. The numerical value of the solubility also indicates this, lithium tartrate being more soluble at 0° than it is at 30 and 60°.

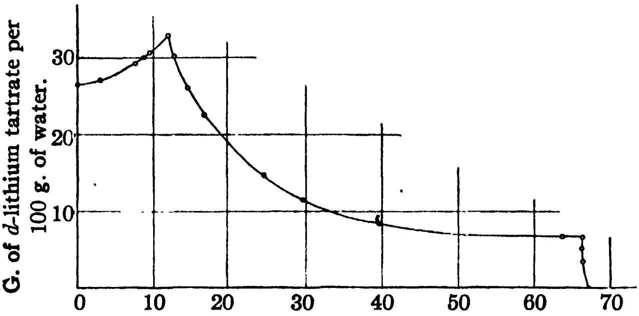

Fig. 3.—30°.

No reference to the hydration of lithium tartrate could be found in the literature, and it became advisable to determine the transition temperature of lithium tartrate dihydrate to anhydrous lithium tartrate. The dilatometric method and the solubility method were employed. By the former method the transition temperature resulted as 21.52°. The solubility figures are given in Table II.

TABLE II

SOLUBILITY OF LI *d*-TARTRATE IN WATER

Temp., °C....	60.0	45.0	30.0	25.0	20.0	10.55	8.0	0.0
Lithium tartrate per 100 g. of water, g.	29.522	27.510	26.663	26.711	27.052	31.495	33.451	42.106

When these figures are plotted against temperature, a marked point of inflection occurs at a temperature of 21.81°. Averaging the two results, the mean transition temperature for $Li_2C_4H_4O_6 \cdot 2H_2O \longrightarrow Li_2C_4H_4O_6 + 2H_2O$ results as 21.67°.

Solid Model.—In order to construct a solid model of the system, NH_4 *d*-tartrate–Li *d*-tartrate–H_2O, showing the behavior of the system with respect to temperature, it was also necessary to know the solubility curve of ammonium tartrate, since the solubility curves of the two simple salts form the boundaries of the model. The solubilities of ammonium tartrate were therefore determined and are expressed in Table III.

TABLE III

SOLUBILITY OF AMMONIUM TARTRATE

Temp., °C..........................	0.0	15.0	30.0	45.0	60.0
Ammonium tartrate per 100 g. of water, g.	43.916	58.101	63.813	79.450	87.171

An inspection of the solid model (not shown) reveals that the area representing stable existence of the double salt widens as the temperature increases, indicating that the double salt is more stable at higher than at lower temperatures.

At all temperatures between 0 and 60°, double salt formation takes place. In this temperature interval (a) ammonium tartrate is anhydrous; (b) lithium tartrate possesses two molecules of water of crystallization, which it loses at 21.67°; (c) the double salt is anhydrous. A rough extrapolation of the boundary lines of the area of stable existence of the double salt gives the transition temperature of $(NH_4)_2C_4H_4O_6 \cdot Li_2C_4H_4O_6 \rightleftharpoons (NH_4)_2C_4H_4O_6 + Li_2C_4H_4O_6$ as −80°. An examination of the triangular diagrams also shows that the temperature interval investigated is outside of the transition interval, that is, that the double salt can be recrystallized from water without partial decomposition.

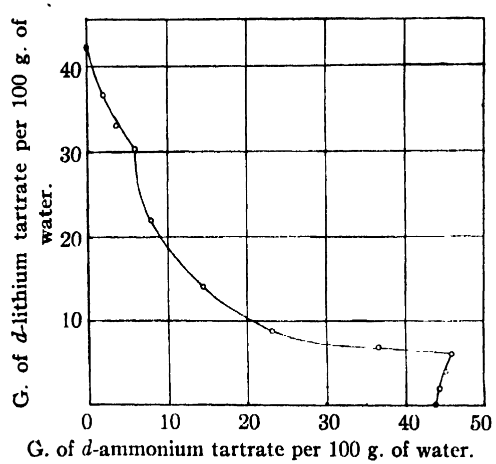

Fig. 4.—0°.

The System NH₄ Li d-Tartrate–NH₄ Li l-Tartrate–H₂O

The solubility of the inactive double salt was first determined by Schlossberg[9] who states that at 20° 100 g. of solution contains 13.104 g. of salt.

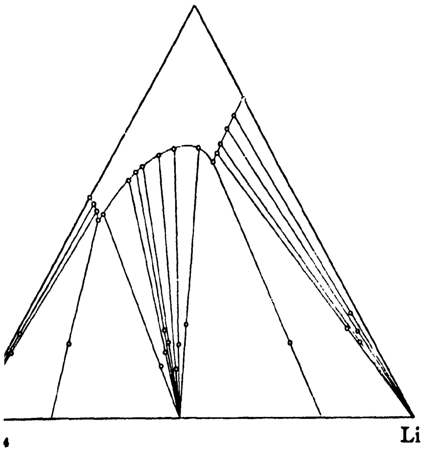

Fig. 5.—60° isothermal.

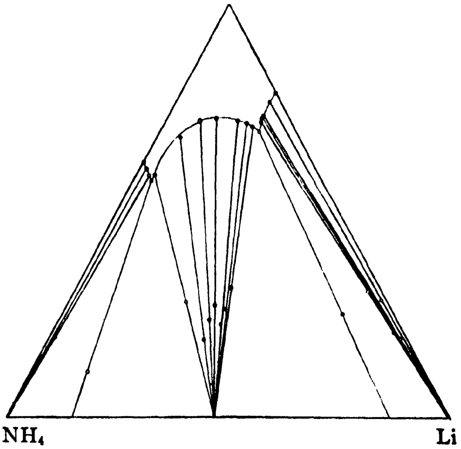

Fig. 6.—30° isothermal.

This solubility is much higher than that which was obtained in this work. It is possible that Schlossberg's double salt contained some ammonium lithium mesotartrate, which is much more soluble than the corresponding salt of racemic acid. Schlossberg's figure for the solubility of the active double salt (14.186 g. per 100 g. of solution at 20°) is considerably lower than ours.

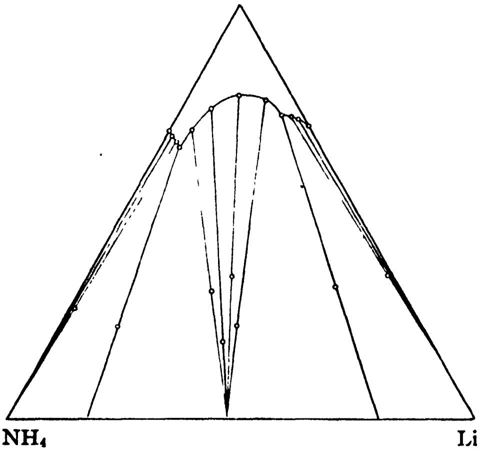

Fig. 7.—0° isothermal.

The experimental technique was the same as that of the previous system, except that the solutions and solid phases containing both active and inactive salt had to be analyzed polarimetrically. For this purpose it was necessary to determine the rotation of solutions of pure NH_4-Li *d*-tartrate at different concentrations. This was done for the sodium D line and at a controlled temperature of 30°, although it was subsequently found that the temperature coefficient of rotation for small changes of temperature is quite negligible. For experimental purposes, it was found simplest merely to plot observed rotation against the salt content of the solution, but for comparison with the literature, the figures are given as specific rotations.

TABLE IV

SPECIFIC ROTATIONS OF SOLUTIONS OF NH_4LI *d*-TARTRATE AT 30° AND FOR NA LIGHT

Concn. in g. per 100 cc. of soln.	4.00	12.00	16.00	20.00	28.00
Concn. in g. per 100 g. of H_2O	4.0829	12.7480	17.4080	22.3791	32.7772
$[\alpha]_D^{30}$	+33.0°	+32.1°	+31.3°	+31.4°	+31.2°

Since the object of this study was merely to find the transition temperature of NH_4Li *r*-tartrate to its active component, the 30 and 60° isotherms were not investigated in full, but only the three invariant points were determined. Such "stability curves" are hypothetical as to their curvature, but they are sufficient to define the boundaries of the area of stable

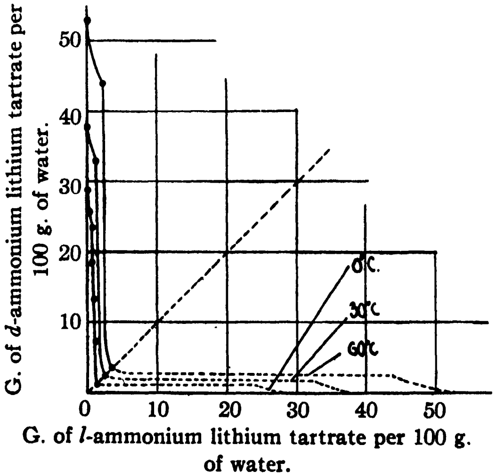

Fig. 8.

existence of the racemate. At 0°, however, the isothermal was fully investigated, in order to determine the degree of hydration of the inactive double salt. The complete data are given in Table V.

TABLE V

Solid phase	Solubility in g. per 100 g. of H_2O 0°	30°	60°

r- (total *d* + *l*)	2.806	6.542	11.480
d + *r*	*d* 23.250	*d* 32.917	*d* 44.103
	l 0.731	*l* 1.416	*l* 2.312

ISOTHERMAL 0°C.

Solubilities expressed as grams of salt per 100 g. of water and also as percentages

Liquid phase: Solubility in g./100 g. of H_2O *d*-form	*r*-form	Percentages *d*-form	*r*-form	Solid phase: Percentages *d*-form	*r*-form
0.0	2.806	0.0	2.19	...	...
6.531	2.363	6.00	2.17	2.52	74.20
12.241	1.860	10.72	1.63	3.35	67.50
17.690	1.64	14.75	1.37	6.30	56.02
23.251	1.462	18.69	1.18	45.09	29.86
24.810	0.98	19.80	0.70	76.19	0.62
28.519	.0	22.19	.0	...	...

All racemic solubilities when plotted were divided in two and one-half added to the solubility of the *d*-form, and the other half plotted as total *l*-form.

The results are plotted on rectangular coördinates in Fig. 5, and the 0° isothermal on a triangular diagram in Fig. 6.

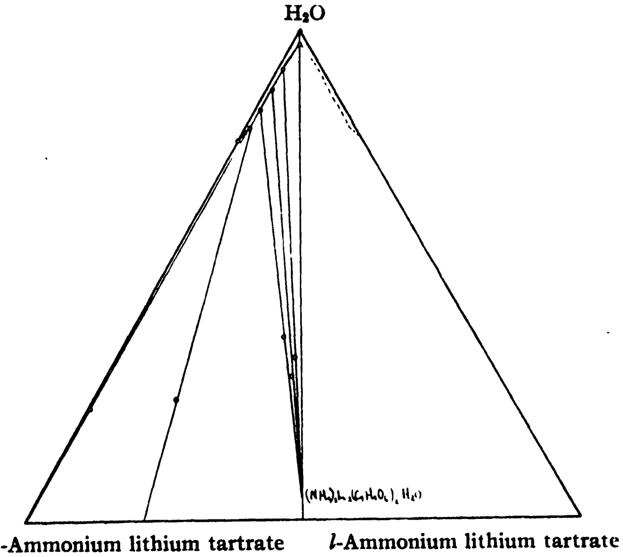

Fig. 9.—Isothermal at 0°.

The large intermediate portion of the rectangular graphs shows the racemate to be very stable at the temperatures investigated and that the transition point is well below 0°. When the solubilities of the inactive salt alone and of inactive salt plus active are plotted against temperature, the curves are found to intersect at a temperature of $-62°$. Consequently, if a solution of ammonium lithium racemate were allowed to crystallize below this temperature, it would deposit the two enantiomers. This is, of course, experimentally impossible owing to the solidification of the solvent.

The angle of intersection of the solubility curves for racemic and racemic plus active forms is large, indicating a large heat of formation.

The intersection of the double salt tie-lines on the 0° isothermal indicates for the inactive double salt the formula $(NH_4)_2Li_2(C_4H_4O_6)_2 \cdot H_2O$. This is in agreement with the findings of Scacchi and Schlossberg.[9] The hydrate also exists at 30° and quite possibly at 60°, although complete solubility measurements were not carried out to confirm this.

Summary

1. The solubility relations in the ternary systems ammonium *d*-tartrate–lithium *d*-tartrate–water and ammonium lithium *d*-tartrate–ammonium lithium *l*-tartrate–water have been determined at 0, 30 and 60°.

2. A double salt was found to be formed at all three temperatures, and its composition was established as $(NH_4)_2Li_2(C_4H_4O_6)_2$. The double salt is stable at all temperatures from 0 to 60°, becoming more stable as the temperature is raised. In the latter system a true racemate was found to exist at all three temperatures and its formula was established as $(NH_4)_2Li_2(C_4H_4O_6)_2 \cdot H_2O$.

The Ammines of Chromous Chloride

BY H. I. SCHLESINGER AND EDITH S. HAMMOND[1]

Chromous ammines were first prepared by Peters[2] by the action of gaseous ammonia on chromous chloride. His results were later partially verified by Ephraim,[3] who measured vapor tensions of the compounds at various temperatures. Although both investigators report the existence of a hexammine and a triammine, neither of them succeeded in causing the chromous chloride to add quite six moles of ammonia to one of the simple salt and they do not agree in their description of the color of the product. Furthermore, withdrawal of ammonia to form the triammine from the hexammine was not accompanied by an abrupt drop in the pressure as should have been the case had the measured tensions corresponded to equilibrium conditions.

Our preliminary experiments gave evidence of the existence of a pentammine and a diammine in addition to the compounds mentioned above, and showed that reinvestigation of the others was necessary to prove their existence definitely and to define their properties accurately. It very soon became obvious that the causes of the difficulty in the earlier work lay in the failure to use sufficiently purified samples of chromous chloride and to recognize the slowness with which equilibrium is attained.

Preparation of Chromous Chloride.—Chromous chloride was prepared by reducing chromic chloride with hydrogen at a furnace controlled temperature near 420°. The hydrogen was purified by passing it over hot platinized asbestos, then through a liquid air trap, followed by a phosphorus pentoxide tube, which had been evacuated and washed several times with hydrogen. The samples of chromic chloride used as starting material in the preliminary experiments were obtained by drying anhydrous chromic chloride in a stream of chlorine; for the final results, chromic chloride was resublimed in an atmosphere of pure chlorine before it was reduced. The chief difficulty is the prevention of secondary reduction of chromous chloride to chromium. The addition of hydrogen chloride to the hydrogen affords some protection against over reduction, but even under these conditions careful control of the temperature, and interruption of the reduction as soon as the color becomes pure white, are necessary. The chromous chloride thus obtained was transferred in an atmosphere of dry nitrogen to the reaction vessels in which it could be sealed, weighed and stored.

Preparation of Hexammine-Chromous Chloride.—The typical reaction vessel consisted of a glass tube about 14 × 200 millimeters, expanded at the lower end to a small flat bulb in which the chromous chloride could be spread over a fairly large area. The upper end was sealed after the chromous chloride had been introduced. Near the top was attached a side tube and stopcock through which the vessel was connected to a

vacuum apparatus in which the ammonia pressure, as well as the volume of ammonia absorbed, could be measured.

After the tube containing chromous chloride was evacuated and weighed, pure dry ammonia at approximately 75 cm. pressure was admitted to the vessel. Absorption began at once with evolution of heat. To make certain that the reaction was complete, weighings were made only after the material showed no absorption for a period of about twenty-four hours. By deducting from the gain in weight of the vessel the weight of ammonia remaining in the gas phase, the amount of ammonia absorbed by the solid was obtained. In several experiments this weight was checked by measuring the volume of ammonia absorbed, but the gravimetric measurements proved more reliable. The data are reproduced in Table I.

TABLE I

COMPOSITION IN THE SYSTEM OF HEXAMMINE–CHROMOUS CHLORIDE

Sample number	Mole of chromous chloride	Approximate temperature, °C.	Final ammonia pressure, cm.	Ammonia absorbed, mole	Moles of ammonia per mole of $CrCl_2$

4	.001286	24	21.14	.00771	6.00

The table shows clearly the importance of using only the purest possible chromous chloride in experiments of this type. The data obtained with samples 1, 7, 9 and 11 which were made from unsublimed chromic chloride, while consistent among themselves, lead to the incorrect conclusion that absorption of six moles of ammonia does not occur until the pressure is near 100 cm. The more nearly pure the sample of chromous chloride, the lower the pressure required for the absorption of ammonia, as is seen from the experiment with sample No. 6 in which 5.91 moles of ammonia are taken up at pressures between 21 and 29 cm. The amount of ammonia absorbed by the most carefully purified sample (No. 4) is that required for the hexammine, and remains constant in a pressure range from about 20 to between 30 and 35 cm. At pressures below 18 cm., ammonia is again lost and the color changes from deep blue to violet. These pressure values, however, represent merely convenient criteria for the preparation of the hexammine; the determination of the equilibrium pressures and definite evidence for the existence of the hexammine are described below.

Before turning to these measurements, a word should be said about the phenomena which accompany increase of the ammonia pressure beyond the limits mentioned above. At higher pressures the material becomes green, and when the pressure reaches 90 cm., gray. During these color changes small amounts of ammonia are absorbed very slowly; but even though the pressure is raised to 2 atmospheres and the temperature lowered to $-15°$, the maximum absorption corresponds to only 0.34 mole of ammonia in excess of that required for the hexammine. At present the most satisfactory explanation of these phenomena is that ammonia, first taken up as a solid solution, ammonolyzes the salt to the mixture of gray color. This interpretation is confirmed by the fact that the gray color cannot be discharged by decrease of the ammonia pressure, and that liquid ammonia extracts what appears to be ammonium chloride from the solid. The reaction, however, is so slow and incomplete that it could not be satisfactorily studied at the temperatures of our experiments.

It is evident from these results that Ephraim confused the gray color which resulted from the action of an excess of ammonia on the hexammine with the color of the hexammine itself. Furthermore, in experiments on dissociation pressures in this system the formation of the gray material must be avoided because it retards greatly the attainment of equilibrium and obscures the interpretation of analytical data. Unfortunately it is formed more rapidly at high temperatures, at which the dissociation pressures of the ammines would otherwise be more readily determined, and therefore the work must be done at temperatures at which the reactions are very slow.

The System Chromous Chloride–Ammonia.—Because of the difficulties just discussed, dissociation pressures of the various ammines could not be determined in the usual way by observing the pressures which are ultimately reached by mixtures of ammonia and chromous chloride ammines of various compositions. Instead, it was necessary in each case to prepare the mixture of hexammine and pentammine by allowing the former to remain in an evacuated vessel for a short period of time. Ammonia was then admitted and the pressure changes observed. If the pressure fell, its value obviously was above the dissociation pressure of the hexammine; consequently a portion of the gaseous ammonia was removed, and the observations were repeated. If the pressure continued to fall, more ammonia was removed from the gas phase. If the pressure rose, ammonia was readmitted but not in sufficient amount to bring the pressure back to its initial value. By repeated observations made after successive evacuations and readmissions of ammonia, the equilibrium value could be bracketed by approaching it from both sides. Finally an ammonia pressure could be found under which no changes occurred over a period of three or four days. This was taken as the equilibrium value. The procedure was very time-consuming, often requiring several weeks to establish a single point on the pressure composition diagram, but it led to reliable results. The equilibrium pressures thus found at 35.5° are reproduced in Table II and Fig. 1.[4] Compositions represent (moles NH_3)/(moles $CrCl_2$).

Table II

Compn.	5.85	5.3	5.19	4.95	4.81	4.54	3.6	3.2	2.95	2.21
Pressure, cm. Hg	23.25	23.25	23.25	3.5	3.5	3.5	3.5	3.5	0.85	0.85
	Hexammine			Pentammine					Triammine	

When the composition of the diammine is reached the pressure becomes immeasurably small, and further removal of ammonia cannot be effected even by raising the temperature to 140–150° for twenty-four hours; at still higher temperatures ammonium chloride is given off. Inspection of the table and figure makes clear that chromous chloride forms ammines

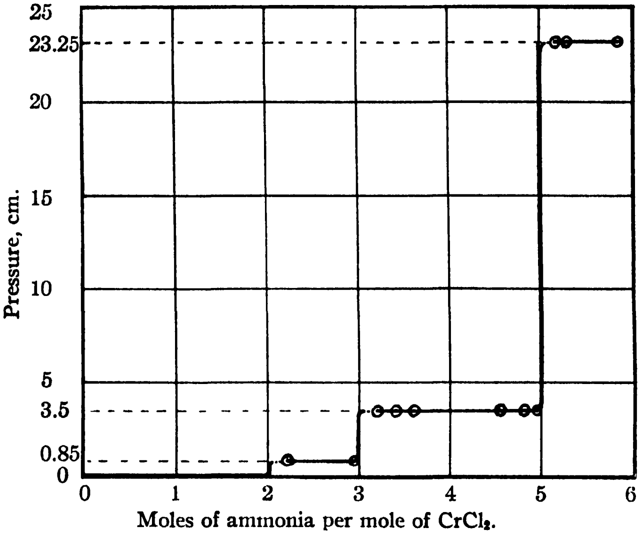

Fig. 1.—System chromous chloride–ammonia at 35.5°.

with 6, 5, 3 and 2 molecules of ammonia, respectively. The equilibrium pressures for the pentammine were also determined at 41 and 50° and found to be 5.7 and 10.3 cm., respectively; for the triammine the value is 5.38 cm. at 62°. These values are obtained from measurements at a single composition in each case. Since only two measurements were made for the triammine at 35.5°, because of the slowness with which equilibrium is reached at this temperature, measurements at the compositions 2.95, 2.54, 2.3 and 2.21 were made at 42°, and gave the constant value 1.1 cm. This confirms the conclusion drawn on the basis of the small number of determinations at the lower temperature.

Preparation of the Lower Ammines.—The dissociation pressures show

---

(4) In interpreting the curve it should be borne in mind that the abrupt changes shown in the pressure are changes in the equilibrium values. At no composition is there a rapid transition from one constant pressure to another.

that the data of both Peters and Ephraim are erroneous in several respects, for they recognized only a hexammine and a triammine. In many instances their data do not correspond to equilibrium conditions.[5] Ephraim's failure to obtain a constant vapor tension as ammonia is removed from the hexammine has been shown to be due to an extremely slow attainment of equilibrium. He also assigns to the triammine the vapor tension which, according to our results, is more nearly that of the pentammine. Our observations also indicate confusion in the earlier descriptions of the properties of the ammines, particularly with regard to their colors. It was, therefore, desirable to prepare each of them in as pure condition as possible.

If a vessel containing a sample of the hexammine is continuously evacuated at room temperature, the pressure falls steadily to about four millimeters, during which time there is a gradual change in color from blue to deep violet. The hexammine is thus completely decomposed; small amounts of ammines other than the pentammine are removed by allowing the material to stand for some time in contact with ammonia at a pressure just below the dissociation pressure of the hexammine.

Removal of ammonia from the pentammine is much hastened by raising the temperature to 60 or 70°. If the sample is not heated too long, the gray material described above is not formed in appreciable quantity, probably because of the low pressure at which removal is effected. At a composition of approximately three moles of ammonia to one of chromous chloride, the color has changed again, this time to a light blue, and the equilibrium pressure has changed to that of the triammine. In similar fashion the sage green diammine can be prepared. The data concerning these ammines are summarized in Table III.

TABLE III

Ammine	Analysis,[a] moles NH_3 per mole $CrCl_2$	Dissociation pressure, cm.[b]	Color
$CrCl_2.6NH_3$	6.01	23.25	Dark blue
$CrCl_2.5NH_3$	4.95	3.5	Violet
$CrCl_2.3NH_3$	3.03	0.85	Light blue
$CrCl_2.2NH_3$	2.00	Practically zero	Sage-green

[a] Calculated from the average of data obtained from the purest sample.

[b] Values for the dissociation pressures at other temperatures are given on p. 3974.

The Reactions of Chromous Chloride Ammines with Chlorine.—It seemed possible that reaction of chlorine with the diammine, which because of its low ammonia tension is particularly suited to such a study, might lead to the formation of a diammine of chromic chloride. This

---

(5) Ephraim gives the vapor tension of the hexammine as

Temperature, °C.	0	13	16	27	33.5	43.5
Pressure, mm.	104	194	228	387	517	744

For the violet intermediate product which he calls the triammine, he gives the following tensions

Temperature, °C.	44	59.5	72	86	92	95
Pressure, mm.	45	97	198	433	618	730

substance would have peculiar interest because the normal coördination number of trivalent chromium is six. For carrying out the reaction, the reaction tube was connected into a closed system provided with a manometer in which the mercury was protected from the chlorine by a small layer of concentrated sulfuric acid. The system was evacuated and pure dry chlorine admitted. There was no apparent reaction in the cold, but at 250° the absorption of chlorine became noticeable and resulted in the formation of a reddish-violet hygroscopic substance which was unstable in air. At approximately 275° the color changed to a deep purple and ammonium chloride was evolved. At still higher temperatures complete reaction to form chromous chloride, ammonium chloride and nitrogen occurred. All the intermediate stages seemed to be mixtures of variable composition.

The fact that chlorine should oxidize the ammonia in the complex molecule without affecting the powerfully reducing chromous ion was unexpected. A similar reaction occurs with the triammine; this may be due to the fact that by oxidation of ammonia the diammine is first formed and then reacts further with chlorine. The essential reaction of chlorine with the ammines is oxidation of the ammonia; the color changes were shown by direct test to be due to interaction of hydrogen chloride formed by this oxidation, on the residual amines. The product of the reaction of hydrogen chloride on the ammines is a mixture which could not be separated into its components.[6]

The authors take pleasure in acknowledging their indebtedness to Professor W. C. Johnson, who supervised the work for a time while the senior author was out of residence, and to Dr. Anton B. Burg for his aid in many technical problems.

Summary

A blue hexammine, a violet pentammine, a light blue triammine, and a sage-green diammine of chromous chloride were prepared.

Methods were developed for determining the dissociation pressures of these substances in spite of the fact that equilibrium is attained very slowly. Dissociation pressures of $CrCl_2{\cdot}6NH_3$, for $CrCl_2{\cdot}5NH_3$, and for $CrCl_2{\cdot}3NH_3$ were determined at 35.5°; in addition ammonia tensions for the pentammine were measured at 41 and 50°, and for the triammine at 42 and 62°.

Chlorine oxidizes the ammonia of these complex chromous compounds but does not affect the chromous nucleus.

The Kinetics of the Reduction, in Acid Solution, of Hydrogen Peroxide by Iodide Ion

BY HERMAN A. LIEBHAFSKY AND ALI MOHAMMAD

Introduction

The first successful quantitative investigation in chemical kinetics, completed in 1866 by Harcourt and Esson,[1] proved that the rate of the reaction

$$H_2O_2 + 2H^+ + 3I^- = 2H_2O + I_3^- \qquad (1)$$

is proportional to the amounts of peroxide and iodide present, and that it is "accelerated" by the addition of acid. A quarter century later Magnanini,[2] in a remarkable investigation, which we shall subsequently consider in some detail, demonstrated how this "acceleration" is related to the acid added. Noyes,[3] interested chiefly in clarifying the fundamental concept "order of a chemical reaction," was the first to point out that Magnanini's results and those of Scott[3a] followed a differential equation of the form

$$d(I_3^-)/dt = k_1^\circ(H_2O_2)(I^-) + k_1(H_2O_2)(I^-)(H^+) \qquad (2)^4$$

He regarded the "accelerating" action of hydrogen ion as catalytic even though this substance is consumed in the reaction. Other investigators,[5] however, have preferred to interpret Equation 2 in terms of two independent rate-determining steps, which may be formulated

$$H_2O_2 + I^- \xrightarrow{k_1^\circ} H_2O + IO^- \qquad (3)$$

$$H_2O_2 + H^+ + I^- \xrightarrow{k_1} H_2O + HIO \qquad (4)$$

Reaction 3 is a compensating reaction in the catalytic decomposition of hydrogen peroxide by the iodine–iodide couple, which has been much investigated;[6] Reaction 4, however, seems to have been studied recently only as a means of determining hydrogen peroxide.[7] Consequently, the specific rate of the former reaction (k_1° = 0.69 at 25°) is well established, while no very accurate value can be assigned to that of the latter.[8]

Reactions whose rate laws involve hydrogen ion in the manner of Equation 2 are not very common; one of this type is the reduction of iodate by hydrogen peroxide,[9] the study of which suggested a reinvestigation of Reaction 1 in order that accurate values for the heats of activation of Reactions 3 and 4 might be secured for comparison with those of the corresponding rate-determining steps involving iodate ion. Such a reinvestigation may be regarded, also, as contributing to research of a more general type that has long been under way in this Laboratory,[6a,b,9,10] namely, the interaction of hydrogen peroxide and iodine compounds of all valences. Further, Reactions 3 and 4 are simple, and their rates can be measured accurately; consequently, they are well adapted to studies of the kinetic salt effect. And, finally, they possess low apparent heats of activation so that they may be investigated over a considerable range of temperatures for the purpose of determining how these heats vary with the temperature.

(8) For these constants at 25°, Bray in 1906 chose the values k_1° = 0.60 and k_1 = 16; since the first value is too low, the second is probably too high.

The Experimental Method

Results Obtained at 25°.—An examination of Equation 1 will reveal that tri-iodide ion is formed as the reaction proceeds; the simplest experimental conditions obtain when no appreciable change in the concentration of iodide ion results from such complex ion formation. One way of realizing these conditions is by using an amount of hydrogen peroxide so small that no great change in (I^-) has resulted when reaction is complete; if (H^+) and (I^-) are comparable, then (H^+) also will be (nearly) constant during the experiment. Under these conditions the rate law, Equation 2, will assume the simple form

$$d(I_3^-)/dt = -d(H_2O_2)/dt = k'(H_2O_2) = [k_1^\circ(I^-) + k_1(H^+)(I^-)](H_2O_2) \qquad (5)$$

So long as the experimental method employed shows k' to be unchanged during the course of an experiment, average values of (H^+) and (I^-) may be used to calculate k_1° and k_1. All experiments that were carried out by the method described below (the "analytical method") meet this test.

In such experiments all the reaction mixture (C. P. sodium iodide and perchloric acid were used) except the peroxide, contained in a glass-stoppered flask, was placed in a thermostat at the desired temperature and shielded from direct light. After temperature equilibrium had been reached, a measured volume of hydrogen peroxide solution from a reservoir in the bath was added to start the reaction, zero time being taken when the addition was half complete. From time to time 25-cc. samples were withdrawn with a pipet and permitted to flow into 125 cc. of water at 0°, in order to retard Reaction 1 by cooling and dilution. The time of sampling

[9] Liebhafsky, THIS JOURNAL, **53**, 896 (1931). No completed investigations are available, but the preliminary results obtained in this Laboratory by Liebhafsky indicate definitely that the rate laws for the reduction of hydrogen peroxide by bromide and by chloride ions have the form of Equation 2; the approximate values at 25° of the specific rates for the steps analogous to Reaction 3 are 2×10^{-7} (chloride) and 2.3×10^{-5} (bromide).

[10] (a) Bray and Liebhafsky, THIS JOURNAL, **53**, 38 (1931); (b) Bray and Caulkins, *ibid.*, **53**, 44 (1931); (c) Liebhafsky, *ibid.*, **53**, 2074 (1931); (d) Bray, *Chem. Rev.*, **10**, 172 (1932).

was recorded as the time when the pipet was half emptied. So soon as was convenient,[11] these samples were titrated with a 0.004 *N* thiosulfate solution. The increase in the thiosulfate titer of the samples served to measure the rate of Reaction 1.

The evaluation of k', which is independent of concentration units, is easily accomplished. If a represents the thiosulfate titer of a sample when reaction is complete, and x represents this quantity at time t, then

$$d(x)/dt = k'(a - x) \tag{5a}$$

for a is proportional to the initial (H_2O_2), and $(a - x)$ to (H_2O_2) at time t. Values of log $(a - x)$ for experiments done by this method were plotted as ordinates against the time (*cf.* Fig. 1 and Table I); the slopes of the resulting straight lines, when multiplied by 2.303, gave the values of k' for these experiments.

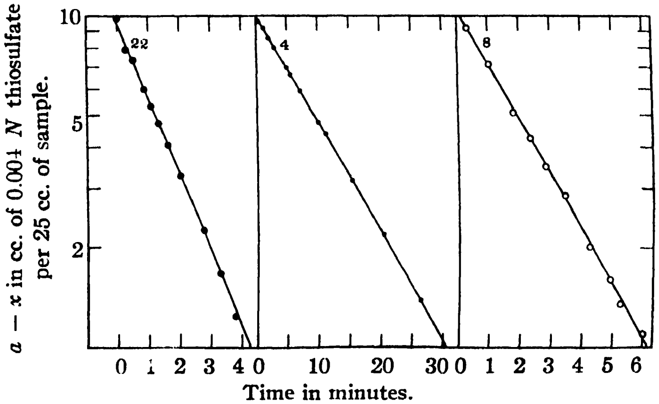

Fig. 1.—Detailed experimental results at 25°. The plot is on *semi-logarithmic* paper. The composition of each reaction mixture is given in Table I (*cf.* footnote b).

To obtain k_1^0 and k_1, values of k' obtained from experiments at various concentrations of iodide and of hydrogen ion are necessary. If Equation 5 is valid, experiments at constant (H^+), but at different (I^-), should yield

---

[11] A sample was usually titrated within one minute after its withdrawal; in exceptional cases, when successive samples were taken rapidly, titration was postponed longer—but never for more than ten minutes. During the interval between the time of a sample and the time of its titration, the samples were kept in the dark at 0°.

The amount of iodine formed in a sample while it awaited titration was obtained as follows. Before the beginning of a run a blank, having the volume and composition that would result from diluting a sample of the reaction mixture before iodine formation had begun, was prepared and kept in the dark at 0°. When the experiment was over this blank was titrated with thiosulfate. If C represents the amount of iodine formed during this time (t minutes), then C/t represents the rate of its formation (C is so small that (H^+) and (I^-) and (H_2O_2) in the sample may be regarded constant). If Δt minutes have elapsed between the time of dilution and the time of titration in a sample of reaction mixture, the iodine formed in this interval is equivalent to $(\Delta t/t) \times ((a - x)/a) \times C = d$; the second factor corrects for the difference in the peroxide concentrations of the blank and of the actual sample (*cf.* Equation 5a above). This amount of iodine, d, which must be subtracted from the iodine equivalent to the thiosulfate titer of a sample, was always small; it seldom exceeded 0.5% of the latter, and was usually very much less.

k' values that lie on a straight line intersecting the origin when these are plotted as ordinates against (I^-); from the slope of this line, which is equal to $k_1^\circ + k_1(H^+)$, the specific rates are easily calculated. Curve I, Fig. 2, gives the results of a series of such experiments; its slope has the value 1.128. If, on the other hand, (I^-) is kept constant for a series of experiments, and (H^+) is varied, Equation 5 demands that the resulting k' (or $k'/(I^-)$) values yield a straight line intersecting the ordinate axis when they are plotted against (H^+) as abscissa. If $k'/(I^-)$ values are thus plotted, the intercept on the ordinate axis should give directly the value of k_1°; the slope, that of k_1. Curve II, Fig. 2, represents the results of two such series of measurements: its intercept yields k_1° = 0.69, in perfect agreement with the recent measurements of

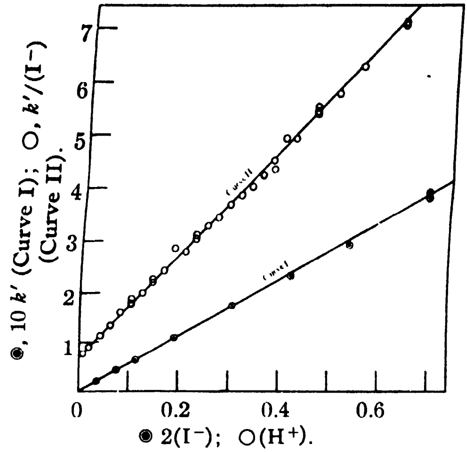

Fig. 2.—Summary of rate measurements at 25° in perchloric acid–sodium iodide solutions.

		37.8	4.33		k_1 = 10.4	39.9	4.92
						k_1° = 0.69;	k_1 = 10.4

[a] Initial (final) values of (H^+) and (I^-) may be obtained by adding (subtracting) $8(10^{-4})$ moles/liter to (from) the average concentrations.

[b] In Fig. 1, (I^-) = 0.3471 is No. 8; (H^+) = 0.0623 and 0.841 are Nos. 4 and 22, respectively.

[c] This value of $k'/(I^-)$ coincides exactly with Curve II, but it could not be plotted in Fig. 2 because of the restricted scale.

Liebhafsky;[6b] its slope, 10.4, gives the value of k_1; both values are for 25°. Using $k_1^\circ = 0.69$ and $(H^+) = 0.0413$, the acid concentration corresponding to the k' values for Curve I, $k_1 = 10.6$, is obtained from the slope of this curve. The agreement of these independently obtained values of k_1 is satisfactory. We may thus consider Equation 5 to be established definitely over a concentration range sufficiently large.

Reëxamination of Magnanini's Data.—The desirability of comparing Magnanini's results with ours led us to reëxamine his data.[12] It was then observed that Magnanini's rate constants decreased during each run, and that this decrease became pronounced earlier in experiments in which the absolute rates were higher; *e. g.*, in experiments at high (H^+). In Table II are given the data for the experiments with the lowest (in which only hydriodic acid was used to furnish H^+) and the highest (H^+) in his series of measurements with hydrochloric acid. Values of $\Sigma(I_2)$, the sum of (I_2) and (I_3^-), are those given by Magnanini; and the concentrations of I_3^- were computed with the aid of the equilibrium constant $(I^-)(I_2)/(I_3^-) = 0.00140$ at 25°.[13] The "corrected" values of $k'/(I^-)$ resulted from Magnanini's when the latter were multiplied by $[(I^-) + {}^1/_2(I_3^-)]/(I^-)$.[14] Although this correction is only approximate, the constancy of the "corrected" values is sufficiently good to leave no doubt that failure to consider the diminution in (I^-) resulting from I_3^- formation caused Magnanini's rate constants to decrease as the reaction proceeded.

In Fig. 3 Magnanini's results with the strong acids are plotted, the values of $k'/(I^-)$ used corresponding to measurements over the first time interval at each concentration of acid; correction for I_3^- formation has been made.[14] The slope of the line is 11.0, a value of k_1 in excellent agreement with ours. Had no correction for I_3^- been made, and Magnanini's results plotted as he gives them, this agreement would not have been altered, since this correction is very small during the initial time intervals; a plot of his

---

(12) The results of Scott[3a] cannot yield an accurate measure of k_1, since (H^+) in his experiments varied only from 0.005 to 0.020; under these conditions Reaction 4 contributes less than 25% to the absolute rate.

(13) Jones and Kaplan, THIS JOURNAL, **50**, 1485 (1928).

(14) Magnanini obtained $C(100\ C = k'/(I^-)$; the factor 100 is necessary because of a difference in concentration units) from the integrated form

$$C = \frac{1}{t}\,\frac{1}{2a - 2x} - \frac{1}{2a}$$

of the second order rate law for the special case $2a = b$ (we have used only those of his experiments in which this restriction holds). Here a and x have the meanings of Equation 5a and b represents the initial (HI), also the initial (I^-). x further represents $\Sigma(I_2)$ at time t; $\Sigma(I_2) = (I_2) + (I_3^-)$. Now, this evaluation of C implicitly assumes that $(I^-) = (b - 2x)$ as the reaction proceeds; and, since $(b - 2x)$ really represents $(I^-) + (I_3^-)$, values of C will be too small when (I_3^-) is appreciable. At time t the rate calculated by use of C (or of $k'/(I^-)$) must be multiplied by $[(I^-) + (I_3^-)]/(I^-)$ if the actual rate is to be obtained; at $t = 0$, however, (I_3^-) is negligible and this multiplicative factor is $(I^-)/(I^-)$, or unity. The mean of these two factors, or $[(I^-) + {}^1/_2(I_3^-)]/(I^-)$ may thus be used as an average correction for C, if this rate constant has been calculated for the interval $t = 0$ to $t = t$; multiplication of C by this average factor will give approximately the value that would have been obtained had the correction for I_3^- formation been included in the differential equation for the rate; the evaluation of C from this exact expression for the rate would naturally be very laborious.

TABLE II

DETAILED RESULTS OF TWO EXPERIMENTS BY MAGNANINI

(a) "No acid added" (Ref. 2, p. 479)

Initially, $(H^+) = (I^-) = 2(H_2O_2) = 0.0111$; temperature, 25°

Time in minutes	5	15	30	60	120
$\Sigma(I_2) \times 10^4$	2.40	6.40	11.10	17.85	25.35
$(I_3^-) \times 10^4$	2.00	5.00	8.2	11.8	13.5
Magnanini $k'/(I^-)$	0.82	0.78	0.75	0.71	0.63
Corrected $k'/(I^-)$	.83	.80	.79	.77	.71[a]

[a] The remaining decrease in the "corrected" values is due principally to the decrease in (H^+) resulting from the progress of Reaction 1; this causes a decrease in the rate of Reaction 4, for which Magnanini made no allowance in his calculations. The corrected values for the "50 HCl" experiment are much more nearly constant.

(b) "50 HCl" (Ref. 2, p. 482)

Initially, $(I^-) = 2(H_2O_2) = 0.0111$; $(H^+) = 0.567$; temperature, 25°

Time in minutes	3	5	8	10	12	14
$\Sigma(I_2) \times 10^4$	1.01	1.47	1.97	2.25	2.47	2.64
$(I_3^-) \times 10^4$	7.5	10.0	12.0	13.0	13.6	13.8
Magnanini $k'/(I^-)$	6.66	6.44	6.19	6.12	5.98	5.84
Corrected $k'/(I^-)$	7.03	6.90	6.76	6.80	6.75	6.70

uncorrected constants yielded $k_1 = 10.6$, in perfect agreement with the results from Fig. 2.

With hydrochloric and nitric acids Magnanini obtained identical results over the entire concentration range he studied; but with sulfuric acid he found that the effectiveness of the acid in "accelerating" Reaction 1 decreased with the stoichiometric concentration thereof, as the solid circles in Fig. 3 show. This decrease is due principally to an increase in the concentration of the weak acid, HSO_4^-, at the higher concentrations of sulfuric acid; for this reason the ratio $(H^+)/\Sigma(H^+)$ becomes smaller as (H_2SO_4) increases. If kinetic salt effects are absent, rate measurements may, under proper conditions, yield the dissociation constant of HSO_4^-, a circumstance which has already been turned to use in this Laboratory.

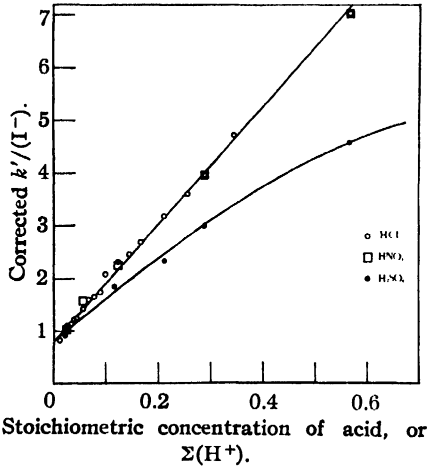

Fig. 3.—Summary of Magnanini's rate measurements in hydriodic acid solutions with hydrochloric, nitric or sulfuric acid added.

Magnanini also employed weaker acids, such as acetic and oxalic, for additional rate measurements. The results of these we have not recalculated because of the great difference in (H^+) and $\Sigma(H^+)$, which renders these acids almost ineffective in "accelerating" Reaction 1. It is worthy of special mention that Magnanini, over forty years ago, appreciated the cause of this ineffectiveness.

We cannot dismiss Figs. 2 and 3 from consideration without calling attention to the absence of appreciable kinetic salt effect for Reaction 4; did such an effect exist in the ionic strength range investigated, the excellent agreement of the various k_1 values could not have been secured.

Effect on the Reaction System of Changing the Temperature.—The results of experiments showing how the specific rates vary with temperature are given in Table III and plotted in Fig. 4.

TABLE III

VALUES OF SPECIFIC RATES AT DIFFERENT TEMPERATURES

Results of measurements in acid solution, by the "analytical" method. $(I^-) = 0.0572$ moles/l.; (H^+) variable

T, °C.	0.0	15.0	25.0	40.0
k_1°	0.094	0.35	0.69	2.19
k_1	2.05	5.50	10.4	22.9

Results of measurements[a] in slightly alkaline solution, by the oxygen evolution method

T, °C.	15.4	20.8	25.1	30.0	31.1	35.7	41.3	45.0	49.4
k_1°	0.344	0.528	0.71	0.98	1.19	1.55	2.50	3.14	4.23

[a] These measurements were made at different iodide concentrations, all below 0.1 M.

Most of these data were obtained from Curve II, Fig. 2, and from similar curves at 0, 15 and 40°; the rest (the solid circles) are hitherto unpublished values of k_1°, which Liebhafsky determined by following the rate of oxygen evolution from (initially neutral) solutions containing iodide ion and hydrogen peroxide (*cf.* Ref. 6b). From these combined data we deduce

$$k_1^\circ = 4.91(10^9)e^{-13,400/RT} \quad (6a)$$
$$k_1 = 4.58(10^8)e^{-10,450/RT} \quad (6b)$$

Over the temperature ranges investigated, Equations 6 will give to within 3% ($\epsilon = 0.0130$ for $\log k_1^\circ$ and 0.0122 for $\log k_1$)[15] the values of k_1° and k_1; for the average

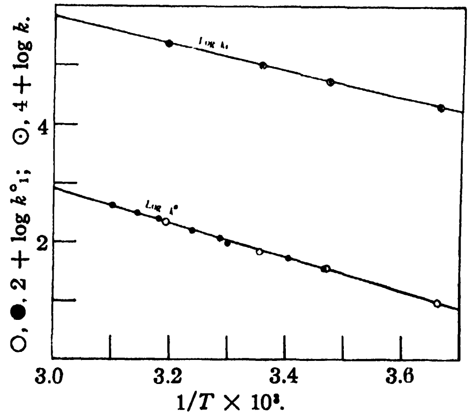

Fig. 4.—Variation of the specific rates with temperature.

---

(15) No systematic procedure is uniformly followed in determining the values and the accuracies of the parameters A and Q defined by $k = Ae^{-Q/RT}$. We have employed the following approximate method, which, though not mathematically rigorous, is simple and yields reasonable values for our errors in Q. Values for log k are plotted as ordinates against $1/T$, sufficiently large scales being employed. By successive trials, that line is found for which $\epsilon = \sqrt{\Sigma d^2/(n-2)}$ is a minimum. ϵ is the average error in log k, d is the vertical distance of any point from the line (or curve), n is the number of different temperatures for which observations exist. (In calculating ϵ, n must be diminished by 2 be-

errors in the apparent heats of activation, we have computed $\epsilon_{Q_1^\circ} = 105$ and $\epsilon_{Q_1} = 120$ calories. Obviously, these data extend over a larger temperature range and possess higher accuracy than is usual.

The relationship of the data in Equation 6a to those in 6b is roughly that which obtains also for the similar rate-determining steps involving iodate ion and hydrogen peroxide;[9] a complete discussion of this significant relationship is best postponed until the complete data are available for the analogous pairs of rate-determining steps by which chloride and bromide ions reduce hydrogen peroxide.

One point, however, may be considered briefly. It is well known that, for diverse reasons, the apparent *heat* of activation, Q, defined by

$$\mathrm{d}\ln k/\mathrm{d}\,1/T = -Q/R \tag{7}$$

should normally vary with the temperature. Using the results of investigations in the kinetics of gaseous reactions to guide us,[16] we may write

$$-\frac{Q}{R} = -\frac{E}{R} - \frac{T}{2} + (n-1)T - sT - \frac{1}{R}\sum_{i=1}^{i=m} \Delta H_i \tag{8}$$

In this equation E represents the true *energy* of activation, *i. e.*, the minimum energy that a molecular system can have if the reaction in question is to occur; $-T/2$ is to be included only if the reaction is bimolecular, and because the collision number varies as $T^{1/2}$; $(n-1)T$ represents the effect on Q of the change in energy distribution that accompanies a change in temperature if $2n$ "squared terms" contribute to the activation energy; $-sT$ results if the probability of reaction for a molecular species increases in somewhat the way assumed by Kassel[17] with the amount of energy in

cause 2 values of log k are necessary to fix A and Q. Unless there are special reasons for not doing so, it seems advisable to plot for each temperature only the arithmetic mean of the observations thereat. If d is noticeably larger or smaller at high temperatures than at low, a system of weighting may be introduced.)

We have taken $\epsilon_Q = 2.3R\epsilon/\Delta(1/T)$ calories, $\Delta(1/T)$ corresponding to the temperature interval over which measurements exist. This method of calculating the error in Q emphasizes the importance of measuring log k over a large temperature range; the method probably gives values of ϵ_Q that become increasingly too large as $\Delta(1/T)$ becomes smaller, n remaining constant.

If Q deviates appreciably from constancy in the temperature range investigated, this method of calculation must be modified; we suggest that it be used to calculate values of Q and ϵ_Q for sections of the temperature range over which the former may be considered constant.

Since ϵ_A is of less importance than ϵ_Q, it need not usually be given; one must always remember, however, that an uncertainty in Q implies a corresponding uncertainty in A.

In work of high precision, the change in the concentrations of reactants due to thermal expansion of the reaction mixture should be considered; the effect of such expansion will be to render the values of rate constants measured at T°, and calculated by using the concentrations of solutions at room temperature, approximately $(m - 1)\,\Delta$ per cent. too low (here Δ is the percentage change in the volume of water between T° and room temperature, and m is the order of the reaction). In none of our work is this correction appreciably over 1%, and we have not applied it; Equations 6, therefore, are based on concentrations of solutions at room temperature, which is convenient.

(16) For an excellent discussion of the heat of activation in gaseous reactions, the reader is referred to Kassel, "Kinetics of Homogeneous Gas Reactions," The Chemical Catalog Co., New York, 1932.

(17) Kassel, *Proc. Nat. Acad. Sci.*, **16**, 358 (1930). As one second order reaction for which Q increases with T as though the probability of reaction varied with the energy of the reacting molecular species approximately in the manner he postulates, Kassel cites the classical decomposition of gaseous hydrogen iodide, so thoroughly and carefully investigated by Bodenstein [*Z. physik. Chem.*, **29**, 295 (1899)]. Bodenstein gave two empirical equations to reproduce Q as a function of T; Kassel modified

excess of E that this system possesses (for systems with energy less than E the reaction probability is zero); and the last term is obtained by summing the heats of reaction for all equilibria involving a substance concerned in the rate-determining step.[18] (If such an equilibrium is not always maintained, its contribution to Q may not always be the ΔH of the corresponding reaction; in this event, its contribution to $\partial Q/\partial T$ will not be merely ΔC_p, the change in heat capacity, but must compensate also any significant change in the nearness to which the equilibrium is appproached at the different temperatures.)

For the temperature coefficient of Q we now have

$$\partial Q/\partial T = R\left(0 + {}^1/_2 - n + 1 + s - \sum_{i=1}^{i=m} \Delta C_{p_i}\right) \tag{9}$$

if E, n, and s are constant.[19] Equation 9 is to be regarded as tentative, even in form, until accurate experimental material has accumulated in an amount sufficient to render sound judgment possible.

If the errors in Q_1° and Q_1 are not larger than we have calculated, $\partial Q/\partial T$ is not greater than, say, 6 cal./deg. for either Reaction 3 or 4. In the interpretation of these results, the possibility that $\partial Q/\partial T$ is very small because some of the terms in Equation 9 are opposed in sign must not be disregarded; to render this possibility less likely, additional measurements are to be made on analogous reactions. We shall conclude this discussion by pointing out that aqueous solutions may prove better adapted to testing Equation 9 than are gases; for what disadvantage the former suffer in offering a more limited temperature range (0 to 100°, under ordinary conditions) may be more than compensated by the opportunities for more accurate rate measurements which they usually give. The interpretation of these measurements, however, will normally be less certain for the solutions because of the enhanced importance of all kinds of intermediates, which is reflected in the last term of Equation 9; that is, the order of a

---

the simpler of these by decreasing the coefficient of the log T term from 16 to 13, a change not greater than the uncertainty in the value of this term; the corresponding value of s is $13 + 2 - {}^1/_2 = 14{}^1/_2$.

Bodenstein's data are discussed by Hinshelwood [*cf.* Hinshelwood, "Kinetics of Chemical Change in Gaseous Systems," Oxford, 1929, Fig. 1a, p. 42, and pp. 47 and 48)]; but the significant variation of Q with T, given by Bodenstein, has not been mentioned. Calculation of the Q values for the successive pairs of temperatures (*cf.* p. 48) will show that, in spite of irregularities presumably due to slight experimental inaccuracies, Q does decrease with decreasing T.

(18) For convenience we may group the hydration equilibria, the formation and decomposition of Debye-Hückel "clusters," the closely related repulsion process between ions of like sign, and similar reactions, with the better defined equilibria (such as, for example, the hydrolysis equilibrium of iodine in the oxidation of hydrogen peroxide by that substance, *cf.* Ref. 6c) that may influence a rate-determining step.

(19) There seems to be no reason for assuming E to be in any way a function of T; the temperature concept appears meaningless for a molecular system undergoing chemical transformation since such a system is probably effectively isolated at the instant chemical change occurs. Further, it should be mentioned that, in writing Equations 8 and 9, we have tacitly assumed any steric factor concerned in a successful collision, such as the necessity of proper orientation, to be unaffected by a change in temperature. Also, in these equations, we have assumed, as is usually done, that the chance of an energy greater than E in $2n$ "squared terms" is given by

$$[e^{-E/RT}\,(E/RT)^{n-1}]/(n-1)!$$

an approximation sufficiently good so long as E/RT is large.

reaction in solution, coupled with data like those in Equations 6, indicates far less definitely the *intimate mechanism* of a rate-determining step than does the same information in the case of a gaseous reaction—in solutions probably all third-order reactions, and many of the second order as well, involve equilibria, which need not always be established: a third-order reaction might well be unimolecular under one set of limiting conditions, bimolecular under another, and neither alone in the intermediate region. Obviously these complexities render impossible any simple general interpretation of the Arrhenius constant, A,[15] in terms of the collision number Z.

It will be observed that the point of view indicated above differs radically from that just advanced by La Mer.[20]

Summary

1. The rate of the reaction

$$H_2O_2 + 2H^+ + 3I^- = 2H_2O + I_3^- \qquad (1)$$

has for the first time been measured under the simplest experimental conditions, with the result that the law, previously established

$$d(I_3^-)/dt = k_1^\circ(I^-)(H_2O_2) + k_1(H^+)(I^-)(H_2O_2) \qquad (2)$$

has been formally corroborated. Accurate values of k_1 can now be given.

2. The simplest kinetic interpretation of this rate law assumes the rate-determining steps

$$H_2O_2 + I^- \xrightarrow{k_1^\circ} H_2O + IO^- \qquad (3)$$

$$H_2O_2 + H^+ + I^- \xrightarrow{k_1} H_2O + HIO \qquad (4)$$

to proceed simultaneously and independently. At 25°, $k_1^\circ = 0.69$ and $k_1 = 10.5$; these measured values probably do not differ by more than 1% from the true values of these specific rates.

3. An examination of the early work of Magnanini[2] shows it to be in excellent agreement with our results. Certain trends in his rate measurements have been explained.

4. Within the ionic strength range investigated (roughly, from μ_c = 0.05 to 0.5) Reaction 4 is without appreciable kinetic salt effect.

5. We have found

$$k_1^\circ = 4.91(10^9)e^{-13,400/RT} \text{ from 0 to } 50°; \text{ and} \qquad (6a)$$
$$k_1 = 4.58(10^8)e^{-10,450/RT} \text{ from 0 to } 40° \qquad (6b)$$

Over the temperature ranges investigated, these equations give to within 3% the values of the specific rates. By use of an approximate method, the details of which are described, we have calculated the average error in Q_1° to be 105, and that in Q_1, 120 calories.

6. A brief discussion of the variation with temperature to be expected for the apparent heats of activation of reactions in aqueous solution has been given.

Acetamide as a Solvent

BY O. F. STAFFORD

Assuming a measure of validity for the doctrine that a substance dissolves other substances of its own kind, a most interesting case should be presented by acetamide as a solvent. This substance melts at about 80° to form a fairly mobile liquid. The fact that it contains a methyl group should give it solvent powers for hydrocarbons; its carbonyl group relates it to ketones, esters and acids; its tautomeric hydroxyl group gives it kinship to water and the alcohols; its amino group brings it into line with ammonia and its derivatives, while the ease with which it yields nitrile suggests a relationship to cyanogen compounds. In the field of inorganic chemistry the above considerations are supplemented by the fact that acetamide outranks all but a half dozen substances in the magnitude of its dielectric constant (59.2).

To test these assumptions the approximate solubilities of some 400 organic compounds and about half that number of inorganic compounds have been ascertained. The procedure, in general, was merely to add the substance to fused acetamide (at about 100°) and to note whether much or little would dissolve. Where in any instance the solubility thus appeared to be slight, the influence of higher temperatures was investigated. Sparingly soluble inorganic compounds were not only tested directly, but in most cases were precipitated by suitable double substitution reactions. It is interesting to note that these precipitation reactions occur with the same readiness as in water or ammonia as solvent.

The general results may be summarized by saying that of the 400 organic substances the only one showing no indications of solubility was cellulose. Asparagine, barbituric acid, oxamide and uric acid are sparingly soluble at low temperatures (*i. e.*, below 100°). It is significant that these same substances are but slightly soluble in water and are rated as insoluble in alcohol and ether. The solubilities of the inorganic compounds are strikingly analogous to those in water. Exceptions are presented by potassium perchlorate, the halides of mercury and lead, and the phosphate and oxide of mercury, all of which are more soluble in acetamide than in water.

More specifically, it was found that among organic compounds sixty-five ammonia-nitrogen derivatives (except uric acid), seventeen carbohydrates (excepting cellulose but including starch), sixty-eight dyestuffs, forty-four alcohols, eleven nitro and nitroso compounds and a number of miscellaneous nitrogen derivatives, all dissolve readily. Of the twenty hydrocarbons tested, anthracene, phenanthrene and triphenylmethane are quite soluble. The others are soluble at higher temperatures, but separate out to form two-phase systems at lower temperatures (80 to 120°). Forty-five acids tested are all soluble, but those with very long hydrocarbon chains are less soluble than the others.

Some twenty oxygen compounds were tested, in this class the ethers appearing to be somewhat less soluble than the others.

Among inorganic compounds bismuth nitrate gives a white insoluble compound similar to that formed by hydrolysis or ammonolysis. Mercurous nitrate undergoes some transformation in contact with the solvent. A similar action appears to take place with mercurous halides. Chromates are slowly reduced in acetamide solutions, although even the solution of chromium trioxide (which in color exactly resembles solutions of chromates) is stable for quite a while. The brown silver carbonate precipitate is presumably in the form of silver oxide, as in the case of precipitation from water.

The close analogy between acetamide and water as solvent is proved not only by the close correspondence which is shown by solubilities of inorganic compounds in these two substances but also by the chemical behaviors of dissolved substances. Mention has already been made of the fact that double substitution reactions occur with the same readiness in acetamide solution as in water solution. In such cases the precipitates in acetamide are even similar in appearance to those formed in water, colored sulfides, for example, appearing precisely as when precipitated from water. A search of the literature reveals that conductivity curves for a considerable number of salts in acetamide solution have been determined and that these curves resemble those obtained in water solutions. Furthermore, it has been shown that electrodeposition occurs readily in acetamide solutions with metals not more active than zinc. Numerous instances are described in which acetamide seems to function analogously to water of crystallization.

It follows, therefore, that the expectations enumerated in the opening paragraph of this article are surprisingly substantiated by experiment. Seemingly acetamide has a wider range of solvent powers than any other substance which has been reported.

The Activity of Potassium in Dilute Potassium Amalgams

BY H. E. BENT AND E. S. GILFILLAN

The primary purpose of this investigation was to determine the activity of potassium in amalgams as a function of concentration and temperature. The need for these data arose during the investigation of potassium triphenylmethyl as an electrolyte, and the study of equilibria involving organic free radicals,[1] and alkali metal amalgams.[2] Seven cells have been constructed. The electrolytes have been a water solution of potassium hydroxide, a solution in diethyl ether of the potassium addition compound of organic free radicals and a solution in ethylamine of potassium iodide.[1] We are greatly indebted to Mr. E. S. Fetcher, Jr., who constructed the first of the ethylamine cells used in this investigation. All seven cells gave very good agreement. However, the last two cells were so much superior that these alone were used in computing the final results. In the final section of this paper the bearing of these results on the nature of amalgams is discussed.

Experimental Method

Much of the experimental detail has been described elsewhere.[1]

The method of filling the cell is indicated in Fig. 1. The cell proper (A) has five fingers, permitting the use of amalgams of five different concentrations. At the bottom of each finger is sealed a platinum wire. This was sealed into ordinary Pyrex glass to give a gas-tight joint by using very fine ribbon. Number 40 wire was rolled into a ribbon about one-half millimeter wide. This was drawn through a small constriction and the glass worked in the flame until the joint was tight. Care must be exercised to avoid pulling, as the slightest tension will sever the wire. A safe method is to push the glass together at all times while making the seal. Contact was made outside the cell by pouring mercury into the leads (C).

A handle (B) served to support the cell after all other tubes had been sealed off.

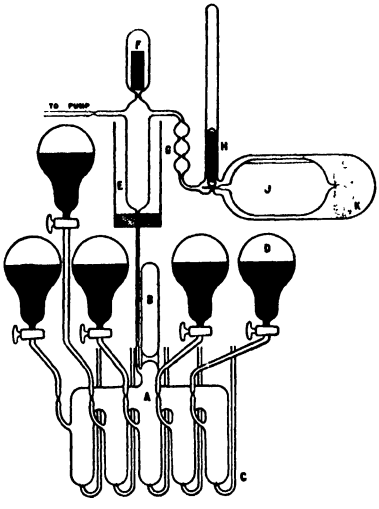

Fig. 1.—Method of filling the cell.

The amalgams were prepared and stored in the flasks (D). They were analyzed by drawing off samples in exactly the same way in which the amalgams were run into the cell. About 99.5% of the equivalent amount of half normal sulfuric acid was added to the amalgam from a weight buret, the flask heated on a steam-bath and air, free from carbon dioxide, slowly bubbled through the amalgam. When the solution became alkaline it was titrated with one-hundredth normal acid (diluted by weight from the half normal acid) using brom thymol blue as the indicator. With the help of a color standard the end-point could be determined within 0.04 mg. of potassium. Addition of the dilute acid was continued until the solution no longer became alkaline after three hours on the steam-bath. The stock half normal acid was standardized by comparison with constant boiling hydrochloric acid prepared according to the directions of Bonner and Titus.[3]

---

[1] Bent and Gilfillan, THIS JOURNAL, 55, 247 (1933).

[2] Bent, Dorfman and Bruce, *ibid.*, 52, 1498 (1930); 53, 1786 (1931); 54, 1393 (1932); 54, 3250 (1932).

The capsule of ethylamine (J) was padded with glass wool (K) in order to prevent the rebound shattering the tube when the capsule was opened by means of the weight (H). The small bulbs (G) served to throttle the amine and prevent too rapid a rush of vapor into the cell. The amine was condensed in the cell by placing solid carbon dioxide in the tube (E). The potassium iodide was washed from the platinum boat (F) by cooling this tube with a little solid carbon dioxide.

The cell was then placed in a thermostat which consisted of a five-liter Dewar flask filled with water. This was easily controlled manually to 0.01°.

Experimental Results

The data recorded in the following tables were obtained from two cells. The first of these contained amalgams I, VI, VII, VIII and IX and the second contained amalgams II, III, IV, V and VI. The amalgam used by Lewis and Keyes in their cell containing metallic potassium had a composition of 0.2216 weight per cent. potassium, the same as that of amalgam VI. This amalgam was included in both cells in order to make the comparison of the different amalgams with each other and with metallic potassium more simple. These two cells had a resistance of a little more than 100,000 ohms. The composition of the amalgams is given in the first line of Table I.

The e. m. f. data recorded in Table I have already been corrected for three very small errors. The first of these is the calibration error of the potentiometer. These errors amounted to less than 0.016 mv. The second error is a small thermal e. m. f. observed in the potentiometer which was determined by short circuiting the leads. This amounted to 0.02 mv. A third correction was discovered by comparing the potential between amalgams *a* and *c* with the sum of the potentials for the pair *a* and *b* and for the pair *b* and *c*. It was found that the sum was almost invariably less than the single measurement by about 0.04 mv. This can be explained by assuming a contact potential in the switches of this amount. When this quantity was added to the observed readings there was no longer any consistent variation in these differences. The values obtained after making these three corrections are recorded in Table I.

The experimental or observed values are marked Obs. in the table. The difference between these values and those calculated by equation (1) are marked Diff. and will be discussed in the following section. Each recorded value is the mean of a great many readings, several hundred measurements having been made on each cell. Measurements involving an interval of time of but a few minutes did not differ by more than one hundredth of a millivolt. Measurements on different days or after the temperature had been varied usually differed by less than one tenth of a millivolt. The probable error will be discussed later.

---

[3] Bonner and Titus, This Journal, **52**, 637 (1930).

Table II gives the data for amalgams containing a solid phase measured against amalgam VI as the reference electrode. These values were always obtained from both lower and higher temperatures and usually did not differ by as much as 0.1 mv. for a given cell. Equilibrium was established by gentle shaking for about an hour at a given temperature.

In order to apply a correction to the e. m. f. data on account of the change in the pressure of the ethylamine with temperature it is necessary to determine the partial molal volume of potassium in these amalgams. Two measurements of the density of the amalgams were made for this purpose. The pycnometer consisted of a 20-cc. Pyrex bulb to which was sealed a capillary of 0.5 mm. inside bore. The final volume was calculated from the position of the meniscus in this capillary as determined by means of a micrometer microscope. The pycnometer was carefully evacuated before filling with the amalgam. The density is given relative to that of mercury at 25°.

Interpretation of Results

In the discussion of the data the nomenclature of Lewis and Randall[4] and the physical constants of Birge are used.[5]

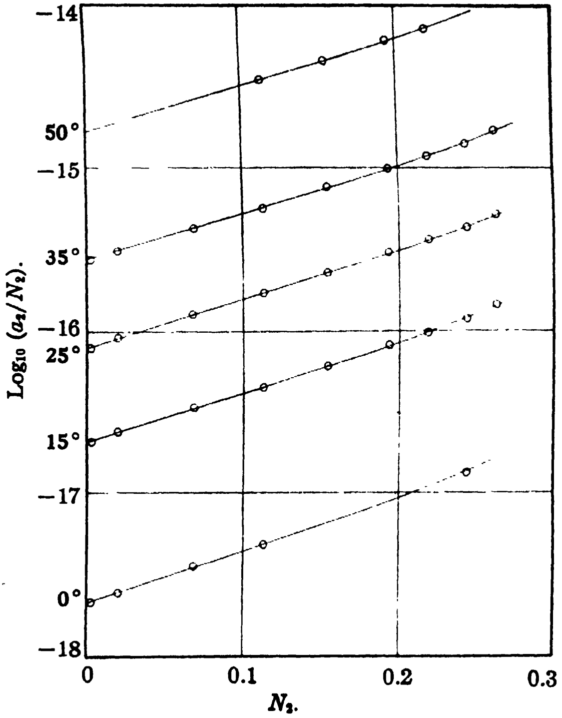

Fig. 2.—The deviation of potassium amalgam from Raoult's law.

The experimental data may be well represented by empirical equations, the use of which, however, is unfortunately time consuming. For convenience, therefore, the data have been represented graphically in Fig. 2

---

(4) Lewis and Randall, "Thermodynamics," McGraw-Hill Book Co., Inc., New York.

(5) Birge, *Phys. Rev. Supplement, Reviews of Modern Physics*, 1 (1929). These values are as follows: 0°C. = 273.18 abs.; 1 int. volt equ. = 23,065 calories. R = 1.98643. At. wt. Hg = 200.61. K = 39.096.

and the various computed thermodynamic quantities in Table III. Since four of the quantities given in this table are approximately linear functions of the concentration, rough values may be obtained, at concentrations not given, by interpolation. Only in the case of $\bar{F}_2$ and $\bar{S}_2$ is it not permitted to extrapolate to lower concentrations, as in these cases the partial molal quantity becomes infinite as the concentration becomes zero.

If we take the e. m. f. data of Table I and multiply each value by the faraday equivalent and divide by *RT* we obtain the difference in the natural logarithms of the activity of the potassium in the two amalgams. The values so obtained were found to be represented by the equation

$$\Delta \log_{10} a_2 = \log_{10} N_2 + (2446/T^{0.77700})\Delta \left\{N_2 + {\cdot}3430 N_2^4\right\} \qquad (1)$$

The difference between the experimental value and that calculated from equation (1) is given in the third line for each temperature. If one assumes that the form of the expression is correct, then the probable error can be computed to be 0.04 mv. This is perhaps too small an estimate. If we calculate the error by considering only a series of measurements at a given temperature, we obtain a more conservative estimate of 0.08 mv. We have taken this latter value as a measure of the accuracy of the data.

TABLE III

RELATIVE PARTIAL MOLAL DATA FOR POTASSIUM AMALGAMS

	Temp., °C.	Concn. (mole fraction) 0.001	0.005	0.01	0.02
$\Delta\bar{F}_2$	0	−26,048	−25,018	−24,446	−23,658

	25	− .01550	− .3888	−1.568	− 6.557
	50	− .01580	− .3956	−1.596	− 6.674

In equation (1) the exponent of *T* must be used to five significant figures in computations although the data are not accurate enough to determine this constant beyond the second significant figure.

A more useful way of expressing the data is to refer the activity of the potassium to the pure metal as standard state. This can be accomplished by combining these data with the measurements of Lewis and Keyes.[6] They have found the e. m. f. between metallic potassium and an amalgam in which the weight fraction of potassium is 0.2216 to be 1.0481 and the temperature coefficient to be −0.000272 volt per degree.

Before going farther with these data, however, it is necessary to consider the effect of pressure on the e. m. f. of the cell. During the course of our experiments the pressure of the ethylamine varied by as much as two atmospheres. The effect of this change in pressure may be computed providing we know the partial molal volume of the potassium in the amalgams. This we can compute from the density measurements recorded above. The apparent molal volume, that is, the change in volume when one mole of potassium is added to mercury to give an amalgam of the desired concentration, is found to be 24.57 cc. for the amalgam of weight fraction potassium 0.002339 and 24.61 for the amalgam of weight fraction potassium 0.004730. Since these figures differ so little from each other and the amalgams are very dilute, we may take these values to represent the partial molal volume of the potassium. Taking the volume of one gram atom of potassium as 45.5 cc., we find a change in volume for the cell reaction of 20.9 cc. Since the pressure of ethylamine is about 1.4 atmospheres at 25°, this introduces a correction of only 0.01 mv. in the e. m. f. of the Lewis and Keyes cell, which is much less than their experimental error. The correction in their temperature coefficient is relatively more important, giving a value of −0.000273. These calculations show that the correction becomes important only at the higher temperatures.

We can now combine equation (1) with the measurements of Lewis and Keyes to give the activity of the potassium referred to the solid metal as standard state

$$\log \frac{a_2}{N_2} = -\frac{5{,}695.6}{T} - \frac{27.69}{T^{0.77700}} + 3.3249 + \frac{2446}{T^{0.77700}} \left\{ N_2 + 3430 N_2^4 \right\} \pm 0.0017 \qquad (2)$$

Curves obtained with the aid of this equation are shown in Fig. 2. If Raoult's law were obeyed, $\log a_2/N_2$ would be independent of the concentration and would approach zero at the melting point of potassium.

With the aid of the above equation one may now obtain three relative partial molal quantities, namely, the free energy, entropy and heat content. The reference state for mercury is the pure liquid and for potassium is the solid metal. The relative partial molal free energy is obtained by adding $\log N_2$ and multiplying equation (2) by $RT \log_e 10$, giving

$$\begin{aligned} \bar{F}_2 = -26{,}051 + 4.5739\ \{\log_{10} N_2 + 3.3249\}\ T + \\ 4.5739\ \{2446(N_2 + 3430 N_2^4) - 27.69\}\ T^{0.22300} \pm 2 \qquad (3) \end{aligned}$$

By differentiating equation (3) with respect to the temperature the relative partial molal entropy is obtained

---

(6) Lewis and Keyes, THIS JOURNAL, **34**, 119 (1912).

$$\bar{S}_2 = -15.21 - 4.5739 \log_{10}N_2 - 1.0200 \{2446(N_2 + 3430N_2^4) - 27.69\} T^{-0.77700} \pm 0.1 \qquad (4)$$

Finally from the relation $H = F + TS$ the relative partial molal heat content can be obtained

$$\bar{H}_2 = -26{,}051 + 3.5539 \{2446(N_2 + 3430N_2^4) - 27.69\} T^{0.22300} \pm 20 \qquad (5)$$

Four equations may be obtained for the mercury analogous to equations 2–5. Substituting in the Duhem equation, d log $(a_1/N_1) = -(N_2/N_1)$ d log (a_2/N_2), the value of log (a_2/N_2) given by equation (2), and integrating we obtain the activity of the mercury as a function of N_2 and T. The integration constant is zero inasmuch as at zero concentration of potassium log a_1/N_1 equals zero. In this way equation (6) is obtained

$$\log \frac{a_1}{N_1} = -\frac{2446}{T^{0.77700}} \left\{ \frac{N_2^2}{2} + \frac{N_2^3}{3} + \frac{N_2^4}{4} + 13{,}721 \left(\frac{N_2^5}{5} + \frac{N_2^6}{6} \ldots \right) \right\} \qquad (6)$$

Following the method just employed for potassium three more equations may be derived for mercury.

$$\bar{F}_1 = 4.5739 \left[T \log_{10}N_1 - 2446T^{0.22300} \left\{ \frac{N_2^2}{2} + \frac{N_2^3}{3} + \frac{N_2^4}{4} + 13{,}721 \left(\frac{N_2^5}{5} + \frac{N_2^6}{6} \ldots \right) \right\} \right] \qquad (7)$$

$$\bar{S}_1 = -4.5739 \left[\log_{10}N_1 - 545T^{-0.77700} \left\{ \frac{N_2^2}{2} + \frac{N_2^3}{3} + \frac{N_2^4}{4} + 13{,}721 \left(\frac{N_2^5}{5} + \frac{N_2^6}{6} \ldots \right) \right\} \right] \qquad (8)$$

$$\bar{H}_1 = -8693T^{0.223} \left\{ \frac{N_2^2}{2} + \frac{N_2^3}{3} + \frac{N_2^4}{4} + 13{,}721 \left(\frac{N_2^5}{5} + \frac{N_2^6}{6} \ldots \right) \right\} \qquad (9)$$

The Solid Phase

We turn now to a discussion of the data involving amalgams in which a solid phase is present. These data are recorded in the second column of Table II. The plot of these measurements is shown by the steep curve in Fig. 3. The equation for this curve is

$$\Delta E = 0.00533 + 1.5153 \times 10^{-3}(T - 273.2) + 6.94 \times 10^{-6}(T - 273.2)^2 \qquad (10)$$

On the same plot are shown the curves for single-phase amalgams, points to the left of the curve of equation (10) representing supercooled amalgams. These five curves were drawn with the aid of equation (1). Each of the five curves thus represents an amalgam of known concentration. Each intersection with the two-phase amalgam curve gives a concentration and a temperature. Thus by simultaneous solution of equations (1) and (10) the data of Table IV for the solubility of potassium in mercury have been obtained. These data are shown graphically in Fig. 4. The equation for this curve is

$$x = 0.00252 + 8.12 \times 10^{-5}(T - 273.2) + 8.40 \times 10^{-7}(T - 273.2)^2$$

in which "x" is the weight fraction of potassium in the saturated amalgam.

TABLE IV

THE SOLUBILITY OF POTASSIUM IN MERCURY

Values of the mole fraction are obtained by simultaneous solution of equations (1) and (10)

Temp., °C.	Mole fraction	Weight fraction	Temp., °C.	Mole fraction	Weight fraction
0	0.01271	0.00250	18.82	0.02191	0.00435
6.15	.01544	.00305	23.09	.02428	.00483
14.35	.01951	.00386	25.00	.02536	.00505
15.00	.01986	.00393	26.79	.02638	.00525

The free energy and heat of formation of the solid phase may also be calculated from these data. Smith and Bennett[7] have shown that the solid phase in equilibrium with dilute potassium amalgams has the composition represented by KHg_{12}. At equilibrium the free energy of solution of this compound in the liquid is zero. The free energy of formation of the compound is, therefore, just the sum of the relative partial molal free energies of the elements in the liquid. $\Delta F = 12\bar{F}_1 + \bar{F}_2$. $\bar{F}_1$ is found from equation (7) to be -29.43 calories and $\bar{F}_2$ is found from equation (3) to be $-23,077$ calories. Therefore ΔF for the formation of solid KHg_{12} from the elements is $-23,430$ calories.

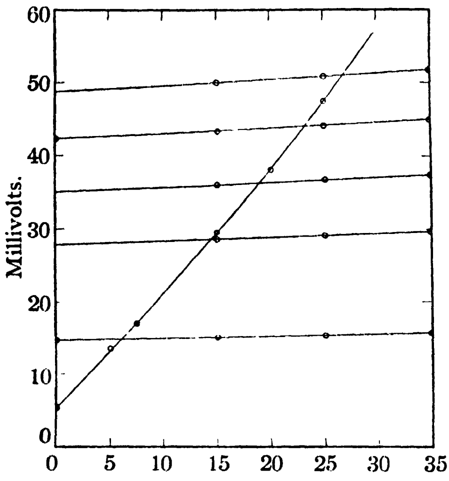

Fig. 3.—The e. m. f. of two-phase amalgams against amalgam VI. Also corresponding values for single phase amalgams against amalgam VI.

Under the restriction that the solution is to remain saturated F_1 and F_2 are functions of the temperature alone and

$$\frac{d\Delta F}{dT} = 12\frac{d\bar{F}_1}{dT} + \frac{d\bar{F}_2}{dT}, \text{ and}$$

$$\frac{d\bar{F}_1}{dT} = \frac{\partial\bar{F}_1}{\partial T} + \frac{\partial\bar{F}_1}{\partial N_2}\frac{dN_2}{dx}\frac{dx}{dT} = -\bar{S}_1 + \frac{\partial\bar{F}_1}{\partial N_2}\frac{dN_2}{dx}\frac{dx}{dT}$$

From equation (8) $\bar{S}_1$ is 0.6166, from equation (7) $\partial\bar{F}_1/\partial N_2$ is -1877 calories per mole per mole fraction unit. From the definition of the mole fraction dN_2/dx is 4.9235 when N_2 is 0.02536. From equation (11) dx/dT is 0.0001232 at 25°. Consequently $d\bar{F}_1/dT = -1.2002$ calories per mole.

The easiest way to obtain $d\bar{F}_2/dT$ is to go back to the e. m. f. data. We may write

---

(7) Smith and Bennett, THIS JOURNAL, **32**, 624 (1910).

$$\frac{d\bar{F}_2}{dT} = -23{,}065\left(\frac{dE_1}{dT} + \frac{dE_2}{dT}\right)$$

in which E_1 is the e. m. f. measured by Lewis and Keyes, potassium to our amalgam VI, and E_2 is the e. m. f. of the saturated amalgam to this same amalgam VI. After the slight correction for the pressure effect dE_1/dT is -0.000273. Equation (10) on differentiation gives dE_2/dT as -0.001862. Hence $d\bar{F}_2/dT$ is the sum of these two values multiplied by 23,065 or 49.24 calories. Hence $d\Delta F/dT = -\Delta S = 49.23 - 14.49 = 34.84$ calories per mole per degree. From the relation $\Delta H = \Delta F + T\Delta S$ one finds that $\Delta H = -33{,}819 \pm 30$ calories per mole.

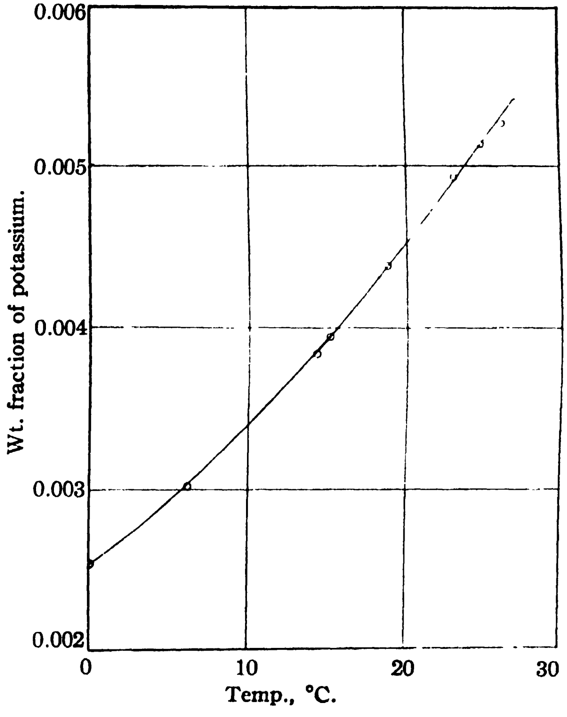

Fig. 4.—The solubility of potassium in mercury.

These figures enable one to calculate the heat of solution of the compound in the saturated solution. Equations (5) and (9) enable one to calculate the heat of formation of the compound in solution and give a value of −25,705 calories. Hence the heat of solution of the compound in saturated solution is 8114 calories per mole. Finally, equation (5) gives the heat of solution of potassium at infinite dilution as −26,150 calories. Hence the heat of solution of the compound in a large amount of mercury is 7669. Finally the relative partial molal heat content of the compound in the saturated solution referred to the infinitely dilute solution as the standard state is −445 calories.

Discussion of Results

In discussing the extreme deviations from Raoult's law exhibited by potassium amalgams we will approach the subject in two quite different ways. We will discuss first the significance of compound formation and later some inferences to be drawn from the thermodynamic data.

One may start by assuming that there are compounds in the liquid phase which have the same formulas as the solid phases indicated by the phase diagram. One may also assume that these compounds are only slightly dissociated in the liquid phase and that the various molecular species obey Raoult's law. This last assumption is only a first approximation. It has previously been shown that with the aid of these assumptions one may account for the vapor pressure of mercury and for the activity of sodium in dilute sodium amalgams.[8] The agreement of the calculated vapor pressures with the experimental values is not very good if one uses only the formulas of definitely established solid compounds. There is some uncertainty, however, as to just how many of these compounds exist and there is no proof that the same compounds exist in solution. By assuming additional compounds in solution one can obtain excellent agreement with the experimental data. This treatment does not prove that these compounds exist but indicates that the experimental facts are not incompatible with compound formation. The experimental data of Richards and Conant which were used in the above computation are not of sufficient accuracy in the most dilute range of concentration to enable one to say whether the hypothesis of compound formation accounted well for the data or not. On a plot such as that in Fig. 2 the data of Richards and Conant showed a decided dropping off in the range of low concentration. A curve obtained by assuming only one compound, $NaHg_{16}$, on the other hand, showed a slight flattening out in the range of small concentration. The data obtained in this research on potassium, on the other hand, show not the slightest deviation from a straight line in the range of small concentration. Our most dilute amalgam was about one-tenth the concentration of the most dilute amalgam of Richards and Conant. One could doubtless obtain a curve which would fit the experimental data by assuming a compound containing still a larger percentage of mercury. Such a procedure at present, however, seems quite useless. We have no reason for thinking that the various molecular species obey Raoult's law to anything more than a first approximation, and until we can calculate or determine these deviations it is impossible to push the hypothesis of compound formation farther. At present it is only possible to say that a large part of the deviation from Raoult's law exhibited by amalgams of the alkali

---

(8) Bent and Hildebrand, THIS JOURNAL, 49, 3011 (1927).

metals may be accounted for by assuming slightly dissociated compounds in the liquid phase.

Turning now to the partial molal quantities given in Table III we see some interesting facts. All of these partial molal quantities change very little with changing temperature. This result is perhaps due in part to the limited amount of data on cells containing potassium. Thus Lewis and Keyes made measurements at but two temperatures in order to obtain the temperature coefficient of the e. m. f. If we assume that d^2E/dT^2 is zero we are probably not introducing a very serious error in our computations since the first derivative is not large. However, it is just this assumption which causes the partial molal entropy and heat of potassium to be essentially constant. Since $\bar{F}_2$ is large it follows that it will not change much with the temperature but will change more than the heat or entropy as may be seen from the equation $\bar{F}_2 = \bar{H}_2 - T\bar{S}_2$. Multiplying $\bar{S}_2$ by T causes this product to change with the temperature even when $\bar{S}_2$ is constant. Turning now to the curves in Fig. 2 we note that their displacement with changing temperature is, therefore, due chiefly to the T coming into the equation $\bar{F}_2 = RT \ln a_2$.

The effect of temperature on deviations from Raoult's law has been discussed by Shibata and Oda[9] in a recent article in which they come to the conclusion that at 300–400° these amalgams become ideal solutions! This seems an extraordinary conclusion based on the extrapolation of an equation which is essentially empirical. Thus they find that the slope of their curves, when plotting data as in Fig. 2, is decreasing as the temperature rises. Assuming that the decrease in slope is a linear function of the temperature they arrive at a comparatively low temperature at which amalgams should become ideal solutions. In a similar manner if we take equation (2) which expresses our results within the error of our experiments we find that the coefficient of N_2 does not become zero until the temperature becomes infinite. Neither of these conclusions can be justified. In both cases empirical equations are being extrapolated far beyond the range of temperature for which they have been found to hold. This point will be discussed further in the next paragraph.

Another significant observation is that the partial molal entropy of the potassium is negative. For an ideal solution it would be positive and equal to $-R \ln N_2$. This rather large negative value more than offsets the small positive partial molal entropy for mercury with the result that there is actually a decrease in entropy in forming all but the most dilute amalgams from the elements. This clearly indicates that the amalgam does not have the random distribution of atoms that one would expect for an ideal solution but that some process, such as compound formation, has taken place to decrease the entropy.

(9) Shibata and Oda, *J. Chem. Soc. Japan*, **52**, 352–364 (1931).

One must conclude from these facts that the various physical theories of binary mixtures are not applicable to potassium amalgams.[10] Not only is the entropy very much less than that which is assumed by the physical theories but there is a large contraction during the formation of the amalgam. This latter fact prevents one from calculating surface fractions or volume fractions as is done by Langmuir and Scatchard. However, these values would differ little from the mole fraction and could not be of significance in such dilute solutions. In view of the fact that potassium amalgams are so decidedly irregular, using the definition of regular given by Hildebrand, it is perhaps surprising that the data may be represented by the same equations as have been derived by the various physical theories. It is not apparent at first glance that this is so. However, equations (2) and (6) reduce to much simpler equations at constant temperature if one is not interested in an accuracy of more than a few tenths of a per cent. Equation (2) then assumes the familiar form $\log a_2/N_2 = \beta N_2$ and equation (6) becomes $\log a_1/N_1 = {}^1/_2\beta N_2^2$. At higher concentrations, which unfortunately cannot be secured at room temperature on account of the appearance of a solid phase, doubtless such simple equations could not be used. Perhaps the most significant inference which one may draw from these facts is that considerable caution is necessary in drawing any conclusion as to the correctness of a theory from the fact that the data agree with the results of the theory. Thus potassium amalgams very definitely do not conform to the assumptions of the theory of Heitler, yet they may be described quite well by the form of equation obtained by him.

In spite of the very "irregular" nature of potassium amalgams, a rather simple picture of the system is still possible. We may sum up the facts which we now have as follows. There are large forces acting between mercury and potassium atoms ($\overline{H}_2$ is large and negative). The forces as a first approximation are not affected by a rise in temperature. The organization or arrangement of atoms in the amalgam is also not affected, as a first approximation, by a change in temperature ($\overline{S}_1$ and $\overline{S}_2$ change little with temperature). The activity of potassium, however, is increased to a marked degree by increasing the temperature. This may be considered to be due to the fact that the heat of vaporization of potassium from an amalgam is much larger (due to $\overline{H}_2$ being large and negative) than from the pure metal and hence the vapor pressure increases much more rapidly from the amalgam than it does from the pure metal.

Finally, we might point out that some of the amalgams used in this investigation were kept for as much as six months. During this time there was apparently no change in the activity of the alkali metal. Some of the cells were studied for many weeks and also showed no change in e. m. f. with either variation in temperature or with the lapse of time. If these

---

(10) Scatchard, *Chem. Rev.*, **8**, 321 (1931).

amalgams were colloidal, as suggested by Paranjpe and Joshi,[11] one would not expect such reproducibility.

Summary

1. Galvanic cells have been studied in which the reaction is the transfer of potassium from an amalgam of higher concentration to one of lower concentration. The e. m. f. of such cells has been determined as a function of temperature and concentration of the amalgam.
2. The partial molal free energy, heat and entropy of the potassium and mercury have been calculated.
3. The solubility of potassium in mercury has been determined from 0–50°.
4. The free energy and heat of formation of the compound KHg_{12} and the heat of solution of this compound have been determined.
5. The significance of these data is discussed.

Kinetics of Gas Explosions. IV. Ozone Explosions Induced by Hydrogen[1,2]

BY BERNARD LEWIS[3]

Introduction

The influence of hydrogen on the thermal decomposition of ozone was studied by Belton, Griffith and McKeown.[4] They found that two reactions occurred simultaneously, the decomposition of ozone and the formation of water. The addition of hydrogen to ozone increased the specific rate of ozone decomposition. For example, their bimolecular velocity constant of ozone decomposition increased sixfold when 156 mm. of hydrogen was added to a mixture of 70 mm. of ozone and 650 mm. of oxygen. The velocity constant for the formation of water by the assumed reaction $H_2 + O_3 = H_2O + O_2$ increased less rapidly, it being only threefold on increasing the hydrogen pressure from 33 mm. to 156 mm. in a similar mixture. The amount of hydrogen converted to water was small in comparison with the ozone decomposed. The available data published by these authors indicate that the percentage of hydrogen converted (measured when most of the ozone had decomposed) depends much more on the ozone concentration than on the hydrogen concentration. It increases

a little with increasing initial ozone concentration. The effect of increasing the temperature is to increase the percentage conversion of hydrogen. Thus at 78° it amounted to about 7% in a mixture 38 mm. of ozone, 230 mm. of hydrogen, 450 mm. of oxygen, while at 100° it was about 9.5% in a mixture 35 mm. of ozone, 145 mm. of hydrogen and 500 mm. of oxygen. Our own results agree reasonably well with these values, the percentage conversion of hydrogen being about 7 to 8% in a mixture 50 mm. of ozone, 90 mm. of hydrogen and about 3 mm. of oxygen at 85°.

It is the purpose of this paper to present some rather striking results which indicate that the reaction mechanism of the process is much more complicated than Belton, Griffith and McKeown assumed, that the enhanced rate of ozone decomposition in the presence of hydrogen is due to the initiation of a chain reaction through the medium of hydrogen atoms.

Apparatus and Procedure

Details of the experimental arrangement are given in Part I of this series. In these experiments pure ozone (98–99%) was used. Electrolytic hydrogen was purified by passing it through a layer of charcoal cooled to liquid air temperature. The rise in pressure due to reaction was measured with a quartz spiral manometer. The method of preparing the gases ensured such a purity that the ozone alone or ozone in the presence of hydrogen was extremely stable at room temperatures, there being no appreciable rise in pressure over a period of several hours. Spherical glass reaction vessels of about 200 cc. capacity were used.

The formation of water involves no pressure change, but since the amount of hydrogen converted is small, the rise in pressure represents, as a first approximation, the ozone decomposed.

Results

It was found that the addition of hydrogen to pure ozone at 85° has an enormous effect on the rate at which the pressure increases. For a given ozone pressure (50 mm.), $\Delta p/\Delta t$ is practically proportional to the hydrogen pressure, for relatively low pressures of the latter. Above 50 mm. of hydrogen the rate increases very rapidly, the normal rate of ozone decomposition increasing by hundreds of times for about 70–75 mm. of hydrogen. At about 80 mm. of hydrogen an explosion occurs. Table I shows the time required for the pressure to increase the first 8 mm. for increasing amounts of hydrogen added to 50 mm. of ozone.

TABLE I

INFLUENCE OF HYDROGEN ON THE RATE OF PRESSURE INCREASE (OZONE PRESSURE, 50 MM.)

Pressure of hydrogen, mm.	None	10.1	30.5	50.0	80.0
Time in minutes for Δp = 8 mm.	120	29	11	5.25	Explosion

The pressure of hydrogen necessary to cause explosion increases as the pressure of ozone decreases. Thus, for 40 mm. of ozone the pressure of hydrogen necessary to explode the mixture at 85° is 100 mm.; for 50 mm.

of ozone it is 80 mm. Presumably there is some lower limit of ozone pressure and hydrogen pressure below which no explosion is possible.

A very interesting effect was observed. If the reaction rate is measured for several successive runs using a similar but fresh mixture after evacuating for about five minutes between each run, the reaction rate increases in each succeeding experiment. With each experiment the reaction vessel becomes more active. If a mixture just above the explosion limit is admitted to an inactive vessel, it does not explode until several such experiments are carried out in the vessel. If the mixture is below the explosion limit the rate reaches a constant maximum value. This effect is illustrated in the following table in which the time is given for Δp to reach a certain value for several runs starting in an inactive vessel with a mixture below the explosion limit.

TABLE II

EFFECT OF PREVIOUS EXPERIMENTS ON THE RATE OF PRESSURE INCREASE

Ozone pressure, 50 mm. Hydrogen pressure, 50 mm.

Experiment	1	2	3	4
Time in minutes for Δp = 10.5 mm.	13	8.2	7.3	7.2

The activity acquired by the vessel after the above treatment lasts for several hours, and even after twenty hours the vessel still shows small evidences of it. The vessel can be deactivated by heating and pumping with a mercury vapor pump for some time.

It is believed that the increased activity of the vessel is due to the formation during the reaction of some substance which is adsorbed on the wall and which facilitates the process. This substance may be water or some active radical or atom. While it was found, in agreement with Warburg,[5] that the presence of water increases the rate of decomposition of ozone, this effect is very much smaller than that encountered in the above phenomenon. The following experiment shows that water is not the cause of the enhanced activity of the vessel. A vessel was activated to the explosion point by running several experiments with a mixture 50 mm. of ozone and 90 mm. of hydrogen. During an explosion all the hydrogen is burned to water. The products of the explosion were allowed to remain in the vessel for about thirty hours, after which they were pumped out quickly, leaving a layer of water on the wall. If the activity were due to water, a similar explosive mixture might be expected to explode. Instead, a reaction occurred comparable in rate with that to be expected in an inactive vessel.

It was suspected that the cause of the activity was the adsorption on the walls of hydrogen atoms formed during the reaction. This was shown to be very probable by the following set of experiments. The inactive vessel was pumped out for some time, hydrogen admitted to a pressure of about

---

(5) Warburg, *Sitzb. preuss. Akad. Wiss.*, 644 (1913).

0.5 mm. to 1 mm. and a discharge passed through the gas for about fifteen minutes at room temperature. A mixture of 50 mm. of ozone, 80 mm. of hydrogen, was admitted to the vessel, which was still at room temperature. The reaction which occurred was negligibly small. (Similarly, the reaction is inappreciable at room temperature in a very active vessel, made active by first running several experiments at 85°.) The vessel was pumped out, heated to 85°, and three hours later received a similar mixture. The mixture exploded promptly. Thus, even after this time the vessel was sufficiently active to explode the mixture, which without the previous sparking treatment would have reacted non-explosively. It may be concluded that hydrogen atoms formed during the discharge, likewise during a reaction, are adsorbed on the wall in some active form which is responsible for the enhanced activity of the vessel.

That the activity is not attributable to oxygen atoms is shown by the fact that the explosion of pure ozone alone (ignition by local heating with a flame) in an inactive vessel, during which many oxygen atoms are formed, does not alter the activity of the vessel appreciably.

Discussion

It is proposed that the adsorbed active hydrogen facilitates the starting at the walls of reaction chains which then spread out into the gas phase.[6] The following mechanism may be suggested as being consistent with the known facts.

At the outset, a certain number of oxygen atoms are formed during the normal thermal decomposition of ozone.

$$O_3 \longrightarrow O_2 + O \qquad (1)$$

Hydrogen atoms may be generated as follows

$$O + H_2 = OH + H\ (+\ 1\ \text{Kcal.}) \qquad (2)$$

The velocity of formation of hydrogen atoms for a given ozone concentration would be proportional to the hydrogen concentration. The hydrogen atoms now react with ozone relatively easily giving rise to active OH radicals which in turn react with ozone, regenerating hydrogen atoms; *i. e.*

$$H + O_3 = OH^* + O_2^*\ (+\ 78\ \text{Kcal.}) \qquad (3)$$

$$OH^* + O_3 = 2O_2 + H\ (-10\ \text{Kcal.}) \qquad (4)$$

where the * indicates an energy-rich molecule. The initial presence on the walls of active hydrogen (supposedly behaving as atomic hydrogen), as in the activated vessel described above, would enable reactions 3 and 4 to proceed therefrom without waiting for the hydrogen concentration to build up through reaction 2. If a sufficient number of reaction 3 is started in unit time the gas will heat up and accelerate all four reactions.

---

(6) A similar phenomenon was reported by Farkas, Haber and Harteck [*Z. Elektrochem.*, **36**, 711 (1930)] in the explosion of hydrogen and oxygen. If the vessel had been prepared by exploding a mixture of hydrogen and oxygen with a spark at 420°, a second and similar mixture admitted to the evacuated vessel a minute or two later exploded spontaneously. This effect was attributed to the adsorption on the walls of an active product, presumably hydrogen atoms.

Under suitable conditions an explosion results. More hydrogen atoms may be formed by means of the following step coupled with reaction 2.

$$O_2^* + O_3 = 2O_2 + O\ (-25\ \text{Kcal.}) \qquad (5)$$

The oxygen atoms may also decompose ozone, giving rise to another chain of reactions, the nature of which is not entirely clear[7] but which may be written for the time being simply as

$$O + O_3 = 2O_2^*\ (+\ 93\ \text{Kcal.}) \qquad (6)$$
$$O_2^* + O_3 = 2O_2 + O\ (-25\ \text{Kcal.}) \qquad (7)$$

The mechanism of the formation of water from hydrogen and oxygen is still in a state of uncertainty. So far these experiments throw no additional light on the subject. The Bonhoeffer–Haber[8] mechanism would indicate the following step

$$OH + H_2 = H_2O + H\ (+\ 14\ \text{Kcal.}) \qquad (8)$$

The efficiency of this reaction at 85° is quite low,[9] but with the energy attached to the OH^* radical emerging from reaction 3, reaction 8 would be expected to occur fairly frequently, although OH radicals from reaction 2 would be comparatively ineffective. With reaction 3 removing hydrogen atoms rather easily and the existence of a competition for OH between reactions 4 and 8, it should be difficult to complete the Bonhoeffer–Haber chain, especially while the ozone concentration is appreciable. It is apparent that the amount of hydrogen converted to water should be low in comparison with the ozone decomposed, which is in agreement with the experiment. Of course, the reaction

$$O_2^* + H_2 = H_2O + O\ (-\ 1\ \text{Kcal.}) \qquad (9)$$

is not impossible. A quantitative study of the amount of hydrogen and ozone converted from point to point in a given run might contribute valuable information toward elucidating the mechanism of the burning of hydrogen. This involves elaborate technique and has not been attempted so far.

If the formation of water occurs through the medium of hydrogen peroxide, it might be argued that the enhanced decomposition of ozone is also due to this molecule. It is, however, difficult to understand how a regenerative chain could be set up under these conditions to account for the high rate of ozone decomposition. The point could be tested experimentally by mixing hydrogen peroxide and ozone and if a reaction occurs determining whether more ozone decomposes than corresponds to the equation $O_3 + H_2O_2 = H_2O + 2O_2$.

Summary

Experiments were carried out at 85° to determine the influence of hydrogen on the thermal decomposition of ozone. With addition of hydrogen, the rate of decomposition increases enormously up to the point of

explosion, which occurs under suitable pressure conditions. Thus 50 mm. of ozone requires 80 mm. of hydrogen, while 40 mm. of ozone requires 100 mm. of hydrogen to cause the mixture to explode at 85°. The amount of hydrogen converted to water in the non-explosive reaction is only a fraction of the ozone decomposed.

An ordinary glass vessel becomes activated during the course of a reaction. In each succeeding reaction the vessel exhibits increased activity. The criterion for activity is the rate of reaction. Thus, an explosive limit mixture will not explode until several runs are carried out in the vessel first, while with a non-explosive mixture the reaction rate increases in each succeeding experiment until a constant value is reached. The activity lasts for several hours. Experiments were performed which indicate that the activity is due to the formation, during the reaction, of hydrogen atoms which are adsorbed on the walls. A mechanism of the process is suggested by which hydrogen atoms take part in a chain of reactions accounting for the bulk of the enhanced decomposition of ozone, *i. e.*, $H + O_3 = OH^* + O_2^*$ and $OH^* + O_3 = 2O_2 + H$, where * represents a molecule rich in energy.

A Note on the Heat of Sorption of Water Vapor by Massive Gold

BY ELLIOTT PIERCE BARRETT

A paper by Barry and Barrett[1] describes the methods used and the results obtained in a study of the heat of sorption of water vapor by massive gold in a saturated atmosphere. It is the purpose of this communication to point out that the relationship between heat of sorption and weight of vapor sorbed obtained from that investigation is similar to that found by other investigators working with quite different systems.

In the joint paper to which reference has been made, it was shown that for water vapor and gold, the integral heat of sorption, H, at any time, t, measured from the beginning of sorption, is given by the relation

$$\log H = a - b/t^c \qquad (1)$$

where a, b and c are empirical constants. An analogous equation

$$\log W = a' - b'/t^{c'} \qquad (2)$$

was shown to describe the increment in weight, W, of the gold which accompanied the liberation of heat and which was assumed to measure the quantity of water vapor sorbed by the gold.

---

[1] Barry and Barrett, THIS JOURNAL, 55, 3088 (1933).

Since it was also found that c and c' were identical to well within the limits of experimental error, equations 1 and 2 can be combined and the quantity t eliminated from them so that H is expressed directly as a function of W by the relationship

$$H = mW^n \qquad (3)$$

which is identical in form with the equation $q = ax^b$ found by Lamb and Coolidge[2] to describe the relationship between heat of sorption and weight sorbed in the case of eleven organic vapors sorbed by steam-activated coconut charcoal.

The constants m and n of equation 3 have been evaluated from the experimental data and a comparison between the integral heat of sorption as measured and as calculated from equation 3 is made in Table I.

TABLE I

COMPARISON OF OBSERVED VALUES OF INTEGRAL HEAT OF SORPTION WITH THOSE CALCULATED FROM THE EQUATION $H = 13.3W^{0.340}$

Time, hours	Wt. sorbed per sq. cm. in grams × 10⁶	Obs. heat per sq. cm. in milli-calories	Calcd. heat per sq. cm. in milli-calories	Time, hours	Wt. sorbed per sq. cm. in grams × 10⁶	Obs. heat per sq. cm. in milli-calories	Calcd. heat per sq. cm. in milli-calories
0.5	1.08	13.7	13.7	4.0	6.54	25.2[a]	..
1.0	2.34	17.8	17.8	4.5	6.92	25.7	25.7
1.5	3.32	20.1	20.0	5.0	7.25	26.2	26.1
2.0	4.21	21.7[a]	..	5.5	7.57	26.6	26.4
2.5	4.86	22.9	22.8	6.0	7.95	27.0	26.9
3.0	5.51	23.5	23.8	Infinity	24.85[b]	39.7[c]	39.7
3.5	6.03	24.6	24.5				

[a] Used to evaluate m and n. [b] Calculated from equation 2. [c] Calculated from equation 1.

It is interesting to compare these results with the data of Lamb and Coolidge, to which reference has been made above. Their values of n for the several vapors vary from 0.900 to 0.959, indicating that the change in the differential heat of sorption with increasing sorption is small. The relatively small value of n which appears in Table I shows clearly that, for water vapor and gold, the differential heat of sorption changes rapidly with increasing sorption for small values of W and that, as the weight sorbed increases, the value of the differential heat changes more slowly.

Since the actual measurements of the heat of sorption of water vapor by gold only covered a period of six hours, measured from the beginning of sorption, and since it is impractical to make calorimetric measurements over a sufficient length of time to determine even three-quarters of the integral sorption heat at equilibrium, it becomes important to form some estimate of the reliability of equation 3, when it is used to calculate values of H beyond the experimental time limit. Such an estimate can be made readily since the experimental conditions were such that it was thermodynamically necessary for the differential heat of sorption to approach the heat of evaporation of water as the system approached equilibrium.

---

[2] Lamb and Coolidge, THIS JOURNAL, 42, 1146 (1920).

Extrapolation, by means of equation 2, gives 24.85×10^{-6} g. as the weight of water vapor sorbed per square centimeter of gold at equilibrium. Differentiation of equation 3 gives

$$dH/dW = 4.52/W^{0.66} \tag{4}$$

Substitution of 24.85 in equation 4 gives 543 calories per gram as the heat of evaporation of water, which value is in error by 6%. Since the estimated error of measurement is 5%, it may be said that equation 3 describes the phenomenon with reasonable accuracy.

It is apparent from the form of equation 4 that, as W approaches zero, the differential heat of sorption approaches infinity. There are two possible interpretations of this observation. One is that the equation does not hold for very small values of W, although it does describe the phenomenon through the experimental range and, by deductive inference, out to infinite time. The other is that the equation does have significance even though W be an infinitesimal. The rational consequence of the second assumption is not that the first molecule of vapor sorbed liberates infinite heat but, simply, that it is impossible to remove the last molecule of water from a gold surface.

In the paper by Barry and Barrett[1] it was suggested that the exceedingly protracted nature of the phenomenon was probably due to diffusion of water vapor into the massive gold; so that, although sorption upon the exposed surface was extremely rapid, being, in all probability a true adsorption, the nature of the initial process was masked, since diffusion of adsorbed water into the gold would unsaturate the surface, thereby necessitating the adsorption of further water vapor in order to establish equilibrium between the gold surface and the saturated atmosphere.

Recently W. R. Ham, Professor of Physics at the Pennsylvania State College, has interested himself in this phase of the problem and has very kindly communicated to the writer the results of his preliminary measurements of the rate of diffusion of water vapor through gold. Ham has found that the diffusion at 400° and higher temperatures is readily measurable and although diffusion at these temperatures cannot be regarded as proof that the phenomenon occurs at room temperature, it does lend credibility to the original hypothesis.

It is possible to calculate from Ham's data the differential heat of sorption for very low relative humidities. His average value for measurements of about two hours' duration is 2500 calories per gram. The average heat of sorption found by Barry and Barrett during the first two hours of measurement was 5100 calories per gram. In view of the different working conditions the agreement in order of magnitude is gratifying.

Summary

It is shown that the integral heat of sorption of water vapor by massive gold is described by the equation $H = mW^n$, which is identical in form with the equation of Lamb and Coolidge for the sorption of organic vapors by charcoal.

The consequences of this observation are discussed and a possible mechanism by which the sorption occurs is considered.

Hydrides of Boron. II. The Preparation of B_5H_{11}: Its Thermal Decomposition and Reaction with Hydrogen

BY ANTON B. BURG AND H. I. SCHLESINGER

The development of a rapid and efficient method of preparing diborane (B_2H_6)[1] has made desirable the finding of efficient methods of preparing from it the less volatile hydrides of boron. Our experiments in this direction have led to the development of a satisfactory procedure for the preparation of the hydride B_5H_{11} and to a study of the properties of this hitherto little known substance. These investigations, in turn, have made possible improvements in the preparation of B_5H_9 from diborane, and have indicated a method by which useful quantities of the tetraborane (B_4H_{10}) may be prepared without recourse to the less efficient procedures involving the use of boron alloys.

When the pentaborane, B_5H_{11}, is heated at 100° without addition of excess of hydrogen, the first detectable effect is the production of small quantities of hydrogen, diborane, tetraborane and traces of a slightly volatile substance which seems to be an octaborane. Non-volatile solids appear soon afterward, but the formation of the latter seems to be inhibited to a certain extent by the accumulation of hydrogen. Within an hour the system, involving the substances named above, seems to reach a condition of equilibrium which is slowly shifted by the very gradual formation of B_5H_9,[2] traces of $B_{10}H_{14}$ and the non-volatile solids.

The indications that reversible changes are involved in these reactions led to the study of the effect of a high initial concentration of hydrogen. Under these conditions, the first reaction proceeds almost entirely according to the equation $2B_5H_{11} + 2H_2 \rightleftharpoons 2B_4H_{10} + B_2H_6$. The tetraborane reacts further, but more slowly, mainly according to the equation B_4H_{10} +

---

(1) Schlesinger and Burg, THIS JOURNAL, 53, 4321 (1931).

(2) Because of the existence of the two substances B_5H_9 and B_5H_{11} which cannot be satisfactorily named till more is known about their structure, we shall refer to them only by formula. The term pentaborane will hereinafter be used only to refer to mixtures of the two.

$H_2 \leftrightarrows 2B_2H_6$, until the whole system reaches a state of equilibrium in which the concentrations of B_4H_{10} and B_5H_{11} are low. Here, also, further heating results in the formation of B_5H_9, $B_{10}H_{14}$ and the non-volatile solids; the last are formed much more slowly and are much lighter in color than those produced in the absence of hydrogen.[3]

Although the presence of hydrogen inhibits the formation of the non-volatile hydrides, the latter do not themselves react with hydrogen to reproduce the volatile substance. The effect of the hydrogen is, therefore, best explained by assuming that it decreases the concentration of slightly volatile products (among which may be the octaborane mentioned above) which yield the solids by a secondary reaction.

On the other hand, hydrogen seems not to interfere at all with the formation of $B_{10}H_{14}$ and B_5H_9. For this reason it has been found possible to improve the yields of the latter by adding a high concentration of hydrogen to the reaction mixture before heating it.

The thermal decomposition of B_5H_{11} and its reaction with hydrogen are most easily understood by supposing that the structure of this substance is an open chain, whose most probable mode of decomposition is a break at one end. This picture accounts very well for the reaction with hydrogen, which produces one molecule of tetraborane from each molecule of pentaborane used up. This reaction may be an addition of hydrogen to the tetraboryl and monoboryl radicals produced by the breakdown of the five-atomic chain. The same assumption would account for the formation of an octaborane in the absence of hydrogen, under which conditions some of the tetraboryl radicals might unite to form eight-atomic chains.

Whatever the mechanism, the reaction of B_5H_{11} with hydrogen gives us an efficient means of preparing tetraborane. The development of a convenient technique for carrying on this reaction on a large scale should make this substance considerably more easily available than it has been before. A flow method should be suitable for the purpose.

Stock and Siecke[4] have given reasons for believing in the existence of a third pentaborane, distinct from B_5H_9 and B_5H_{11}. We have been unable to find any evidence in support of this assumption. On the contrary, our observations of the behavior of B_5H_{11}, whether alone or mixed with a large proportion of B_5H_9, agree perfectly with the observations of Stock and Siecke on the behavior of "$B_5H_{>9}$" in its mixtures with B_5H_9. It is reasonable to believe that "$B_5H_{>9}$" and B_5H_{11} are identical. At the same time we must recognize that our observations on B_5H_{11} do not agree perfectly with those of Stock and Siecke, who were led to suppose that B_5H_{11} is an intermediate in the formation of $B_{10}H_{14}$. It seems best to ascribe the discrepancies to differences in the quantities and kinds of impurities, rather than to any difference in the substance itself.

---

[3] This effect of hydrogen makes it useful as a preservative of the volatile hydrides. A sample of diborane at room temperature produces non-volatile solids amounting to 10% of the sample in one year. In the presence of an equal volume of hydrogen, the loss of volatile substances is scarcely observable.

[4] Stock and Siecke, *Ber.*, **57B**, 562 (1924).

The Preparation of B_5H_{11}

I. At Room Temperature.—In our first experiments we obtained B_5H_{11} by allowing samples of diborane to stand for months at a time in sealed bulbs at room temperature (20–30°). The material in each bulb was introduced into the vacuum apparatus by means of the tube-opener[5] and the products were separated by the method of fractional condensation (B_5H_{11} trapped at −85°, B_4H_{10} at −124° and B_2H_6 condensed at −190°). The results are shown in Table I.

TABLE I

Conditions			Products (cc. gas)			Results	
Vol. of B_2H_6, cc.	Vol. of bulb, cc.	Time, months	Hydrogen	B_4H_{10}	B_5H_{11}	% Reaction of B_2H_6	% Yield B_5H_{11} + B_4H_{10}, %
1050	3400	0.5	..	...	2.5	0.6	100
447	1050	3.3	37.6	1.4	8.3	8.5	80
495	600	3.3	37.0	1.4	8.3	7.7	80
380	1050	13.5	88.8	6.8	8.0	21.8	40
1080	1100	4.0	111.0	13.0	20.6	9.7	75

In each case except the first, the bulb had become iridescent, showing that non volatile boron hydrides had been formed, and a few small volatile crystals, evidently $B_{10}H_{14}$, had appeared.

Comparison of these results shows that the ratio of B_5H_{11} to diborane tends toward an upper limit, reached in a time near three months, at which point the rate of removal of the B_5H_{11}[6] becomes equal to its rate of formation. The results indicate that the preparation of B_5H_{11} at a temperature near 25° can be made most efficient by allowing each sample to stand about six weeks at a time. The B_5H_{11} so obtained is less contaminated with B_5H_9 than that obtained after longer standing at room temperature.

II. The Flow Method.—The preceding method is too slow for the preparation of large quantities of B_5H_{11}. The rate of reaction is increased greatly by exposing the diborane to higher temperatures, which must be applied only for short periods of time in order to avoid decomposing the product. The reaction is carried out quickly and conveniently by the use of a flow method, employing the apparatus shown in Fig. 1.

In this apparatus M is a 15-cc. measuring tube having 10 mm. internal diameter and 1 mm. wall thickness. The U-tube U4A is made of tubing having 15 mm. internal diameter and is 15 mm. high; its volume is 55 cc.[7] C is a small in-sealed capillary tube which regulates the flow rate. The rate of flow may be changed by replacing one capil-

---

(5) Stock, *Ber.*, **51**, 985 (1918).

(6) This removal may occur by decomposition to form non-volatile solids, or by reaction with hydrogen to give diborane and tetraborane.

(7) It should be mentioned that the U-tube used in our experiments happened to be etched in places (about one-fifth of the heated area). It is shown below that the formation of B_5H_{11} seems to be a wall-catalyzed reaction. The etching therefore may be a factor in determining the yield.

lary tube by another. The size of U4 is not critical, but it should be wide enough to allow condensation of the whole sample of diborane (one or two liters of gas) without stoppage. The system is connected through the mercury float-valve V 11 to the central tube of the apparatus.

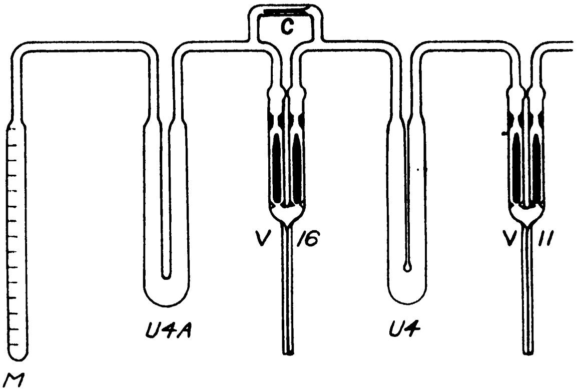

Fig. 1.

The diborane evaporates from M, which is held at a temperature of −78.5° (pressure near two atmospheres). It passes through U4A, which is kept at a suitable temperature (100 to 120°, depending on the experiment), and then goes with the reaction products through the capillary tube and is condensed in U4 at −196°. The hydrogen, which passes into the central tube, is pumped out by a Töpler pump and measured. Its quantity serves as an indication of the extent of reaction. The condensate in U4 may be returned to M and the process repeated again and again, to convert any desired fraction of the diborane into B_5H_{11} and B_4H_{10}. The results of these experiments are shown in Table II.

TABLE II

In this table the effective volume of diborane is the product of the average volume of the sample by the number of repetitions of the passage. The flow rate is the volume of gas (referred to standard conditions) passing through per minute. For the third and fourth of these experiments the percentage reaction was calculated by comparison with the quantities of hydrogen produced in the first two experiments. In the fourth experiment the temperature of U4A during the first five minutes was 120°. In that time 8 cc. of hydrogen was produced, and solid products appeared in the hot region. In the fifth experiment the temperature sometimes rose as high as 119° for short periods of time. It is believed that the main loss of material, due to the formation of solids, occurred during such intervals. There is good reason to believe that 115° is the temperature for greatest efficiency under the conditions here described.

Physical Constants.—The most trustworthy determinations of the vapor tensions and melting point of B_5H_{11} were made with a sample obtained from 1100 cc. of diborane which had stood six weeks in diffuse light at room temperature, in the presence of 300 cc. of hydrogen. The sample, 5.6 cc. of gas, was subjected to a long series of fractional condensations, by which 4.6 cc. of it was purified to the last possible degree. The vapor tensions of all fractions of this sample were exactly the same: 53.0 mm. at 0° (mercury at room temperature). The two determinations of the melting point of this sample gave the values −123.3° and −123.4° (measured by means of the ethylene vapor tension thermometer).

The vapor tensions were measured at different temperatures, established in a well-stirred ether bath and measured by means of a carefully calibrated alcohol thermometer (graduated to 0.2°). Each value given in Table III is the average of at least two measurements. The pressures were corrected to 0° by subtracting 0.45%.

TABLE III

t, °C.	−43.6	−39.0	−35.8	−33.4	−31.5	−25.5	−23.4	−20.2
p, mm.	3.5	5.0	6.1	7.2	8.5	12.2	14.0	17.0
t, °C.	−16.4	−13.4	−9.6	−7.0	−2.8	0.0	8.4	
p, mm.	21.7	25.6	32.1	35.8	45.6	52.8	77.7	

These values deviate less than 0.5° from the equation

$$\log_{10} p = 7.901 - (1690.3/T)$$

From this we calculate that the molal heat of vaporization is 7734 cal., and the normal boiling point, 63°. The Trouton constant is found to be 23.0 cal./deg. This abnormally high value suggests that any values taken at higher temperatures would have fallen below those predicted by the linear equation given above. The true boiling point might be one or two degrees higher than that given.

Results obtained with another sample illustrate the importance of selecting a sample as free as possible from B_5H_9. A·65-cc. sample (combined products of the second and third experiments of Table I and the first and second of Table II) was divided into eleven fractions; the middle seven showed vapor tensions varying 0.5 mm. from the average 54.5 mm., and melting points varying as much as 0.4° from the average value −123.2° A 7.48-cc. portion of the sample, decomposed completely in a heated quartz tube, gave 5.49 volumes of hydrogen and a weight of boron corresponding to 4.86 volumes of gas. It is evident that such an analysis is not sensitive enough to detect the small quantity of B_5H_9 which seems to have been present.

The vapor tension values reported by Stock and Pohland[8] agree well with our values at low temperatures, but deviate markedly at higher temperatures (4 mm. high at 0°). It is evident that their sample was free from tetraborane, but must have been considerably contaminated with B_5H_9. This is to be expected in a sample accumulated in a period of ten months. One of our samples, obtained from diborane which had stood for thirteen and one-half months at room temperature, was analyzed by complete thermal decomposition and found to contain about 12% B_5H_9. Its vapor tension at 0°, after the most rigorous fractionation, was 57 mm. The melting point was three degrees lower than that of our purest sample. The presence of B_5H_9 in carefully purified pentaborane samples is indicated very well by the deviation of the vapor pressure at 0° from the value 53.0 mm.

---

[8] Stock and Pohland, *Ber.*, **59B**, 2211 (1926).

Heavier By-product of the Preparation.—The tenth fraction of the 65-cc. sample, 1.65 cc., had a vapor tension of 53 mm. at 0°, and the residue, 0.57 cc., only 23 mm. The latter was subjected to further fractionation, until a sample (0.25 cc.) having 10-mm. vapor pressure at 0° was obtained. The quantity was too small for positive identification, even by the very fine scale methods now available. Its volatility indicated a hexaborane; whether impure B_6H_{10} or an undiscovered hexaborane cannot be decided until a larger sample is available.

The Thermal Decomposition of B_5H_{11}

Preliminary Experiments.—A number of experiments, for the purpose of obtaining a qualitative idea of the behavior of B_5H_{11}, were performed. In most of these experiments the temperature was 100° and the container had a volume five or six times as great as the standard volume of the sample. It was learned that B_5H_{11} decomposes to give hydrogen, diborane, tetraborane, B_5H_9, $B_{10}H_{14}$ and a non-volatile yellow solid (evidently a mixture), easily hydrolyzable, but insoluble in any ordinary solvent. The yields of tetraborane and diborane were highest when the period of heating was short (ten minutes or less at 100°). The yields of B_5H_9 and $B_{10}H_{14}$ increased with the duration of heating. In most cases only unweighable traces of $B_{10}H_{14}$ were obtained. It was found, however, that reasonable yields of this substance were produced if one end of the tube remained at room temperature while the other end was heated. Neither B_5H_9 nor $B_{10}H_{14}$ appeared in detectable quantity before many other substances had been formed; in one experiment, for example, the sample was heated for twelve minutes at 100°, and was 75% decomposed to produce diborane, tetraborane and non-volatile solids. Only the minutest trace of $B_{10}H_{14}$ was produced, and the B_5H_9 was not detectable.

The non-volatile solid appeared only on the lower side of the container; it seemed to be formed by a homogeneous reaction, and then precipitated as a fine, gummy powder. Moreover, the formation of this substance could not be observed at all after the first hour at 100°, as shown by inverting the container at that time. This observation was explained by further experiments which showed that hydrogen inhibits the formation of the brown solids to a marked degree.

The Incipient Decomposition of B_5H_{11}.—It was observed in the preliminary experiments that a red-brown ring, appearing like the result of condensing a liquid which solidified afterward, always formed on the cool part of any of the tubes not completely immersed in the heating bath. This result made it seem worth while to search for a compound intermediate between B_5H_{11} and the brown solid which seemed to be one of its final decomposition products. In the first experiment in this direction, a 50.7-cc. sample of B_5H_{11} stood for seven and one-half hours at 25° (mainly in the liquid state), and 10% of it was decomposed to produce hydrogen, diborane, tetraborane, a trace of the brown solid, and a quantity of slightly volatile material too small for further study. In another experiment, 80.0 cc. of B_5H_{11} was held at 0° for eighty-eight hours, under conditions such that the reaction products more volatile than B_5H_{11} were removed as soon as they were formed. Five per cent. was decomposed, but the quantity of slightly volatile material again was too small to allow definite conclusions to be drawn.

Since these simple methods led to no clear-cut results, evidently because of the instability of the desired substance, we tried next a flow method. A 75-cc. sample of B_5H_{11} was placed in M (Fig. 1) and allowed to pass through U4A at 50°, under the pressure of its vapor at 22°. The rate of flow was such that the sample evaporated in thirty minutes. The flow was stopped twenty minutes later, and 0.2 cc. of hydrogen was pumped off. The products more volatile than B_5H_{11} (diborane and tetraborane) amounted to 0.4 cc. The remaining pentaborane was distilled very slowly through a U-tube immersed in a bath at −60°, and the fraction condensed at that temperature was found to consist of a very small quantity (estimated 0.1 to 0.2 cc. gas at standard conditions) of a substance having a vapor tension near 1 mm. at room temperature.

This process was repeated four times, with U4A at 65° (same sample of pentaborane); in each case the process was stopped as soon as the evaporation was complete. The reaction products were 2.5 cc. hydrogen, 3.75 cc. diborane, 1.00 cc. of tetraborane, and 0.5 cc. (gas) of a substance whose vapor tension at 24° was 1.2 mm. A small quantity of the brown non-volatile solid appeared in U4A. The slightly volatile substance was purified by the method of fractional condensation (trapped at −33°). Its uniformity was established by the fact that the vapor tension remained exactly the same while the volume of the apparatus was doubled and then tripled; about three quarters of the sample then was in the gas phase. The substance was found to be decidedly unstable: the vapor tension of a 0.15-cc. sample increased from 1.2 mm. to 1.7 mm. in five minutes at room temperature.

Evidence of the Existence of an Octaborane.—The most direct evidence for the belief that this substance is an octaborane is derived from the value of its vapor tension at 24°. The temperature at which each of the known hydrides of boron has a vapor tension of 1.2 mm. may be calculated from the vapor tension–temperature curves, and found to be as follows: B_2H_6, −162°; B_4H_{10}, −90°; B_5H_{11}, −58°;[9] B_6H_{10}, −28°;[10] $B_{10}H_{14}$, 63°. If we plot the temperature against the number of boron atoms in the molecule, we obtain a very regular curve whose intercept at 24° corresponds to 8.05 ± 0.10 boron atoms. It seems reasonably safe to conclude that the slightly volatile substance was an octaborane.

The Behavior of B_5H_{11} and B_4H_{10} with Hydrogen.—The details of the experiments on the behavior of B_5H_{11} with hydrogen are given in Table IV. In each experiment the sample was condensed in the bottom of the container (in most cases a bulb of the shape represented in Fig. 2); then pure hydrogen was added until the pressure was 750 mm., and the container was sealed off. On account of the low temperature of the lower end of the tube, the volume of the hydrogen (standard conditions) in most cases was 15–25% higher than the recorded volume of the bulb (fourth column). After immersion for a sharply controlled time in water at 100°, each bulb was cooled rapidly to room temperature and the contents at once introduced into the vacuum apparatus by means of the tube opener. In pumping the hydrogen out through a trap immersed in liquid nitrogen, it was not always possible to avoid some small loss of diborane. Each mixture of reaction products was separated completely into its components by the method of fractional condensation, and the volume of each component determined. The quantity of B_5H_9 in each of the pentaborane

---

(9) Data for B_5H_9 below the melting point are not available.

(10) Estimated from the vapor tension at 0° (compared with B_5H_{11} by the use of Dühring's rule).

residues from experiments 2, 3 and 4 was determined by decomposing the measured sample in a hot quartz tube and measuring the volume of the hydrogen produced. These determinations were based on the reasonable assumption that the residues contained only B_5H_9 and B_5H_{11}.

In most of these experiments there was no observable formation of solids. Experiment 7 is exceptional, in that there was no hydrogen present at the start—brown solids therefore were formed. In each of Experiments 3c, 4b, and 4c, a barely observable scum of white non-volatile solid appeared.

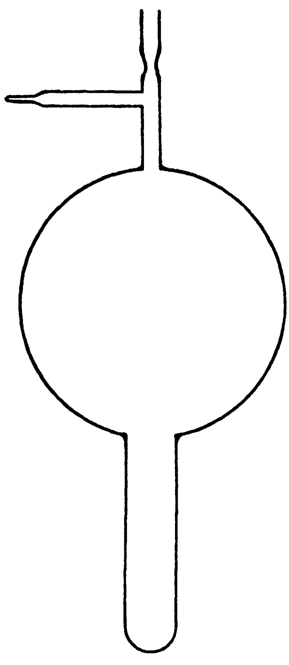

Fig. 2.

Attention is called to the fact that the term "pentaborane" used in the headings of several columns in Table IV refers to mixtures of B_5H_9 and B_5H_{11}. As has already been pointed out, it is exceedingly difficult to prepare samples of the latter entirely free from the former. For our present purpose a slight contamination is of no significance, provided due allowance is made for it in interpreting the results. Present analytical methods do not permit a determination of the amount of B_5H_9 in a sample of nearly pure B_5H_{11}. The data of column 10, "Percentage of pentaborane used up" therefore cannot be accurately transformed into "Percentage of B_5H_{11} used up" because we do not know precisely how pure the original samples in each experiment were. But we can show by the following analysis of the data that the error thus introduced cannot be large.

In Expts. 2 and 3, different portions of the same sample of "pentaborane" were heated at 100° for different periods. The product was then fractionated and the residual "pentaborane" was in each case reheated (2b, 3b). In Expt. 3 this procedure was repeated once more. Experiment 4 was similar, except that a different sample of "pentaborane" was used. As a result of the heating process, the percentage of B_5H_{11} in the residue was decreased to such an extent that a fairly reliable analysis of the percentage of B_5H_9 could be made. If we assume as a first approximation that none of the B_5H_9 thus found was a product of the reaction, *i. e.*, that all of it was present in the original samples, we should conclude that sample 2 originally contained 6.3%, sample 3, 5.3%, and sample 4, 3.2% B_5H_9. But these represent maximum values,[11] even though they represent relatively small contamination with B_5H_9. The difference in the percentage of B_5H_9 found for samples 2 and 3, on the assump-

---

[11] It has been shown by separate experiments that the treatment to which these samples was subjected does not appreciably affect B_5H_9. Of a sample of fairly pure B_5H_9, heated for five days at 125°, only 2% had undergone change.

[a] The container for this experiment was a cylindrical tube. Quantity of hydrogen, 60 cc. [b] No hydrogen present at the start. 8.35 cc. produced during the course of the experiment. [c] The container for this experiment was a series of bulbs, having an estimated ratio of wall area to volume 80% greater than that of the single large bulb used in experiment 6. [d] Entirely at room temperature.

tion that it was all present in the original sample, is too large to be explained by experimental error alone. It must, therefore, be due to the *formation* of more B_5H_9 during the reaction in Expt. 2 than during Expt. 3. This is just what would be expected, for in Expt. 2 the main portion of the material was heated a longer time than in Expt. 3. If this is true, then some of the B_5H_9 found in Expt. 4 must also have been a reaction product.

Hence we conclude that the samples used in Expts. 2 and 3 must have contained considerably less than 5% of B_5H_9 while the sample used in Expt. 4 must have contained less than 3% of B_5H_9. Not only are the total amounts of B_5H_9 relatively small in these samples, but the difference between the amount of contamination is small. Nevertheless, the sample used in Expts. 2 and 3 showed a vapor tension of 54.5 mm. at 0°, while the sample used in Expt. 4 showed 53.5 mm. The vapor tension at 0° thus is shown to be a very sensitive test of the degree of contamination. In the following, we shall consequently assume that two samples showing the same vapor tension, provided its value is not far from 53 mm., have the same composition.

Comparison of Expts. 2a, 3a, 4b, 6 and 7, all of which employed samples of pentaborane[12] having approximately the same vapor tension at 0°, shows that the initial reaction is fairly rapid, but that it soon becomes very slow. In four minutes (Expt. 3a), 58% of the pentaborane had been decomposed and in ten minutes about 75% (Expts. 2a, 6 and 7). Further heating, however, causes but little further change, for the percentage was only slightly higher after twenty minutes of heating (Expt. 4b, in which the percentage reaction is slightly higher than the indicated 74%, because of higher B_5H_9 content). In Expt. 3a the amount of tetraborane formed differs by only 4% from the amount of B_5H_{11} used up, and the amount of diborane produced is slightly over one-half this quantity. These proportions agree reasonably well with the equation $2B_5H_{11} + 2H_2 \leftrightarrows 2B_4H_{10} + B_2H_6$. The deficiency of tetraborane and the excess of diborane are satisfactorily explained by a slower secondary reaction of the tetraborane to form diborane. In the other experiments under discussion, the discrepancies are larger, but always in the same direction; this is due to the fact that in these the time of heating is longer and the secondary reaction, therefore, has had time to proceed farther.

---

[12] Experiments 1 and 5 are not included here because the conditions under which these were carried out were different from those of the others.

The situation was made clear by experiments in which tetraborane was heated with hydrogen. The tetraborane used for these experiments was obtained in very pure condition (vapor tension 388 mm. at 0°) by fractionating the products of the reaction of B_5H_{11} with hydrogen. The experiments, which are numbered as a continuation of Table IV, were as follows.

9. The bulb used in experiment 6 was filled with 14.1 cc. of tetraborane and somewhat more than one atmosphere pressure of pure hydrogen. During twenty minutes at 100°, 6.05 cc., or 43%, of the tetraborane was converted into 10.65 cc. of diborane and 0.45 cc. of B_5H_{11} (nearly pure).

10. The six-bulb container used in Expt. 7 was filled with 13.9 cc. of tetraborane and the usual excess of hydrogen. During twenty minutes at 100°, 7.40 cc., or 53%, of the tetraborane was converted into 12.30 cc. of diborane and 0.75 cc. of B_5H_{11} (vapor tension 54 mm. at 0°).

These results show that tetraborane reacts with hydrogen to form diborane, at a rate accounting very well for the deviations from the equation $2B_5H_{11} + 2H_2 \rightleftarrows 2B_4H_{10} + B_2H_6$. They also show that this reaction is reversible, a fact which may throw light on the sudden slowing of the reaction. But this reverse reaction is only a part of the reaction of tetraborane; it appears that most of it is converted into diborane. The final result must be an equilibrium[13] in which diborane is the predominating boron hydride. This statement is confirmed by the results of an experiment in which diborane and hydrogen were heated together for sixty-four hours at 100°. At the end of this time the 250-cc. bulb contained 150 cc. of hydrogen, 38 cc. of diborane, 0.5 cc. of B_4H_{10} and 2.2 cc. of pentaborane (nearly pure B_5H_9), along with some white solids.

The difference in the percentage reaction of tetraborane in Expts. 9 and 10 shows that the rate of reaction of tetraborane with hydrogen depends upon at least one wall-catalyzed process. It is especially evident that the rate of formation of B_5H_{11} is increased by increasing the wall area, for the

---

(13) Even this equilibrium is slowly shifted by the irreversible formation of B_5H_9, $B_{10}H_{14}$ and nonvolatile solids. We may treat it as a true equilibrium because it can be established before any important quantities of these other substances are formed.

concentration of this substance at the end of each experiment was greater in number 10, which was carried out in a vessel of larger wall area.

Comparison of the behavior of B_5H_{11} with and without initial hydrogen at 100° (Expts. 5 and 6) shows that considerably more reaction occurs when hydrogen is present than when it is absent. This result is plausibly explained by supposing that the B_5H_{11} molecule first breaks up into radicals, which recombine to a large extent when hydrogen is absent. But a large excess of hydrogen prevents much of this recombination because these active radicals unite with it to form diborane and tetraborane, substances whose enduring qualities are greater than of B_5H_{11}; the reforming of B_5H_{11} is thus delayed. The alternate explanation, that hydrogen itself attacks the pentaborane chain, does not seem very probable.

In Expt. 8, which occurred at room temperature, it seems that the reaction of tetraborane with hydrogen occurred at a rate proportionally higher than in similar experiments at 100°; only 5% of the pentaborane was used up, yet the deficiency of tetraborane, below that required by the equation $2B_5H_{11} + 2H_2 = 2B_4H_{10} + B_2H_6$, was 19%. There might be many ways to account for this difference, but no uniquely satisfactory explanation appears.

The Preparation of B_5H_9.—We have performed a number of experiments in the direction of finding the most favorable conditions for the reaction by which diborane is converted into B_5H_9.[14] At the present writing the highest yield obtained represented only 33% of the volatile boron hydrides used up. It was found that a high concentration of hydrogen is an advantage, for it seems to interfere not at all with the rate of formation of B_5H_9, but hinders greatly the formation of non-volatile solids. Hydrogen chloride is not essential to the reaction, but it increases the yield. For this purpose, however, boron trichloride is quite as useful, and has the advantage that it does not convert boron hydride to boron chloride. The temperature used in most of the experiments was 120–130°; at 100° the yields were only about half as high, under comparable conditions. It was found most efficient to heat for three days at a time. The highest yield resulted when the diborane contained a fair quantity of tetraborane at the start; yet the use of a high concentration of tetraborane did not improve the yield, doubtless because of its comparatively rapid conversion to diborane under these conditions. Similar results were obtained when B_5H_{11} was heated for several days at 120°, with approximately one-third of its volume of boron trichloride and a large excess of hydrogen.

Much work is still to be done before we can be certain of the best conditions for the preparation of B_5H_9. This work is hindered by the lack of adequate working hypotheses concerning the mechanism of the reaction and the function of the boron chloride.

Summary

The preparation of B_5H_{11} in quantities suitable for experimental work has been accomplished by the use of a flow method involving diborane. Measurements upon a sample unusually free from B_5H_9 gave $-123.3°$ for the melting point and 53.0 mm. for the vapor tension at 0°.

The thermal decomposition of B_5H_{11} at first gives hydrogen, diborane, tetraborane and smaller quantities of a probable octaborane. Further heating produces non-volatile solids, B_5H_9 and $B_{10}H_{14}$. A ten-fold excess of hydrogen added at the start hinders so effectively the formation of substances less volatile than B_5H_{11} that it is possible to prepare diborane and tetraborane from B_5H_{11} practically without loss. The equilibrium system involving hydrogen, B_5H_{11}, tetraborane and diborane was studied to some extent at a temperature of 100°. Any one of these three boron hydrides may be prepared in quantity from one of the others, by a suitable adjustment of the experimental conditions. The preparation of useful quantities of tetraborane from diborane therefore is feasible.

Improvements in the method of preparing B_5H_9 by long heating of diborane have increased the yields to 33%.

Hydrides of Boron. III. Dimethoxyborine

BY ANTON B. BURG AND H. I. SCHLESINGER

Linkages between boron atoms seldom occur in compounds of boron with elements other than hydrogen. A striking contrast to this situation is presented by the boron hydrides, in all of which the boron atoms are linked together. The tendency for such linking is so strong that monoborine (BH_3) seems incapable of existence and the simplest hydride is diborane (B_2H_6), a circumstance not easily explained by any generally acceptable theory of valence. Substitution of halogens for hydrogen in diborane leads to compounds of the type B_2H_5X[1] and possibly $B_2H_4X_2$, but further substitution leads only to the boron trihalide. The only known simple derivative of monoborine, aside from those in which all of the hydrogen is replaced, is phenylborine ($C_6H_5BH_2$),[2] a compound which has been studied very little. It is thus of considerable interest to prepare compounds of the types HBR_2, H_2BR, HBX_2, and H_2BX, in the hope that a compound showing a tendency toward association by boron linkages may be obtained. Such work might lead to a better understanding of the factors which stabilize the boron to boron bond.

This paper describes the preparation of dimethoxyborine, $(CH_3O)_2BH$, by the reaction of diborane with methyl alcohol. It is a colorless liquid, whose normal boiling point is 25.9° (vapor tension 275 mm. at 0°). In the vapor phase at room temperature it shows a normal value of the molecular weight (73.9), and the only indications of association at lower temperatures are too uncertain to be considered. It is not spontaneously inflammable in air, but is rapidly hydrolyzed according to the equation $(CH_3O)_2BH + 3HOH \longrightarrow B(OH)_3 + 2CH_3OH + H_2$. Its odor is a composite of methyl alcohol and diborane.

Dimethoxyborine decomposes reversibly, according to the equation $6(CH_3O)_2BH \rightleftarrows B_2H_6 + 4(CH_3O)_3B$. No intermediate compound, such as monomethoxyborine or methoxydiborane, could be isolated. The equilibrium point favors the decomposition under all easily attained conditions. The rate of decomposition in the gas phase is comparatively low, and depends but little upon changes of pressure. In the liquid state at temperatures above 0°, the decomposition is so rapid that special precautions are necessary for obtaining trustworthy measurements of the vapor tension.

In all of this work, the only indication of the existence of monomethoxyborine was an unstable, non-volatile white solid, which was formed as a by-product of the preparation of dimethoxyborine. It decomposed on standing at room temperature, to give diborane, dimethoxyborine, and trimethyl borate, in proportions represented by the formula $(CH_3OBH_2)_x$. The substance may have been a polymer of monomethoxyborine, which could be explained as a complex compound in which oxygen in one molecule occupies the fourth position in the coördination sphere of the boron in another. This is not certain, for other explanations are possible.

Experimental

Preparation.—The reaction used for the preparation is represented by the equation $4CH_3OH + B_2H_6 \longrightarrow 2(CH_3O)_2BH + 4H_2$. The methyl alcohol used for the purpose was treated with barium oxide to remove water, and its purity was checked by the vapor tension at 0° (29.6 mm.). The exact proportions of the two substances apparently were not critical, for the yields were about equally good whether the excess of diborane was four-fold or twenty-fold. The yields varied between 75 and 90% of the methyl alcohol; trimethyl borate was obtained as a by-product. The details of our largest-scale preparation were as follows.

Approximately 500 cc.[3] of pure diborane and 270 cc. of methyl alcohol were condensed together upon the outer wall of a 3-cm. wide test-tube, which was sealed into the top of a one-liter flask[4] connected to the vacuum apparatus. Then the two substances were allowed to warm and a rapid effervescence occurred. The hydrogen was pumped off through a trap immersed in liquid nitrogen, and the process was repeated until no further hydrogen was produced. Then the excess diborane was isolated by trapping out the less volatile substances at a temperature of −145°, and two more 270-cc. portions of methyl alcohol were treated with it as before. The dimethoxyborine was purified by fractional condensation, using baths at −90° (to trap out methyl borate completely) and −120°. The fraction condensed at −120° showed a vapor tension of 275 mm. at 0°; further distillation did not change the value; yield, 300 cc.

---

[3] All volumes given in this paper refer to gases at standard conditions.

[4] This reaction vessel is like that used by Stock and Somieski, *Ber.*, **50**, 1742 (1917), for the halogenation of silane.

Analysis.—A sample was analyzed by hydrolysis with a slight excess of water, according to the equation $(CH_3O)_2BH + 3HOH \longrightarrow B(OH)_3 + 2CH_3OH + H_2$. The hydrogen was pumped out and measured. The methyl alcohol was separated from the residual water by distillation methods, and measured as a gas. The boric acid was titrated with 0.1 *N* barium hydroxide, in the presence of excess mannite. A sample whose volume was 8.85 cc. gave 8.95 cc. of hydrogen, 17.5 cc. of methyl alcohol, and 8.85 cc. of boric acid (calculated as a gas). These values check the above equation, leaving no doubt of the identity of the substance.

Solid By-Product of the Preparation.—An unstable white solid was formed as a by-product of the experiment described above. It seemed to be entirely non-volatile at room temperature, but decomposed on heating. The volatile substances were removed completely from the reaction vessel, and the solid was allowed to stand for twelve hours at room temperature. During this time it disappeared completely, and in its place was found 16.0 cc. of diborane, 18.0 cc. of dimethoxyborine, and 6.6 cc. of trimethyl borate. These quantities correspond to the formula $(CH_3OBH_2)_x$, within the probable error.

At first glance this substance appears to be a polymer of monomethoxyborine, which is easily explained as a complex compound in which oxygen in one molecule occupies the fourth position in the coördination sphere of boron in another. But we might also regard it as a complex compound of the type $(CH_3OBH_3)_2BOCH_3$, or $(CH_3OBH_3)BH(OCH_3)$. These possibilities are less probable, in that they require that the hypothetical BH_3 form complex compounds with oxygen, but the present state of our knowledge does not allow us to eliminate them.

The molecular weight was determined by weighing a measured volume of the gas, in a small bulb closed by a stopcock (the substance reacts slightly with grease, but the effect is not serious): first sample, 18.32 cc. weighed 0.0604 g., m. w. = 73.8; second sample, 37.90 cc. weighed 0.1256 g., m. w. = 74.2. The theoretical value for the monomer is 73.9.

The melting point was determined by the aid of the magnetic device of Stock.[5] The temperature was measured by the carbon tetrafluoride vapor tension thermometer. The average value was −130.6°.[6]

The vapor tensions were measured with particular care, on account of their possible relation to association in the liquid state at low temperatures. A 200-cc. sample was purified as thoroughly as possible by the aid of a simple reflux fractionating tube[7] (reflux temperature, −78.5°) and stored at liquid air temperature. Almost all of the measurements were made upon fresh small samples from this large supply. The tensions at temperatures below −40° were registered upon a mercury manometer whose arms were 16 mm. in internal diameter, and measured by a precision cathetometer (probable error not greater than 0.01 mm.). At higher temperatures it was necessary to work more rapidly than the use of the cathetometer would allow. The values given in Table I are either averages of several points near together, or selections from a number of mutually consistent values.

---

(5) Stock, *Ber.*, 50, 156 (1917).

(6) It was noted that slightly different values were obtained, depending upon whether the same sample was melted on the plunger and re-frozen before the determination, or condensed directly as a solid, during a very slow distillation. In the former case, the average was −130.2°; in the latter, −131.0°. The difference is greater than the probable error, but its meaning is not apparent.

(7) Burg, article to be published in an early number of THIS JOURNAL.

TABLE I

t, °C	−95.8	−86.7	−70.9	−64.7	−56.1	−46.3	−36.0	−28.2
p, mm	0.18	0.52*	2.66	4.58	9.60	19.85*	39.2	64.3
t, °C	−20.5	−11.5	−8.9	0.00	6.8	8.9	12.0	13.8
p, mm	100.5	158	180	275*	366	403	453	490

The values marked with an asterisk were used in calculating the constants for the equation

$$\log_{10} p = -(1849.0/T) + 175 \log_{10} T - 0.008221\, T + 7.1895$$

which represents the other values reasonably well. From this equation we calculate the boiling point to be 25.9°, the molal heat of vaporization, 6138 cal., and the Trouton constant, 20.5 cal./deg. The curve representing the relation of log p to $1/T$ (Fig. 1)[8] is definitely concave downward, but this curvature is not much more pronounced than that observed in many other volatile oxygen compounds. We cannot attribute it to any tendency toward formation of linkages between boron atoms.

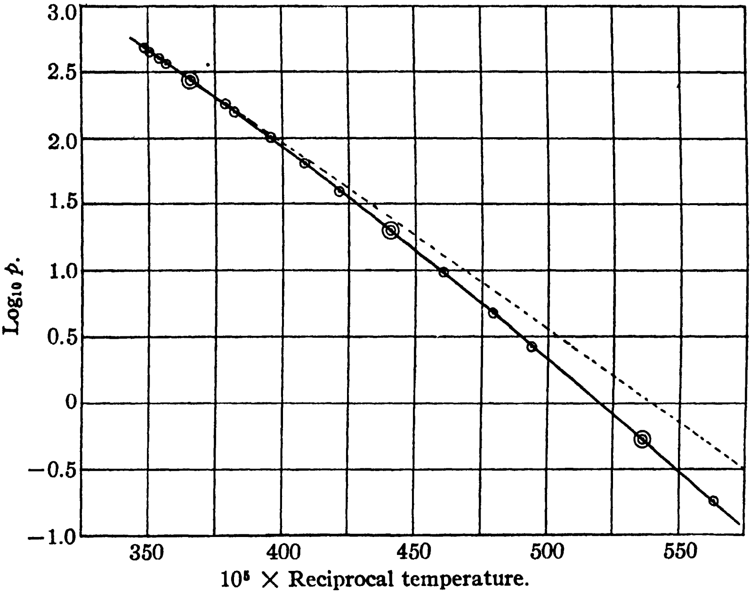

Fig. 1.—Vapor tensions of dimethoxyborine.

The Equilibrium with Diborane and Trimethyl Borate

The Decomposition.—Dimethoxyborine decomposes to form diborane and methyl borate, without indication of any other substance. The change of volume in the process, indicated by the equation $6(CH_3O)_2BH \rightleftarrows B_2H_6 + 4(CH_3O)_3B$, makes it possible to follow the change roughly by

---

(8) The dotted line represents the Clapeyron equation, drawn through the point for 0°, with a slope corresponding to a normal value for the Trouton constant. The points used for calculating the Nernst equation are doubly circled.

measurements of the total gas volume. Table II gives the results of an experiment in which 31.8 cc. of pure dimethoxyborine was placed in a U-tube with adjacent manometer (total available space, 105 cc.), and the volumes determined from time to time by measurement of the pressure and of the temperature, which varied one or two degrees from the average, 20°.

TABLE II

Time, hours	0	20.0	26.5	44.5	57.5	68.0
Volume, cc.	31.8	30.8	30.4	29.8	29.5	29.3

At the end of the experiment, the residual substance and the products were isolated, and it was found that 14.7 cc., or 46%, of the sample had decomposed to form 9.8 cc. of trimethyl borate[9] and 2.5 cc. of diborane, in good agreement with the equation given above and with the observed decrease of volume. The remaining 17.1 cc. of dimethoxyborine was allowed to stand for two hundred and thirty-four hours in a space of 1200 cc. at room temperature. The result was 65% decomposition. In another experiment, a 43.9-cc. sample was allowed to stand for fifteen hours in the 1200 cc. space at room temperature, and was 9% decomposed. In this case the pressure was only one-tenth as high as in the experiment recorded in Table II, but the rate of decomposition was two-thirds as rapid.

The decomposition is far more rapid if the substance is placed in the reaction vessel in which the preparation was carried out, after the disappearance of the white solid. Under such conditions a 300-cc. sample in a space of 1100 cc. was 30% decomposed in one hundred and ten minutes at room temperature. The rate was about seventeen times as rapid as that observed in the experiment recorded in Table II, which occurred at about the same pressure. The catalytic activity of the reaction chamber was destroyed by heating at high vacuum.

The Reverse Reaction.—As a test of the reversibility of the decomposition of dimethoxyborine, 17.2 cc. of diborane and 9.75 cc. of methyl borate (both very carefully purified) were placed together in a space of 105 cc., and left for forty hours in the vapor state at room temperature. The components of the mixture were separated again, and there was isolated 0.15 cc. of a gas having a vapor tension of 1.2 mm. at −78.5°. The process was repeated, this time for seventy-eight hours, and 0.30 cc. of the product was obtained. In ninety-eight hours, 0.40 cc. was produced. The three samples were combined and purified as thoroughly as possible. From two values of the vapor tension, 46 mm. at −33.8° and 17.2 mm. at −48.5°, the substance was indicated to be dimethoxyborine. All doubt was removed by an analysis, in which the 0.78-cc. sample was hydrolyzed to produce 0.8 cc. of hydrogen and 0.75 "cc." of boric acid (methyl alcohol not determined).

---

(9) Identified by the 35.5 mm. vapor tension at 0°, and the value −29° for the melting point. *Cf.* Wiberg and Sütterlin, *Z. anorg. allgem. Chem.*, **202**, 15 (1931).

The decomposition of dimethoxyborine is thus shown to be appreciably reversible. This reaction is not recommended as a means of preparation, even though the yields would be practically quantitative, for any attempts to increase the rate of reaction by heating would be likely to result in some formation of B_5H_{11} and B_4H_{10}, either of which would be very hard to remove from the product.

We are planning to study further the chemical properties of dimethoxyborine, as well as the reaction of a variety of alcohols with various boron hydrides. We have recently found that boron trimethyl, like boron trihalides and trimethyl borate, reacts with diborane. We hope in the near future to be able to report on some new derivatives of diborane, obtained by this method.

Summary

Dimethoxyborine, a compound of the new type HBX_2, has been prepared by the reaction of diborane with methyl alcohol. A white, non-volatile, unstable solid which may be a complex polymer of monomethoxyborine, was obtained as a by-product.

Dimethoxyborine shows no tendency toward association, beyond that common to most volatile oxygen compounds. Its vapor tensions were measured with some care, and expressed by an equation of the Nernst approximation type.

The substance decomposes very easily to form diborane and trimethyl borate. This reaction is reversible to an appreciable extent.

The Quantum Yields of the Photochemical Reactions of Phosgene

BY C. W. MONTGOMERY AND G. K. ROLLEFSON

In the previous work which has been reported[1] on the photochemical oxidation of phosgene, the phosgene-sensitized oxidation of carbon monoxide, and the photochemical reaction of phosgene with hydrogen, kinetic studies of the reactions have been carried out and an attempt has been made to arrive at well-correlated and self-consistent reaction mechanisms in the three cases. This program has been completely successful from the kinetic standpoint with one exception (for a discussion of this case see (1b).

Quantum Yields of the Phosgene Reaction

In order to gain further confirmation of the mechanisms already proposed, for certain photochemical reaction of phosgene it is still necessary to show that the measured values for the quantum yields of the three reactions are in agreement with the values predicted from the reaction schemes.

---

[1] (a) Rollefson and Montgomery, THIS JOURNAL, 55, 142 (1933); (b) 55, 4029 (1933); (c) 55, 4036 (1933).

As a preliminary step in order to facilitate the determination of the quantum yields by eliminating one of the necessary energy measurements, it was decided first to measure the absorption coefficients of gaseous phosgene in the ultraviolet region. Although the absorption spectrum has been fully studied, no available values of the integrated over-all absorption coefficients are recorded in the literature.

For this purpose a photographic method of spectrophotometry was employed. A cylindrical quartz absorption cell 19.9 cm. long and 3.0 cm. in diameter, having plane parallel ends, was filled with phosgene to the desired pressure; the pressure was then read on the manometer, the phosgene frozen out in a convenient quartz side tube, and the absorption cell then sealed off. Photographs were taken of the absorption spectrum by means of a Hilger E-3 quartz spectrograph, using the continuum from a quartz mercury discharge tube as the source. No lenses were used as the light from the discharge tube was sufficiently intense and parallel. A fairly wide slit was used on the spectrograph in order to cut down exposure time as well as to even out any trace of band absorption which might be obtained. "Speedway" plates were used and on each plate were recorded two photographs of the absorption spectrum, two photographs of the wave length scale (which was calibrated with a quartz mercury arc), and photographs of the discharge tube with a series of calibrated screens interposed (the quartz absorption cell being kept in place but the phosgene frozen out in the side tube). The plates were then photometered by means of a Zeiss microphotometer at various intervals throughout the absorption region. Values of I/I_0 were determined by comparison of the photometer curves for the absorption region with those for the arc with screens. The absorption coefficients were then calculated according to the equation $\epsilon = (1/pl) \log_{10} (I_0/I)$, where p is the pressure of phosgene in cm. and l is the length of the cell in cm.

The results are shown in Table I. Three different plates were taken; a pressure of 10 cm. of phosgene was used for I, 5 cm. for II, and 1 cm. for III. The results are also shown graphically in Fig. 1.

Table I

Å....................	2745	2696	2645	2594	2543	2491	2441	2391	2342
I, $\epsilon \times 10^2$..............	0.15	0.26	0.41	0.63					
II, $\epsilon \times 10^2$.............	.13	.26	.41	.64	1.00				
III, $\epsilon \times 10^2$............		.28	.50	.85	1.13	1.42	1.78	1.99	2.04

For the quantum yield measurements, a Hilger quartz monochromator D-33 equipped with a Hilger F-83 thermopile was used. The area of the monochromator slit as used was 5.08 sq. mm. The thermopile, mounted in the monochromator slit block, was calibrated against a standard lamp from the Bureau of Standards and found to have a sensitivity of 7.2×10^{-7} watt per mm. scale deflection with the galvanometer circuit.

The reaction vessel was similar to the cylindrical one used for the absorption coefficient determination. It was mounted flat in a cooling tank with one end about 3 mm. from a clear quartz window in the side of the tank. The transmissions of the quartz window and the plane parallel end of the reaction vessel were measured with the thermopile for the 2537 Å. line and the total transmission found to be 0.71; assuming 0.98 for the transmission of the narrow water layer between reaction vessel and window gave a total transmission for the system of about 0.70. The volume of the reaction vessel and manometer arm was measured and found to be 110 cc.

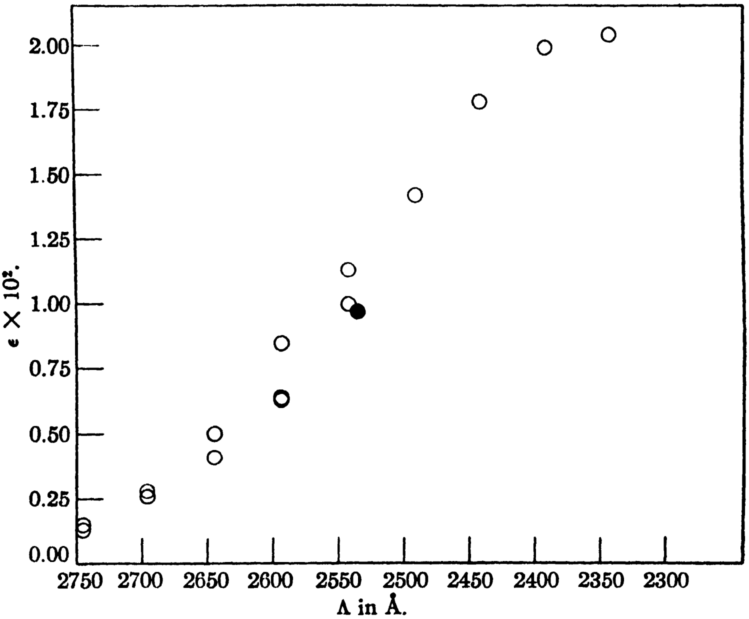

Fig. 1.

The experimental procedure was as follows. The monochromator was set on three or four prominent mercury lines visually and then turned to the 2537 region. Final setting on the line was accomplished by means of the thermopile galvanometer readings. The monochromator was then placed so that the slit was flush against the cooling tank window, directly in line with the reaction vessel. After the mercury arc had warmed up, several thermopile readings were taken. The gases were then introduced into the reaction vessel and the cooling water temperature noted. The thermopile was removed from the monochromator slit finally and illumination begun. The period of illumination varied, of course, with the reaction, sometimes being carried out for two days. At intervals during this time, thermopile readings were taken so that an average value of the rate of energy input might be obtained. Finally the manometer was read with as nearly as possible the same temperature of water in the tank as at the start (usually ±0.5°).

In order to check the value of the absorption coefficient as measured by the photographic method, a more direct measurement was made. This was done by means of the monochromator and thermopile for the 2537 Å. Hg line and gave the result $\epsilon = 0.0097$. This value is somewhat lower than the average value from Fig. 1 but is in fair agreement with the point on the curve taken from plate II. The points from plate III thus appear to be too high, and the thermopile value for ϵ has accordingly been used in the calculations. From the average rate of energy supply and the absorption coefficient of phosgene for $\lambda = 2537$ Å. ($\epsilon = 0.0097$) the amount of absorbed energy could be calculated and the number of molecules reacting was calculated, of course, from the pressure change.

I. The Photochemical Oxidation of Phosgene.—As an example of the data, the following determination is given

$P_{COCl_2} = 6.26$ cm. Hg, $P_{O_2} = 6.82$ cm. Hg
Total no. of quanta absorbed $= 4.4 \times 10^{18}$
$COCl_2$ reacting $= 16.0$ mm. $= 7.84 \times 10^{18}$ molecules
$\gamma = (7.84 \times 10^{18})/(4.4 \times 10^{18}) = 1.78$

Three similar experiments gave values for γ of 1.87, 1.73 and 1.83, the average of all four being 1.80.

II. The Phosgene-Sensitized Oxidation of Carbon Monoxide.—The quantum yield of the sensitized oxidation of carbon monoxide might be expected to vary as the ratio $(CO)^{1/2}/I_{abs.}^{1/2}$ at high pressures of oxygen and as $(CO)^{1/2}(O_2)^{1/2}/I_{abs.}^{1/2}$ at low oxygen pressures. This point was not investigated, however, as the principal object was merely to get some idea of the order of magnitude of the chain length.

Two direct measurements of the quantum yield gave $\gamma = 87$ and 95 for reaction mixtures in which the pressure of each gas ($COCl_2$, CO and O_2) was approximately 30 cm. of sulfuric acid.

An independent check on these values of γ was made by means of a comparison of the rate with the direct phosgene oxidation. Assuming 1.8 for the quantum yield of the latter reaction, γ for any other reaction in which phosgene is the absorbing substance may easily be found by comparing the rates of the two reactions, provided P_{COCl_2} and the light intensity is the same for both reactions. Several rate comparisons on the above reaction mixture were made, the rate being found to be 50–60 times as fast as the direct oxidation. This indicates a value for γ of 90–110, in good agreement with the directly measured values.

III. The Photochemical Reaction of Phosgene with Hydrogen.—No direct measurements of the quantum yield of the phosgene–hydrogen reaction were made but an idea of the value of γ can be had from a comparison of the rates of the oxidation and reduction. The following initial rate results are an example of the values obtained by comparison of rates.

$P_{COCl_2} = P_{H_2} = 40.0$ cm. H_2SO_4

t, minutes	2	4	6	8	10
γ	3.8	2.8	2.6	2.4	2.4

Discussion

In general, the results of the quantum yield determinations confirm the conclusions of the kinetic studies and the mechanisms proposed for the reactions. While the quantum yield of the oxidation is slightly lower than the value 2 predicted by the reaction mechanism, this is not a serious or unusual situation in photochemical work. Much more serious would be an experimental value greater than that predicted. There may be various factors which tend to lower the yield in this case. Although the determination of γ was made with an excess of oxygen present and the reaction was not carried out very far toward completion, still it is possible that the chlorine–oxygen ratio may be a contributing factor in lowering the rate. Furthermore, if CO_3Cl is postulated, this intermediate may take part in some side reaction which might effectively lower the rate of reaction between CO_3Cl and $COCl_2$.

The quantum yield of the phosgene-sensitized oxidation indicates that the reaction involves a long chain of the same magnitude as that of the chlorine-sensitized oxidation and further confirms the similarity of the two reactions. (For a fuller discussion of this point see (2).)

In the case of the hydrogen reaction, the relatively larger value of γ at the start of the reaction is in agreement with the proposed mechanism and rate law. As will be shown later,[1c] this higher initial rate of reaction is probably due to the second term in the rate law

$$\frac{d(CO)}{dt} = I_{abs.}\left[1 + \frac{k(H_2)}{(CO)(M)}\right]$$

which makes a large contribution to the rate at the start of the reaction, then rapidly diminishes. If it were possible to measure the quantum yield at a very short time interval after the reaction started, it is to be expected that even larger values of γ would be found. The lower limiting value of γ as shown by the first term of the above rate law should be 1.

THE PHOTOCHEMICAL REACTION OF PHOSGENE WITH HYDROGEN

Bredig and von Goldberger[2] investigated the photochemical reaction of phosgene with hydrogen. They made no attempt to study the kinetics of the reaction but were concerned solely with the stoichiometry and the question of the existence or non-existence of formaldehyde as one of the reaction products. They found that the predominant reaction (they followed it to 95–98% completion in some cases) could be represented by the equation $COCl_2 + H_2 \longrightarrow CO + 2HCl$, and, further, that formaldehyde was present "only in traces at 10°," and at 80° was not detectable. They concluded that if formaldehyde were formed in some primary process, it was probably immediately decomposed photochemically.

A study of the reaction kinetics has been made in order to determine whether a reaction mechanism could be formulated in essential agreement with those of other phosgene reactions. In the event that formaldehyde appeared to be one of the products it was thought likely that such a study might yield an insight into some new partial reactions involving the intermediate (COCl).

---

(2) Bredig and v. Goldberger, *Z. physik. Chem.*, **110**, 521 (1924).

Experimental

The apparatus used was the same as that previously described for the other phosgene reactions.[1a] Phosgene was purified in the same manner as before. Hydrogen was prepared electrolytically, purified by passing over hot copper, and dried in a storage bulb containing magnesium perchlorate. Carbon monoxide was prepared and purified as before and the carbon dioxide used in the inert gas experiments was taken, without purification, from a cylinder and dried by passing through magnesium perchlorate.

In order to test the stoichiometry of the reaction, several preliminary experiments were made in which from time to time during the course of the reaction the reaction vessel was immersed in liquid oxygen and the manometer readings taken with the condensable gases ($COCl_2$ and HCl) frozen out. It was found that these liquid oxygen pressure readings remained constant throughout each experiment. It was concluded, therefore, that the above equation holds for the over-all phosgene reduction since it indicates that there should be no pressure change at liquid oxygen temperature. If formaldehyde were formed during the reaction, it might be expected that the liquid oxygen pressure readings would gradually decrease as the reaction proceeded. The constancy of the low temperature pressure readings must therefore be interpreted as substantiation of the conclusions of Bredig and von Goldberger that little if any formaldehyde is formed and that their equation holds for the over-all reaction. Furthermore, on the basis of the volume change in their equation, the reaction proceeded quite smoothly and in some experiments was carried out to 90–95% completion.

Results

The experimental results fall into two classes: those results which led to the elucidation of the initial rate law, and the results of further experiments designed to indicate how this initial law might be modified in order to be applicable over the entire course of the reaction.

The effect on the initial rate of varying the hydrogen pressure is shown by the results in Table II.

TABLE II

H_2, cm. H_2SO_4	4.93	15.07	25.20	50.00
Rate, cm. H_2SO_4/min	0.560	0.573	0.600	0.617

Although the hydrogen pressure was varied ten-fold, there is but little change in the initial rate. There is unquestionably a trend, however, toward higher initial rate as the hydrogen pressure increases, but the rate, at most, appears rather insensitive to variations in the hydrogen pressure.

Table III shows the results of a series of experiments in which the effect of varying the phosgene pressure was investigated. Pressures are expressed in cm. and initial rates in cm./min.

From the rates and the phosgene pressures alone, it is impossible to decide how ($COCl_2$) enters the rate law. The rate has an upward trend but appears to approach a limiting value at high phosgene pressures. This apparent independence of the rate on the phosgene pressure is easily

TABLE III

$COCl_2$	$d(CO)/dt$	Absorption, %	$COCl_2$	$d(CO)/dt$	Absorption, %
2.90	0.060	20.0	23.74	0.211	83.5
5.73	.096	35.5	26.75	.233	86.9
8.74	.124	48.5	29.82	.220	89.6
11.80	.156	59.2	32.65	.240	91.6
14.70	.175	67.3	35.80	.250	93.4
20.68	.211	79.2			

explained as follows. From the exponential character of Beer's law it is known that strict proportionality between the amount of light absorbed and the concentration of the absorbing substance exists only for low absorption, *i. e.*, low concentrations. When the amount of absorption is large, this proportionality breaks down, the amount of absorption increasing more and more slowly as the concentration increases. Hence photochemical reactions which are first order with respect to the amount of light absorbed tend to become zero order with respect to the absorbing substance at high concentrations where absorption becomes large. This is exactly the case here. In connection with the work on the quantum yields of the phosgene reactions, the absorption coefficients of phosgene were measured in the predissociation region. Thus it is possible to calculate the percentage absorption, which, unlike the phosgene pressure, should be proportional to the initial rate. This has been done in column 3 of Table III, assuming a value of the absorption coefficient $\epsilon = 0.011$, where ϵ is defined by the equation $\log (I_0/I) = pl\epsilon$, the units of p being in cm. and l in cm. ($l = 3.0$). From this equation the percentage absorption can be calculated by Percentage Absorption $= [(I_0/I) - 1]/(I_0/I)$. The value taken for ϵ is that corresponding to $\lambda = 2537$ Å., the most intense Hg line beyond the predissociation limit.

If the initial rates of Table III are plotted against the corresponding percentage absorption calculated in the above manner, a straight line is obtained, clearly indicating that the rate is a function of the first power of the light absorbed.

In Table IV are summarized the results of a series of experiments in which the effect of variation of the incident light intensity, by means of a set of calibrated screens, was investigated.

TABLE IV

Transmission, %	100.0	69.5	48.6	38.0	29.7	15.6
Rate	0.080	0.057	0.038	0.029	0.027	0.013
Δ	− .002	.000	− .002	− .003	+ .003	+ .002

The third column of the Table shows the deviations from linearity (*i. e.*, from the best straight line through the points). As might have been predicted from the phosgene results, the rate is a linear function of the incident intensity.

From the above results it appears that the rate is much more sensitive to the amount of light absorbed than to the hydrogen pressure. If $d(CO)/dt = kI_{abs.} = kI_0(COCl_2)$, we may write $d(CO)/dt = -d(COCl_2)/dt = kI_0(COCl_2)$, or, $-d \log (COCl_2)/dt = k'$. If, therefore, the rate law were the simple first order expression above, the change in the logarithm of the $(COCl_2)$ per unit time might be expected to remain constant. That this is not so is shown by the results of Table V. δ is the rate of change of the log $(COCl_2)$.

TABLE V

Time, minutes	3	6	10	15	20	25	30	35
δ	0.015	0.013	0.013	0.011	0.009	0.009	0.009	0.007

(71% completion)

In order to investigate the cause of this deviation from the first order law, further series of experiments were undertaken. In Table VI are shown the results of some experiments in which the effect of total pressure was investigated. $(COCl_2)$, (H_2), and the incident light intensity were kept constant and total pressure varied by the addition of (CO_2).

TABLE VI

CO_2, cm.	0.0	10.0	15.0	20.0	25.1	40.1	45.2
Relative rate	1.000	0.909	0.871	0.841	0.775	0.630	0.594
Δ	0.000	− .005	.000	+ .015	− .005	− .015	− .005

The rate appears to be inversely proportional or at least involves a term which is inversely proportional to the first power of the total pressure. A series of experiments in which nitrogen was the added gas yielded quite similar results.

Next, a series of experiments was made in which carbon monoxide was added to the reaction gases in varying amounts. The results appear in Table VII.

TABLE VII

CO, cm. H_2SO_4	0.00	10.09	15.07	21.35	34.91
Relative rate	1.000	0.757	0.722	0.666	0.595

It is evident that the inverse effect on the rate is much more pronounced with carbon monoxide than with carbon dioxide (or nitrogen). Furthermore, when the relative rate is plotted against the carbon monoxide pressure, a distinct curvature is observed so that the curve resembles the graph of an inverse square function. This must be interpreted as due to the fact that carbon monoxide, apart from its total pressure effect, has a specific effect as well in lowering the rate. This means that carbon monoxide probably enters the rate law explicitly.

In the following table the values of δ have been tabulated for a series of three experiments. Expt. A was a "control" reaction showing the usual falling off of δ. In Expt. B hydrogen was added during the reaction and in Expt. C there was a large excess of carbon monoxide present. In other respects the conditions were identical in the three experiments ($P_{H_2} = P_{COCl_2}$ = 10 cm. H_2SO_4).

TABLE VIII

A		B		C	
t, mins.	δ	*t*, mins.	δ	*t*, mins.	δ
15	0.082	10	0.077	10	0.038
25	.069	20	.067	20	.038
35	.066	30	.061	30	.036
45	.063	40	.063[a]	40	.042
55	.058	50	.064	60	.041
65	.057	60	.075[b]	80	.038
75	.052	70	.081	100	.039
85	.047				

[a] 5 Cm. H_2SO_4 of H_2 added. [b] 27 Cm. H_2SO_4 of H_2 added.

The above experiments and other similar ones seem to indicate that the amount of deviation from first order may depend upon the value of the ratio $H_2/(CO)(M)$. By alternate additions of hydrogen and carbon monoxide, it was found possible to vary the deviation almost at will. It is further evident that fairly constant values of δ may be obtained by maintaining an excess of hydrogen as in "B" or by adding a large excess of carbon monoxide as in "C."

Discussion

It has been possible to derive a rate law in formal agreement with the above experimental facts from the following reaction mechanism

$$COCl_2 + h\nu \longrightarrow COCl + Cl \qquad (1)$$
$$Cl + H_2 \longrightarrow HCl + H \qquad (2)$$
$$H + COCl_2 \longrightarrow CO + Cl + HCl \qquad (3)$$
$$CO + Cl + M \longrightarrow COCl + M \qquad (4)$$
$$2COCl \longrightarrow COCl_2 + CO \qquad (5)$$

The rate of reaction according to this reaction scheme is given by

$$d(CO)/dt = k_3(H)(COCl_2) + k_5(COCl)^2 - k_4(CO)(Cl)(M)$$

Assuming that the rates of change of (COCl), (Cl), and (H) are negligibly small compared to their rates of formation and disappearance, we may write

$$d(COCl)/dt = I_{abs.} + k_4(CO)(Cl)(M) - k_5(COCl)^2 = 0 \qquad (I)$$
$$d(Cl)/dt = I_{abs.} - k_2(Cl)(H_2) + k_3(H)(COCl_2) - k_4(CO)(Cl)(M) = 0 \qquad (II)$$
$$d(H)/dt = k_2(Cl)(H_2) - k_3(H)(COCl_2) = 0 \qquad (III)$$
$$I + II + III = 0 = 2I_{abs.} - k_5(COCl)^2$$
$$\text{or, } k_5(COCl)^2 = 2I_{abs.} \qquad (IV)$$

From II we obtain

$$k_3(H)(COCl_2) - k_4(CO)(Cl)(M) = k_2(Cl)(H_2) - I_{abs.}$$

Substituting the right-hand member in the expression for the rate of reaction we have

$$d(CO)/dt = k_2(Cl)(H_2) - I_{abs.} + k_5(COCl_2)^2 \qquad (V)$$

According to IV this becomes

$$d(CO)/dt = k_2(Cl)(H_2) + I_{abs.} \qquad (VI)$$

From I we obtain

$$k_4(CO)(Cl)(M) = I_{abs.}, \text{ or}$$
$$(Cl) = I_{abs.}/k_4(CO)(M) \qquad (VII)$$

Substitution of VII in VI gives

$$d(CO)/dt = I_{abs.} + k_2I_{abs.}(H_2)/k_4(CO)(M) \qquad (VIII)$$
$$= I_{abs.}\left[1 + \frac{k_2(H_2)}{k_4(CO)(M)}\right]$$

Since in most of the experimental work the total absorption was small we may make the substitution $I_{abs.} = I_0(COCl_2)$, which reduces VIII to

$$d(CO)/dt = I_0(COCl_2)\left[1 + \frac{k_2(H_2)}{k_4(CO)(M)}\right]$$

an equation in formal agreement with and capable of explaining the experimental facts.

It may be remarked that a rate law of this form indicates an infinite initial rate of reaction (since carbon monoxide is one of the reaction products). This, of course, is not observed. In every case, however, where carbon monoxide is not added before the start of the reaction, the first two or three values of δ are invariably noticeably larger than succeeding values. The second term thus makes its largest contribution to the rate at the start of the reaction. The fact that the ratio $H_2/(CO)(M)$ decreases so rapidly as reaction proceeds explains the rapid falling off of the δ values.

Special notice should be taken of the manner in which (M) enters the rate law, as any molecule which is capable of taking up the excess energy of, and so stabilizing, the intermediate COCl. In the case of the photochemical formation of phosgene, Lenher and Rollefson[3] identified (M) with (Cl_2) and this was later confirmed on theoretical grounds by Rollefson and Eyring.[4] The possibility of Cl_3 molecules (such as they postulated) reacting with CO to form COCl is indeed remote in the phosgene–hydrogen reaction since no Cl_2 is present. Hence it is difficult to identify (M) with any particular molecular species in our present case. Furthermore, it is undoubtedly incorrect to assume that all the kinds of molecules present are equally capable of stabilizing COCl and thus tacitly to assume the identity of (M) and the total pressure. It is well known from the study of the extinction of fluorescence that molecules differ greatly in their efficiency in taking up energy. In confirmation of this, carbon monoxide was found to have a more pronounced "total pressure" effect than nitrogen. For this reason, (M) should probably be written $(M) = a\,(COCl_2) + b\,(H_2) + c\,(CO) + d(HCl)$, where the coefficients are "stabilizing efficiencies." It is this indeterminate character of (M) which makes a more rigorous analytical test of the rate law impossible.

(3) Lenher and Rollefson, THIS JOURNAL, 52, 500 (1930).

(4) Rollefson and Eyring, *ibid.*, 54, 170 (1932).

In the reaction mechanism, no reaction has been postulated between COCl and H_2 to form, possibly, COH, since there was no evidence of formaldehyde formation, which might be supposed to take place through this latter intermediate. As a consequence COCl may be supposed to build up sufficient concentration to bring about the chain terminating step

$$2COCl \longrightarrow COCl_2 + CO \qquad (5)$$

This step is thus fairly consistent with the other partial reactions of the mechanism.

Summary

The quantum yields have been measured for the photochemical oxidation of phosgene, the phosgene-sensitized oxidation of carbon monoxide, and the photochemical reaction of phosgene with hydrogen. The results confirm the rate mechanisms proposed for these three reactions.

The photochemical reaction between phosgene and hydrogen: $COCl_2 + H_2 \longrightarrow CO + 2HCl$, has been studied. The rate of the reaction has been investigated and a mechanism devised from which the theoretical rate law

$$\frac{d(CO)}{dt} = kI_0(COCl_2)\left[1 + \frac{k_2(H_2)}{(CO)(M)}\right]$$

may be derived. It has been shown that this expression is in essential accord with the experimental facts. The reaction rate has been discussed from the standpoint of this rate law and various experimental points explained. The absence of formaldehyde formation, it has been pointed out, is probably due to the non-reactivity of COCl toward H_2. This non-reactivity in turn is believed to cause an increase in the concentration of COCl so that $2COCl \longrightarrow COCl_2 + CO$ becomes the chain terminating process.

The Phosgene-Sensitized Oxidation of Carbon Monoxide

By G. K. Rollefson and C. W. Montgomery

As the result of a number of investigations concerned with the inhibiting effect of oxygen on the photosynthesis of phosgene[1,2,3,4] it has been shown that at high oxygen pressures the phosgene formation becomes negligibly small, the chlorine-sensitized oxidation of carbon monoxide being predominant. In the various mechanisms proposed for this reaction[5] the formation of carbon dioxide is believed to take place through the action of oxygen on the intermediate COCl. It has previously been shown that in the case of the direct photochemical oxidation of phosgene[6] this same intermediate is produced by the action of ultraviolet light on phosgene, and evidence has been submitted that the same state obtained in such a system as is produced by the action of visible light on a mixture of chlorine, carbon monoxide and oxygen. It is therefore to be expected that the oxidation of carbon monoxide might be sensitized by phosgene in a manner entirely analogous to the chlorine-sensitized reaction. Such has been found to be the case and the reaction has been studied in the hope of arriving at a comparison with the chlorine-sensitized oxidation.

Experimental

The apparatus employed in the kinetic study was, in general, the same as that previously described for the work on the direct oxidation of phosgene.[6] The same cylindrical quartz reaction vessel was used with the same method of water cooling. The source of illumination was the full light of a 220-volt Cooper–Hewitt quartz mercury arc.

The phosgene (Kahlbaum) was distilled from a glass bomb and was purified in the manner previously described. Oxygen was prepared electrolytically, purified and dried as before.[6] Carbon monoxide was generated by heating a mixture of concentrated sulfuric and formic acids, washed in a bubbler containing strong sodium hydroxide solution, and dried in a similar bubbler containing concentrated sulfuric acid. The three gases were stored in three three-liter bulbs from which they could be admitted to the reaction vessel as needed.

The reaction was followed by means of a sulfuric acid (sp. gr. 1.84) manometer or a mercury manometer (with the mercury surface protected by 3 or 4 cm. of sulfuric acid) depending on the total pressures of the gases used. Due to the large Draper effect produced by the reaction, before readings were taken the light from the arc was cut off from the reaction vessel by means of a shutter and the pressure allowed to reach a constant value.

In several of the experiments, in order to check the stoichiometry of the reaction, pressure readings were taken both at room temperature and at

liquid air temperature. From these two sets of readings, the amount of sensitized oxidation according to the reaction

$$2CO + O_2 \longrightarrow 2CO_2 \tag{1}$$

and the amount of direct oxidation of phosgene according to

$$2COCl_2 + O_2 \longrightarrow 2CO_2 + 2Cl_2 \tag{2}$$

were calculated. This was done by means of the relations

$$\Delta P_1 = (\Delta P_R + \Delta P_A)/4;\ \Delta P_2 = -\Delta P_R + \Delta P_1$$

where ΔP_1 is the pressure change due to reaction (1), ΔP_2 is the pressure change due to reaction (2), ΔP_R the over-all pressure change at room temperature, and ΔP_A the over-all pressure change at liquid air temperature converted, by means of an empirical "freeze-out" factor, which was determined for each run, to the corresponding pressure change at room temperature. In all the runs made, the sensitized reaction went to completion according to equation (1) and was so rapid relative to reaction (2) that direct phosgene oxidation could be neglected until (1) was approximately 80% complete.

Results

In Table I are summarized the results of five experiments in which the $COCl_2$ pressure was varied from 2.45 to 20.00 cm. of sulfuric acid, the other variables being kept constant. The fourth column indicates the linearity between rate and the square root of the $COCl_2$ pressure.[7]

TABLE I

$(COCl_2)$	2.45	5.02	10.00	14.45	20.00
$(COCl_2)^{1/2}$	1.57	2.24	3.16	3.80	4.47
$d(CO_2)/dt$	1.00	1.47	1.93	2.40	2.80
$(d(CO_2)/dt)/(COCl_2)^{1/2}$	0.637	0.656	0.611	0.632	0.626

In Table II are summarized the results of a series of experiments in which the incident light intensity was varied by means of a set of calibrated screens. In the table, the intensity with no screen is taken as 100. The rate is seen to be fairly definitely a function of the square root of the incident intensity, in agreement with the previous results on the $COCl_2$ dependence. The fourth column of the table indicates the deviation from linearity, values of Δ being obtained from the best straight line through the points.

TABLE II

I_0	100.0	67.0	47.0	37.9	29.0	5.9
$I_0^{1/2}$	10.0	8.2	6.9	6.2	5.4	2.4
$d(CO_2)/dt$	0.56	0.47	0.36	0.34	0.29	0.12
Δ	+0.010	+0.020	−0.015	0.000	0.000	−0.010

Table III gives the results of a series of experiments in which the carbon monoxide pressure alone was varied. Plotting the rate against the square root of the carbon monoxide pressure yields a straight line indicating the dependence on the square root of the carbon monoxide pressure. In several experiments at very low carbon monoxide pressures, the rate falls away from this square root relationship. In these cases, however, the rate of oxidation of carbon monoxide is so much slower that the rate of direct oxidation of phosgene is no longer negligible in comparison. Since this direct oxidation leads to a pressure change in the opposite direction, the effect produced is to cause an anomalous lowering of the rate of the sensitized reaction.

---

[7] In these and the following results, the pressure has been left in terms of cm. of mercury or sulfuric acid and the rate expressed in cm. of mercury or sulfuric acid per minute.

Table III

(CO)	$(CO)^{1/2}$	$d(CO_2)/dt$
14.02	3.32	5.12
18.39	4.29	6.60
27.85	5.28	8.92
37.32	6.20	10.36
47.07	6.86	11.62
56.98	7.55	12.08
66.65	8.15	13.40
76.22	8.73	14.60
86.15	9.28	15.40

Table IV

Δ	(O_2)	$d(CO_2)/dt$
−0.40	1.47	1.15
− .50	3.24	1.62
+ .20	5.05	2.00
+ .05	6.94	2.07
+ .25	10.87	2.35
− .50	15.62	2.45
− .05	20.70	2.40
+ .10	27.40	2.50
.00	36.25	2.40

It was further necessary to investigate the dependence of the rate on the oxygen pressure, in order to afford a closer comparison with the chlorine sensitized reaction. In the latter reaction it has been shown that the rate although dependent on the oxygen pressure at low pressures, becomes independent of it as the pressure is increased. In Fig. 1 and Table IV are presented the results of a series of experiments in which the oxygen pressure was varied between 1.5 and 36 cm. ($COCl_2$, 5 cm., CO, 10 cm.). The rate obviously becomes independent of the oxygen pressure at approximately 15 cm. pressure. In order to test the oxygen dependence in the region where the curve bends down to the origin, several low pressure experiments were made, the results of four of which are shown in Table V.

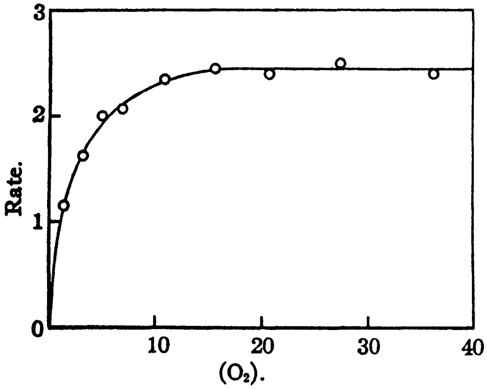

Fig. 1.

Table V

(O_2)(cm. H_2SO_4)	1.73	3.75	6.45	9.30
$(O_2)^{1/2}$	1.16	1.94	2.54	3.05
$d(CO_2)/dt$	2.56	4.28	5.72	6.80
$(d(CO_2)/dt)/(O_2)^{1/2}$	2.21	2.20	2.25	2.23

In this low oxygen region, it is evident that the rate is a function of the square root of the oxygen pressure.

On the basis of the above experiments, the reaction appears to fall into two fairly definite pressure ranges in which the rate laws are different. For low oxygen pressures the rate may be represented by the equation

$$d(CO_2)/dt = KI_0^{1/2}(COCl_2)^{1/2}(CO)^{1/2}(O_2)^{1/2} = kI_{abs.}^{1/2}(CO)^{1/2}(O_2)^{1/2} \qquad (1)$$

(where the substitution $I_{abs.} = I_0(COCl_2)$ is justified by the low light absorption), while at higher oxygen pressures, the oxygen dependence disappears, the rate law becoming

$$d(CO_2)/dt = kI_{abs.}^{1/2}(CO) \qquad (2)$$

This change of order was confirmed by the results of two series of experiments in which the phosgene pressure and light intensity were kept constant and the carbon monoxide and oxygen pressures were kept in constant ratio but their total pressure varied. Under these conditions, the rate should be proportional to the total pressure (carbon monoxide and oxygen) in the region where equation (1) holds, but should fall off from this proportionality in the region of equation (2). The data are presented in Tables VI and VII. The correctness of the above statements is clearly evident in the small deviations from linearity (Δ) in Table VI and the increasingly large deviations in Table VII.

TABLE VI (LOW PRESSURE O_2)

$(O_2 + CO)$(cm. H_2SO_4)	$d(CO_2)/dt$	Δ
10.10	1.9	−0.50
20.66	4.7	.00
40.78	10.0	+ .75
60.55	13.6	.00
80.35	18.1	.00

TABLE VII (HIGH PRESSURE O_2)

$(O_2 + CO)$(cm. Hg)	$d(CO_2)/dt$	Δ
8.0	0.73	0.00
16.0	1.43	− .05
24.0	2.13	− .08
32.0	2.77	− .20
40.0	3.05	− .60

In order to obtain a clearer confirmation of this change of order and the independence of the rate on the oxygen pressure at higher pressures, as well as of the square root relation at low pressures, the data of Table IV have been treated in the following manner. In this series of experiments, the rate is a function of the oxygen pressure alone, the other variables of the system being kept constant. The rate may therefore be represented by the equations

$$d(CO_2)/dt = k(O_2)^{1/2} \qquad (1)$$

for low oxygen pressures, and

$$d(CO_2)/dt = k' \qquad (2)$$

at higher oxygen pressures. Taking the logarithms of both sides of these equations we obtain

$$\log d(CO_2)/dt = \log k + {}^1/_2 \log (O_2) \qquad (1')$$

and

$$\log d(CO_2)/dt = \log k' \qquad (2')$$

If, therefore, we plot the logarithm of the rate against the logarithm of the oxygen pressure, we should obtain a straight line of slope 0.5 for low oxygen pressures and a straight line parallel to the log (O_2) axis at higher pressures. This was done for the data of Table IV and the expected results obtained. In Fig. 2 d log rate/d log (O_2), *i. e.*, the slopes of the log rate *vs.* log (O_2) plot, are plotted against log (O_2). The low and high pressure (O_2) regions are clearly indicated as well as the transition range.

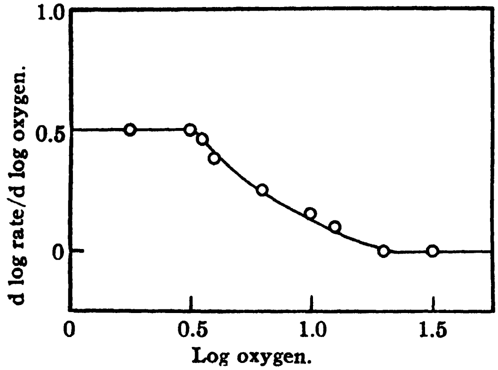

Fig. 2.

The quantum yield[8] has been found to be approximately 100 at pressures of about 40.0 mm. of $COCl_2$, CO and O_2. Schumacher[3] measured the quantum yield of the chlorine-sensitized oxidation and found it to be roughly of the order of magnitude of 1000 molecules per quantum for pressures of (CO) = (Cl_2) = $^1/_2$ atmosphere and O_2 = 1000 mm., in the region of maximum chlorine absorption. If we assume that the rate law which Schumacher found, *i. e.*

$$d(CO_2)/dt = kI_0^{0.71}(Cl_2)^{0.71}(CO)^{1/2} = kI^{0.71}_{abs.}(CO)^{1/2}$$

becomes, at lower chlorine pressures

$$d(CO_2)/dt = kI_0(Cl_2)(CO)^{1/2} = kI_{abs.}(CO)^{1/2}$$

as has been shown by Rollefson,[4b,5] we may obtain a formal expression for the quantum yield by dividing this equation by $I_{abs.}$ thus

$$\gamma = (d(CO_2)/dt)/I_{abs.} = k(CO)^{1/2}$$

At lower pressures of chlorine, the quantum yield should then be only a function of the square root of the carbon monoxide pressure. By a simple calculation we find the quantum yield of the chlorine-sensitized oxidation for a carbon monoxide pressure equal to that (4 cm. of carbon monoxide) at which the quantum yield of the phosgene sensitized oxidation was measured, to be

$$\gamma = \sqrt{40}\cdot 1000/\sqrt{380} \sim 300$$

The quantum yields of the phosgene-sensitized and chlorine-sensitized reactions are thus seen to be of approximately the same magnitude.

Discussion

From the data presented above, it is evident that at low oxygen pressures the rate of oxidation of carbon monoxide may be expressed by the equation

$$d(CO_2)/dt = kI_0^{1/2}(COCl_2)^{1/2}(CO)^{1/2}(O_2)^{1/2}$$

---

[8] The experimental details will be published soon in connection with the determination of the quantum yields of some other reactions.

while at high oxygen pressures ($P_{O_2} > 15$ cm.) the rate becomes independent of the oxygen. As expected, the phosgene-sensitized oxidation appears to be quite similar to the chlorine-sensitized reaction. The fact that the quantum yields are of the same magnitude indicates, of course, that the chain lengths of the two reactions are the same. This gives further confirmation to the view expressed previously that there is no essential difference between the system: phosgene, carbon monoxide, and oxygen illuminated with ultraviolet light of frequency corresponding to the phosgene predissociation region, and the system: chlorine, carbon monoxide, and oxygen illuminated with visible light of frequency corresponding to the region of the chlorine absorption continuum. The similarity in the two systems is further shown by the manner in which the carbon monoxide pressure enters the rate laws of both reactions and by the fact that both reaction rates appear to involve oxygen explicitly at low oxygen pressures and become independent of it at higher pressures.[9] The only interpretation of these facts probably is that both the carbon monoxide and oxygen play identical roles in the rate mechanisms of the two reactions.

Another point of analogy between the two systems is evident in the manner in which the rate depends upon the intensity of light absorbed. A significant difference also exists, however. It has been shown[11] that, in the case of the chlorine-sensitized reaction, the rate at low chlorine pressures is proportional to the light absorbed while at higher pressures it becomes proportional to the square root of the light absorbed. In the intermediate range such exponents as Schumacher's $I_{\text{abs.}}^{0.71}$ are found. This change of function with pressure has been most plausibly explained by assuming two different methods of recombination of the chlorine atoms produced by the light. At low pressures destruction of the chlorine atoms by collision with impurities or the reaction vessel walls is greater, while at higher pressures recombination is brought about predominantly by second order collisions in the gas phase. In the case of the phosgene-sensitized oxidation no such change is found in the dependence of the rate on the light absorbed, the rate remaining proportional to the square root of the light absorbed. Reasoning by analogy, this can be interpreted by assuming the predominance throughout the range studied of some homogeneous second order chain terminating process corresponding to the disappearance of chlorine atoms in the chlorine-sensitized reaction. On the basis of the mechanism of Lenher and Rollefson this would be $COCl + Cl \longrightarrow CO + Cl_2$.

A satisfactory derivation of the rate law from any mechanism yet devised has not been obtained. The derived equations either give the wrong

---

(9) The dependence of the rate of the chlorine sensitized reaction at low oxygen pressures on the oxygen has not been determined quantitatively as the phosgene formation predominates under such conditions. In that case the amount of carbon dioxide formed in a given time is determined by the law governing the division of the carbon monoxide between the two competing reactions, whereas in the system we are discussing in this paper the reaction between carbon monoxide and oxygen can be considered to be the only one occurring.

exponents for the factors involved or else do not, in the limit of high oxygen pressures, yield an expression independent of the oxygen. Likewise no satisfactory derivation has yet been made of the rate law for the chlorine-sensitized reaction. Recently Warming[10] has shown that the mechanism of Schumacher[11] is thermodynamically unsound. There can be but little question, in the light of the experimental results obtained, that practically the same mechanism will be found to fit both the chlorine-sensitized and the phosgene-sensitized reactions, with the exception of the primary process, which in the phosgene reaction must be $COCl_2 + h\nu \longrightarrow COCl + Cl$. After this initial process, it is to be expected that oxygen and carbon monoxide will take part in the same reactions in the reaction chains of both sensitized oxidations. In devising a mechanism, the principal difficulty appears to be to get a set of partial reactions the rate law of which will involve the square root of the oxygen at low oxygen pressures and will become independent of oxygen at higher pressures. It has been found possible, however, to set up the following mechanism from which the low pressure rate law may be derived.

$$COCl_2 + h\nu \longrightarrow COCl + Cl \tag{1}$$
$$CO + Cl + M \longrightarrow COCl + M \tag{2}$$
$$COCl + O_2 \longrightarrow CO_3Cl \tag{3}$$
$$CO_3Cl + CO \longrightarrow 2CO_2 + Cl \tag{4}$$
$$CO_3Cl + COCl \longrightarrow 2CO_2 + Cl_2 \tag{5}$$

This mechanism leads to the rate law

$$d(CO_2)/dt = 2I_{abs.} + kI_{abs.}^{1/2}(CO)^{1/2}(O_2)^{1/2}$$

which, considering the large value of the quantum yield, reduces to

$$d(CO_2)/dt = kI_{abs.}^{1/2}(CO)^{1/2}(O_2)^{1/2}$$

the low oxygen pressure experimental rate law. The assumption of CO_3Cl in the above mechanism presents nothing contradictory to the mechanism already given for the direct photochemical oxidation of phosgene (8), since in that mechanism process (3) as written above is kinetically identical to $COCl + O_2 \longrightarrow CO_2 + ClO$. CO_3Cl may, perhaps, be regarded as a reactive peroxide of the sort postulated by Bodenstein.[12] In the high pressure region it is conceivable that oxygen inhibits the oxidation as has been observed in other cases.[12] This might be brought about through the action of oxygen at some stage following reaction (3), resulting in a process which would terminate the chain. Except for this effect this system is in perfect agreement with the other reactions for which the intermediate COCl has been postulated and must be considered as additional evidence for the existence of that substance.

Summary

A kinetic study of the phosgene-sensitized oxidation of carbon monoxide has been made. The rate law for low pressures of oxygen has been shown

(12) Bodenstein, *Sitzber. preuss. Akad. Wiss.*, 73–88 (1931).

to be: $d(CO_2)/dt = kI_0^{1/2}(COCl_2)^{1/2}(CO)^{1/2}(O_2)^{1/2}$, and for higher oxygen pressures: $d(CO_2)/dt = kI_0^{1/2}(COCl_2)^{1/2}(CO)^{1/2}$. As in the case of the chlorine-sensitized oxidation of carbon monoxide, it has not yet been possible to develop a mechanism for the reaction capable of explaining the experimental rate law over the whole range. The two reactions have been compared and have been found to be very similar in several important respects. It has been concluded, therefore, that probably very similar mechanisms will be found to apply to both chlorine- and phosgene-sensitized oxidations.

The Reduction by Hydrogen and the Thermal Decomposition of Nitrides Made by the Reaction of Ammonia with Various Promoted and Unpromoted Iron Synthetic Ammonia Catalysts

BY P. H. EMMETT AND KATHARINE S. LOVE

Phase rule investigations[1] have in the last few years shown that at least two nitrides of iron are formed by passing ammonia over iron in the temperature range 400 to 525°. At 450° and one atmosphere pressure, for example, an ammonia–hydrogen mixture containing between 30 and 70% ammonia will convert the iron into a body-centered cubic nitride whose composition is close to that of Fe_4N; ammonia percentages ranging from 70 to 100% will convert the Fe_4N into an hexagonal nitride whose composition varies with the percentage of ammonia from one approximating Fe_3N to one that closely corresponds to Fe_2N. As a part of a study being made of the mechanism by which iron catalysts are able to effect the synthesis of ammonia, the rates and nature of the decomposition and of the reduction by hydrogen of the various nitrides, prepared both from active and from inactive iron ammonia catalysts, have been determined.

Experimental

The various nitrides were prepared by passing suitable ammonia–hydrogen mixtures at about 400° over finely divided iron synthetic ammonia catalysts obtained by the reduction in hydrogen of fused Fe_3O_4. Portions of each nitride preparation were analyzed by a modified Kjeldahl method; usually samples were also taken for x-ray photographs. Table I gives the composition of the samples and in some cases the nature of their x-ray pattern. Samples for both x-ray and chemical analysis were obtained in an oxygen-free nitrogen atmosphere.

TABLE I

COMPOSITION OF IRON NITRIDE SAMPLES

Designation of nitride	Source of iron from which the nitride was made[a]	Nitrogen in sample, %[b]	X-Ray analysis
A-1	Cat. 973	5.91	Only Fe_4N lines
A-2	Cat. 973	11.00	Only Fe_3N-Fe_2N lines
B-1	Cat. 984	6.04	Only Fe_4N lines
B-2	B-1	10.81	
B-3	Cat. 984	7.53	Fe_3N-Fe_2N 50% Fe_4N 50%
B-5	Cat. 984*	5.64	
C-1	Cat. 921	6.02	Only Fe_4N lines
C-2	C-1[c]		
D-1	Cat. 920	6.01	Only Fe_4N lines
D-2	Cat. 920*	7.89	
D-3	D-2	6.02	
E-1	Iron oxalate[d]		

[a] The samples designated by * were 8–14 mesh; all others were ground to pass a 200-mesh screen. The catalysts were obtained by the reduction in hydrogen of variously promoted fused magnetites: 984 contains 2.92% Al_2O_3 and 1.05% K_2O; 921, 1.05% Al_2O_3; 920, 0.2% K_2O; 973, 0.15% Al_2O_3. [b] The formula Fe_4N corresponds to 5.90% nitrogen; Fe_2N, to 11.14% nitrogen. [c] C-1 was flushed with N_2 at 100° for two hours. [d] This Fe_4N sample was made by Mr. Brunauer and used by him in phase rule studies.

The decomposition experiments were carried out in an all-glass apparatus, the evolved nitrogen being measured in a gas buret at about atmospheric pressure. The furnace used was fitted with an aluminum block. When once adjusted the furnace could be kept at a given temperature by controlling it with hand rheostats, the variation being about 2° during a decomposition run. The experimental uncertainty in each determination of the amount of nitrogen evolved per five minutes per gram of iron was about 0.03 cc.

The reduction experiments were carried out by bringing the nitride samples to the desired temperature in a stream of nitrogen and then quickly replacing the nitrogen with pure hydrogen. The exit gas was analyzed continually for ammonia.

Results on the Thermal Decomposition of the Nitrides of Iron

(a) Fe_4N Decomposition.—The general nature of the decompositions of the various Fe_4N samples can be judged from the types of curves shown in Fig. 1. The decompositions seem to be autocatalytic, the rates being low at first and increasing as a function of time. One peculiar exception to this rule was noted. The decomposition rate of the Fe_4N made from a doubly promoted catalyst was in a certain temperature range practically independent of the nitrogen content of the sample. This is illustrated in a run on sample B-3, Fig. 1. The first portion of the curve represents the decomposition of a little Fe_3N known to be present. The rate of nitrogen evolution after the sample had attained a composition corresponding to Fe_4N was practically constant at 0.28 to 0.32 cc. of nitrogen per g. of Fe for about thirteen hours; when about 95% of the nitrogen had been evolved the rate decreased rapidly, dropping from 0.3 cc. to less than 0.01 cc. per five minutes per gram of Fe in about one and one-half hours. This zero order solid decomposition made possible the determination of the temperature coefficient of nitrogen evolution from Fe_4N.

Temperature coefficients were determined on four Fe_4N samples, three of them being taken from nitride preparation B-1 and the fourth from an 8–14 mesh sample designated as B-5. The logarithms of the rates of decomposition in these temperature coefficient runs are shown plotted against $1/T$ in Fig. 2. Each point on these curves represents an hour's decomposition run at a given temperature; no change in rate was observed in any of these cases during the hour's run. It is evident however that the temperature coefficient calculated by going back from a higher to a lower temperature is considerably smaller than that obtained by going from a lower to a higher temperature. Thus in run 26 the slope of the line connecting points a, b and c corresponds to 69,000 calories and that connecting points d, e and f, 52,000 calories; however, one connecting points c and d indicates an energy of activation of only 42,000 calories. The real energy of activation of the decomposition is apparently between the two extreme values. From the combined results it is concluded that the energy of activation for the reaction $Fe_4N = 4Fe + 1/2N_2$ is about 50,000 calories.

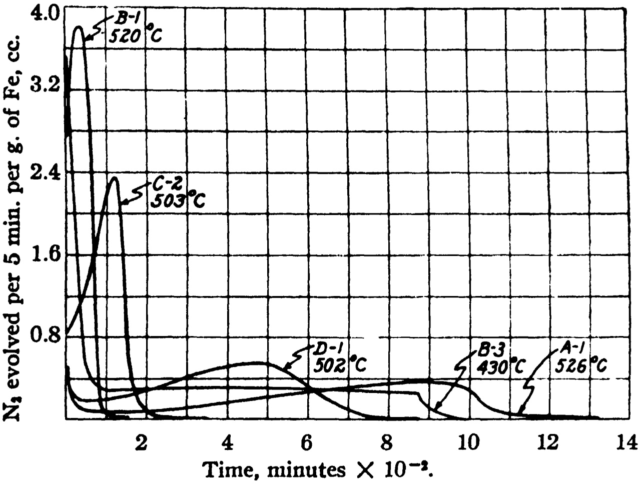

Fig. 1.—Rate of decomposition of Fe_4N prepared from various iron synthetic ammonia catalysts.

In the course of the experiments on thermal decomposition it became evident that some unknown factor was causing the rate of decomposition of the Fe_4N made from doubly promoted catalysts to vary from run to run. In particular, it became evident that the first run (always made within twenty-four hours after preparing the Fe_4N sample) gave higher results than any of the succeeding runs. The cause of this decrease after the initial run was not satisfactorily ascertained. Increased precautions in excluding possible traces of water vapor and of oxygen from the sample during its storage after the first run seemed to decrease the effect; however, it was still very much in evidence in the last few experiments made. To illustrate the magnitude of the disturbing factor and at the same time show the relative approximate rates of decomposition of the various nitrides studied, the logarithms of the maximum rates observed are plotted against $1/T$ in Fig. 2. It must of course be borne in mind that only in the case of the zero order decompositions of the doubly promoted sample is such a method of comparing rates quantitative. Runs 36, 38 and 13 on sample B were all "first runs," as was also run 41 on sample D; a comparison of the rates in these four runs indicates that Fe_4N prepared from an active synthetic ammonia catalyst, B, decomposes much more rapidly than that made from a comparatively inactive catalyst, D. Unfortunately the runs on the pure iron catalyst (2 and 4, Fig. 2) and on the catalyst promoted with Al_2O_3 (10 and 11, Fig. 2) are either "second" runs or made several days after the preparation of the samples. Hence rate comparisons involving these two last catalysts are not warranted. The decomposition of the Fe_4N made from iron obtained by the reduction of ferric oxalate was by far the slowest of all nitride samples tried (Run 6).

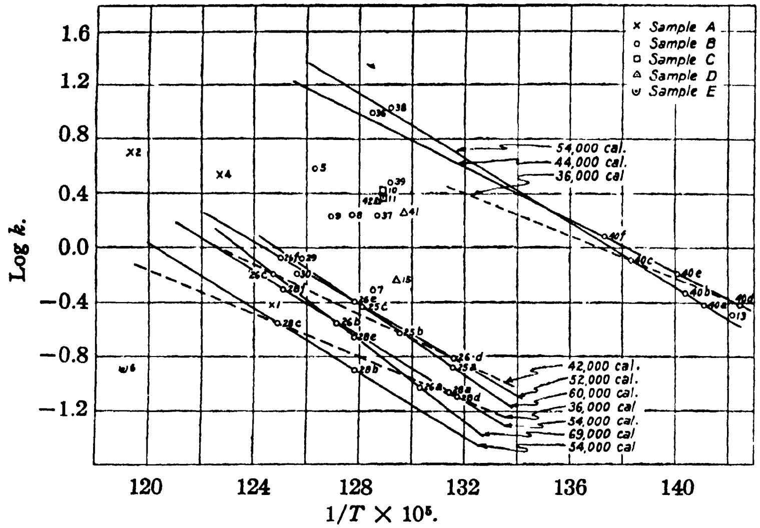

Fig. 2.—Variation of the rate of decomposition of Fe_4N with the temperature and with the type of catalyst used as a source of iron. The temperature coefficient of Fe_4N decomposition as determined by runs 25, 26, 28 and 40 is expressed in terms of the energy of activation, E, involved in the decomposition.

Since it appeared that traces of poison might affect the rate of decomposition of the nitrides quite appreciably, a few experiments were made in which poisons were deliberately added to the nitrides and the effect on the rate noticed. The addition of about 0.2 cc. of either hydrogen sulfide or oxygen to the doubly promoted Fe_4N sample at the end of run 28 produced no appreciable change in rate; however, an additional 1.3 cc. of hydrogen sulfide caused the rate to drop immediately from 0.25 to 0.014 cc. per five-minute period.

(b) **Fe_2N Decomposition.**—Typical decomposition curves for Fe_2N samples are shown in Fig. 3. The decomposition is of a non-autocatalytic nature, decreasing rapidly with the evolution of nitrogen until a composition close to that of Fe_3N is reached. The rate of decomposition of Fe_3N into Fe_4N is much slower than the initial Fe_2N rate, is many times faster than the decomposition of Fe_4N, and at several temperatures is nearly independent of the fraction of the sample decomposed.

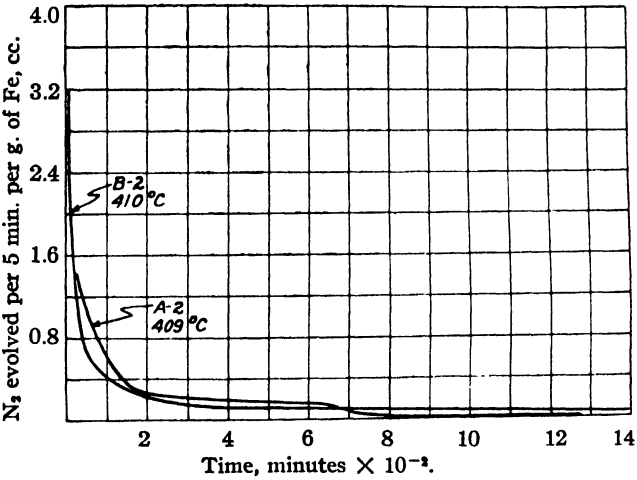

Fig. 3.—Rate of decomposition of Fe_2N into Fe_4N.

Reduction of the Iron Nitrides by Hydrogen

The Fe_2N samples prepared from the various catalysts reduce much more rapidly in hydrogen at about 180° than do the Fe_4N samples. Typical Fe_4N reduction curves, as shown in Fig. 4, indicate that the reaction is slightly if at all autocatalytic. A distinct maximum in the curve was always obtained about ten or fifteen minutes after the beginning of a two-hour reduction run; this apparent maximum might, however, be due to the adsorption of ammonia by the samples, since these were initially carefully flushed with nitrogen to zero ammonia content at the temperature of the run. The agreement between successive reduction runs is illustrated by runs 33 and 34 at 245°.

Two reduction curves for Fe_2N shown in Fig. 4 are characterized by unusually sharp maxima. x-Ray photographs of samples which during a similar run were removed before reaching the maximum reduction rate and at two successive points after reaching the maximum showed increasing amounts of Fe, decreasing amounts of Fe_2N and Fe_3N, and no Fe_4N. The photographs were not sufficiently clear to permit differentiation between Fe_2N and Fe_3N.

Discussion

Mittasch, Kuss and Emert[2] have studied the rate of ammonia decomposition over Fe_2N and compared it with the rate of nitrogen evolution from Fe_2N *in vacuo*. In the course of their work they measured the rate of nitrogen evolution from a sample of promoted iron synthetic ammonia catalyst that had been converted into Fe_2N. The decomposition curves for 350 and 400° published in Fig. 8 of their article permit one to estimate approximately the rates of decomposition of the Fe_4N portion of their nitrides at these two temperatures. The temperature coefficient calculated from the curves corresponds to about 45,000 calories energy of activation for the Fe_4N decomposition, which agrees satisfactorily with the average value, 50,000 calories, found in the present work. They point out that the Fe_2N decomposed at practically a constant rate until about one-half the nitrogen was evolved. Our own results showed similarly constant rates for Fe_3N and Fe_4N under favorable conditions but not for Fe_2N.

Winter[3] has recently studied the rate of ammonia decomposition over iron. In the course of his experiments he found that the energy of activation of the decomposition was about 50,000 calories per mole of ammonia. Furthermore, the kinetics he obtained indicated that the slow step in the reaction was the escape of nitrogen from the surface of the catalyst. It is interesting to note that the temperature coefficient of the decomposition of Fe_4N in our own experiments corresponded to an energy of activation of about this same value.

On several different occasions attempts have been made to correlate the rate of surface reactions with the frequency, f, with which the energy of a surface atom or molecule has an opportunity to readjust itself. Thus, for example, Topley[4] pointed out that if it be assumed that the molecules of adsorbed ammonia on tungsten or platinum have a chance to readjust their energies 10^{12} times per second, then from the known areas of metal involved it can be shown that the observed rate can be accounted for by assuming that the fraction $e^{-E/RT}$ of these energy changes will result in the adsorbed ammonia molecules picking up the observed energy of activation E. The value 10^{12} is about the magnitude of the "restrahlen" vibration frequencies for solids. In an analogous way it is interesting to show by calculation whether or not the observed rate of nitrogen evolution in the zero order decomposition of Fe_4N made from a doubly promoted catalyst can be accounted for by similar postulates. If every nitrogen atom (or molecule) on the surface of the Fe_4N sample gets a chance to change its energy content f times per second, and if all atoms (or molecules) picking up the 50,000 calories per mole average energy of activation noted in the present work escape from the surface, then the rate r of nitrogen evolution in cc./min./g. of iron will be given by the equation $nfe^{-E/RT}$ (60) = r, where n is the number of cc. of nitrogen constituting a monomolecular surface layer on 1 g. of iron, f is the atomic vibration frequency for Fe (about 10^{12} times per second), and E is the energy of activation observed in the present experiments for the thermal decomposition of Fe_4N. An approximate value for n obtainable from the poisoning experiments of Almquist and Black[5] and from some recent adsorption experiments of Emmett and Brunauer[6] is 1 cc. of nitrogen per gram of iron. Inserting 50,000 calories for E and 10^{12} for f, the calculated value of r is 0.17 cc. per minute per gram of iron at 430°. The experimental value is 0.06 cc. per gram. This agreement is of course much better than the accuracy with which the values of E or of n are known. It indicates however that the observed rate is of the right magnitude to be explained on such a basis.

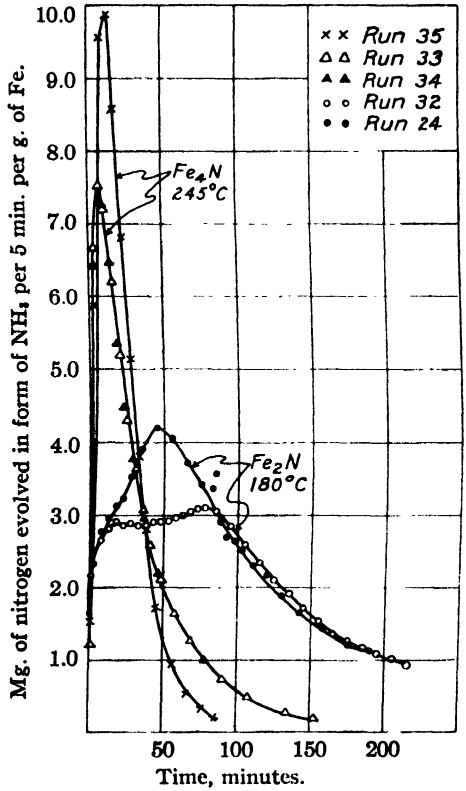

Fig. 4.—Rate of reduction of Fe_4N and Fe_2N by hydrogen.

Attention should be called to one other interesting experimental observation in connection with the thermal decomposition of Fe_4N made from a doubly promoted catalyst. In a decomposition experiment on sample B-3 shown in Fig. 1 and in three other similar experiments on Fe_4N samples from this same doubly promoted catalyst, an abrupt decrease in the rate

---

(5) Almquist and Black, THIS JOURNAL, 48, 2814 (1926).

(6) Emmett and Brunauer, *ibid.*, 55, 1738 (1933).

of nitrogen evolution occurred at the end of the run. The volume of gas evolved after the beginning of this abrupt rate decrease was in all cases about that estimated to correspond to a monomolecular surface layer, being between 1 and 3 cc. of nitrogen per gram of iron. This is in accord with the hypothesis that the escape of nitrogen from the surface of the iron is the slowest step in the decomposition, the sudden break in the rate curve being naturally associated with the point at which all except the surface nitrogen has escaped. However, if the rate of diffusion of nitrogen through iron at 430° is sufficiently great, then the 1 to 3 cc. of nitrogen evolved after the break might include some of the dissolved nitrogen as well as nitrogen adsorbed on the surface of the iron.

The reduction curves for Fe_2N shown in Fig. 4 can be explained as a summation of two non-autocatalytic reactions: $3/2H_2 + 3Fe_2N = 2Fe_3N + NH_3$ and $3/2H_2 + Fe_3N = 3Fe + NH_3$. The very sharp maxima in the Fe_2N reduction curves seem more consistent with this interpretation than with the conclusion that the reduction of Fe_2N proceeds to Fe in one step and is autocatalytic.

In one experiment on the reduction of Fe_2N part of the experimental points were obtained by flushing out any adsorbed ammonia between each five-minute reduction period. These points and those obtained without such flushing lay equally well on the reduction curve, thus showing definitely that the adsorption of ammonia is not sufficiently large to account for the initially low ammonia values obtained at the start of each Fe_2N reduction run.

Summary

The rates of decomposition and of reduction by hydrogen of Fe_4N and Fe_2N made from active and from rather inactive iron synthetic ammonia catalysts have been determined. The decomposition of Fe_4N entails an energy of activation of about 50,000 calories. Fe_4N prepared from active catalysts decomposes more rapidly than that prepared from less active catalysts.

Densities of Mixtures of Benzene with Phenylethyl Alcohol and with Methyl Salicylate

BY RAYMOND C. GLOWASKI AND CECIL C. LYNCH, JR.

In a study of volume relations in mixtures of non-polar liquids it was observed that there were no data available on densities for two of the binary mixtures studied: namely, benzene–phenylethyl alcohol and benzene–methyl salicylate. The present investigation was undertaken to determine at 25° densities of these binary mixtures at various concentrations.

Materials.—Benzene C. P. and phenylethyl alcohol from the Eastman Kodak Company were allowed to stand over anhydrous calcium chloride for about a week and then fractionally distilled at 761 mm. The fraction of benzene boiling between 79.7 and 80.0° and that of phenylethyl alcohol boiling between 217–219° were collected and showed densities of 0.8724 and 1.0160, respectively, at 25°. Repeated distillations failed to alter the density. These densities agreed well with values obtained by Tyrer and by Washburn and Read,[1] for benzene, and by Szamatolski for phenylethyl alcohol.[2]

Methyl salicylate (artificial oil of wintergreen from Eimer and Amend), after the passage through it of dry air for several hours at its boiling point, was fractionally distilled at 18–19 mm. The definitive fraction was collected between 106.9 and 108.1° and showed a density of 1.080 at 25° in good agreement with the values given by Umney.[3]

Density Measurements.—The solutions were prepared by direct weighing of the components into tared glass-stoppered bottles, the more

volatile benzene being added last. The samples were then well shaken and placed in a thermostat at 25.00 ± 0.05° for four to six hours. Pycnometers (of 5 or 25 cc. volume) which had been carefully standardized with distilled water were then filled with the mixtures and kept in the thermostat for two hours. The liquids were in all cases completely miscible.

The densities given in the table are all means of at least three determinations which never differed from one another by six units in the fourth decimal place. The average deviation of these measurements from the means for all the observations was one unit in the fourth decimal place.

Summary

Densities of mixtures of benzene and phenylethyl alcohol and of benzene and methyl salicylate have been determined over the entire range of concentration.

The Induced Oxidation of Anthracene in the Autoxidation of Benzaldehyde

BY G. E. K. BRANCH, H. J. ALMQUIST AND E. C. GOLDSWORTHY

Introduction

It is well known that inhibition of the autoxidation of benzaldehyde by anthracene is temporary. When small quantities of anthracene are added to a benzaldehyde–oxygen mixture, there is a slow absorption of oxygen, which accelerates until the normal rate of absorption of oxygen by benzaldehyde is reached. At this stage the anthracene has been almost entirely oxidized to anthraquinone. This oxidation is an induced reaction, for it does not occur in an inert solvent.

The most likely mechanisms for oxidations of inhibitors are (1) that the inhibitor is oxidized by a link in the autoxidation chain, the products of this reaction being incapable of carrying on the chain, and (2) that the inhibitor is oxidized by the peroxide molecules that are dropped out of the autoxidation chain.

Alyea and Bäckström[1] have conclusively shown that in the inhibition of the autoxidation of sodium sulfite by several alcohols the breaking of the autoxidation chain and the induced oxidation are a single process. Bäckström and Beatty[2] have assumed the same to be true of the autoxidation of benzaldehyde inhibited by anthracene. The evidence was that measurements on extrapolation to high concentrations of anthracene showed a molal equivalence between the anthraquinone and benzoic acid formed. It was necessary for the authors to assume that the first product in the oxidation of anthracene absorbed oxygen to form anthraquinone without the assistance of the oxidation of benzaldehyde.

---

(1) Alyea and Bäckström, THIS JOURNAL, 51, 90 (1929).

(2) Bäckström and Beatty, *J. Phys. Chem.*, 35, 2530 (1931).

Measurements of the rate of absorption of oxygen by benzaldehyde in the presence of varying quantities of anthracene can be used to prove the identity of the act of inhibition with the mechanism of the induced oxidation, and, if the proof is satisfactory, to obtain the rate of initiation, and average length of the chains, which are the fundamental constants of the autoxidation.

Oxidation Induced by Inhibition.—On the assumption that the breaking of a chain is always accompanied by the oxidation of a molecule of anthracene, and is the only source of this induced reaction, we may follow Alyea and Bäckström[1] and set up the equations,

$$\mathrm{d}O/\mathrm{d}t = k_0k_1/(k_2 + k_3A) \qquad (1)$$

and

$$-\mathrm{d}A/\mathrm{d}t = k_0k_3A/(k_2 + k_3A) \qquad (2)$$

in which O is the oxygen absorbed, k_0 is the rate of initiation of chains and $k_1/(k_2 + k_3A)$ is the average length of the chains in inhibited autoxidation. This last expression involves k_1, k_2, k_3 and A, which are the specific rate constants of the chain-continuing process, of the normal chain-breaking reaction and of the chain-breaking reaction involving anthracene and the concentration of anthracene, respectively.

Inspection of equation (2) shows that when k_3A is large with respect to k_2, $-\mathrm{d}A/\mathrm{d}t$ is independent of the concentration and kind of inhibitor. The measurements of Alyea and Bäckström show that this condition is fulfilled in the autoxidation of sodium sulfite inhibited by high concentrations of alcohols.

Combining equations (1) and (2) gives

$$-\mathrm{d}O/\mathrm{d}A = k_1/k_3A \qquad (3)$$

Integration of equations (2) and (3) gives

$$t = \frac{1}{k_0}\left(\frac{k_2}{k_3}\log\frac{A_0}{A} + A_0 - A\right) \qquad (4)$$

and

$$O = \frac{k_1}{k_3}\log\frac{A_0}{A} \qquad (5)$$

Hence

$$t = \frac{1}{k_0}\left\{\frac{k_2O}{k_1} + A_0(1 - e^{-k_3O/k_1})\right\} \qquad (6)$$

in which A_0 is the initial concentration of anthracene.

Figure 1 shows a series of plots of oxygen absorbed against time for autoxidations of benzaldehyde, inhibited by varying initial concentrations of anthracene. The shapes of these curves are those that would be expected from equation (6), if k_3 is large with respect to k_2. But equation (6) demands that the time taken to absorb a given quantity of oxygen be a linear function of the initial concentration of anthracene with the origin at the time taken in the absence of an inhibitor. This is not true when the concentration of benzoic acid is high.

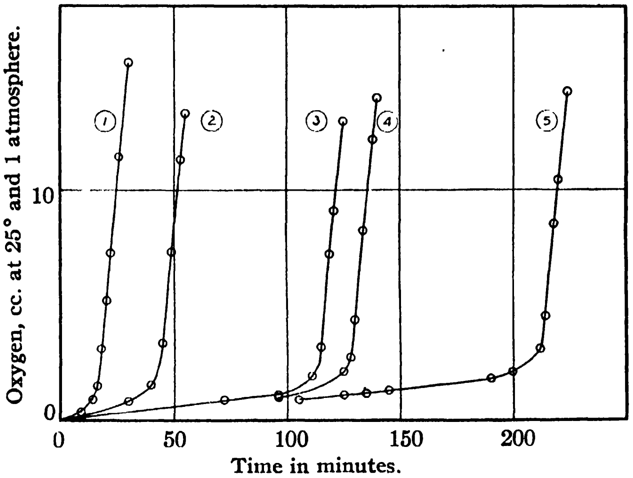

Fig. 1.—Oxygen absorption curves obtained with mixtures of benzaldehyde, benzoic acid, 0.444 molal, and anthracene at the following molalities: 1, 0.000040; 2, 0.000080; 3, 0.000132; 4, 0.000140; 5, 0.000200.

In Table I the times taken to absorb 5 cc. of oxygen at varying initial concentrations of anthracene and benzoic acid are shown. The numbers in the last column of this table are the times taken to absorb 5 cc. of oxygen

minus five minutes, the time that would be taken in the absence of any inhibitor, divided by the corresponding initial concentrations of anthracene. According to equation (6) this quantity should be a constant, whereas it increases with increasing initial concentrations of anthracene, this increase being most accentuated at the higher initial concentrations of benzoic acid.

There are other observations that militate against the theory that in the autoxidation of benzaldehyde inhibitors are oxidized only in the act of inhibition. It can be seen from Fig. 1 that the approach to a normal reaction after a period of inhibition is very rapid. The times taken to reach 90 and 95% of the normal rate of absorption of oxygen differ but little. It is therefore possible to measure fairly definitely the time taken to oxidize practically all of the inhibitor, and to obtain approximately an average rate for this reaction by dividing the initial concentration of the inhibitor by this time. But according to equation (4) these fairly definite inhibition periods could be obtained only if $k_2/k_3 \log A_0/A$ is small with respect to A_0, even when A is so small that the rate of absorption of oxygen is nearly that in the absence of inhibitor. The average rate of oxidation of the inhibitor will then be k_0, which is independent of what inhibitor is used. Also the presence of an extraneous substance that by itself has little inhibitory power should not affect this rate. These expectations are not fulfilled. Anthracene, phenanthrene, potassium iodide and hydroquinone are oxidized at very different rates. Benzoic acid, which by itself has only a small influence on the rate of absorption of oxygen by benzaldehyde, has a marked action on the rate of oxidation of some inhibitors. It decreases the rate of the induced oxidations of anthracene and of potassium iodide, increases that of hydroquinone, but does not affect that of phenanthrene. These facts are shown in Table II.

TABLE II

AVERAGE RATE OF OXIDATION OF SOME INHIBITORS IN MOLES PER LITER PER MINUTE, IN THE ABSENCE OF INITIAL BENZOIC ACID, AND WITH 0.073 *M* BENZOIC ACID

Inhibitor	Concentration, moles/liter	Av. rate without initial benzoic acid	Av. rate with initial benzoic acid
Anthracene	0.0002	0.00001	0.000003
Phenanthrene	.001	.0001	.0001
Potassium iodide	.00002	.0000003	.00000015
Hydroquinone	.0004	.00002	.00004

Induced Oxidation by Peroxides.—The alternative mechanism for the oxidation of inhibitors is a reaction between the inhibitor and peroxide molecules that have insufficient energy to carry on the chain. These peroxides are present in measurable quantities during autoxidations. In the case of the autoxidation of benzaldehyde inhibited by anthracene, the isolatable perbenzoic acid cannot be assigned the role of oxidizer of the inhibitor, for its action on anthracene is known to be too slow. However, it has been shown that peroxides more reactive than perbenzoic acid are present during the autoxidation of benzaldehyde. That anthracene is destroyed by these peroxides is easily demonstrable.

When the autoxidation of benzaldehyde is allowed to occur for a few minutes, the absorption of oxygen is inhibited on the addition of anthracene, but regains its normal rate in a much shorter time than it does when the same charge of anthracene is added before the admission of oxygen. Thus in a reaction started with 0.444 *M* benzoic acid and 0.0002 *M* anthracene, the normal rate of absorption was reached more than two hundred minutes after the start of the reaction, but when the same amount of anthracene was added after the reaction had proceeded for eleven minutes, the period of inhibition was only nineteen minutes. This experiment is depicted in Fig. 2. The curve shown in Fig. 2 should be compared with that on the extreme right in Fig. 1.

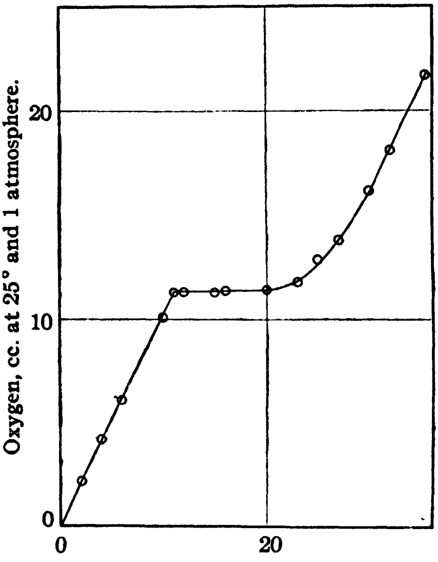

Fig. 2.—Oxygen absorption curve obtained by adding anthracene to a concentration of 0.0002 molal eleven minutes after the reaction of a mixture of benzaldehyde and benzoic acid 0.444 *M* had started.

In this experiment the anthracene is oxidized by peroxides whose concentrations are rapidly diminishing below the values of the steady state of normal reaction, for they are being used up by reaction with benzaldehyde. The way in which this occurs is pictured in Fig. 3, which shows an experiment in which the oxygen is removed by evacuation after an autoxidation has been started. The descending branch of curve 3 shows a removal of peroxides, which is approximately first order with respect to peroxides. The rate constant is about 0.13 reciprocal minutes.

Benzoic acid has a remarkable effect in increasing the life of anthracene exposed to an oxygen-benzaldehyde mixture. This can be described in terms of the times taken to achieve normal rates of absorption of oxygen,

Table III

Variation of Time Taken to Absorb 5 Cc. of Oxygen with Initial Concentration of Benzoic Acid

Initial concentration of anthracene = 0.0002 *M*

Initial concn. of C_6H_5COOH in mole/liter	0	0.039	0.074	0.100	0.229	0.444
Time taken to absorb 5 cc. of O_2 in minutes	20	55	70	105	145	214

or more definitely in terms of the times taken to absorb a chosen amount of oxygen.

This effect of benzoic acid can be explained by the theory of oxidation of the inhibitor by non-chain-continuing peroxide molecules. The oxidation of an inhibitor competes with that of benzaldehyde. It has been shown[3] that the oxidation of benzaldehyde is preceded by an interaction between peroxide and benzoic acid. If this interaction increases the relative chance of the oxidation of benzaldehyde over that of the inhibitor, benzoic acid prolongs the inhibition period, but if the reverse is true it diminishes the inhibition period. The former case is exemplified by anthracene and potassium iodide, the latter by hydroquinone. The oxidation of phenanthrene is not affected by benzoic acid, possibly because this very rapidly oxidized inhibitor attacks the peroxide even before the latter has time to react with benzoic acid.

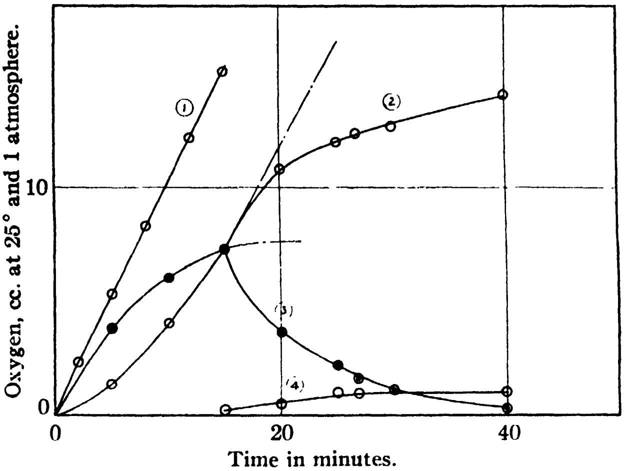

Fig. 3.—The variation with time of the distribution of absorbed oxygen in experiments started with a mixture of benzaldehyde and benzoic acid in which the oxygen was evacuated after fifteen minutes of reaction: 1, the total oxygen absorbed; 2, the oxygen as benzoic acid; 3, the oxygen as peroxides; 4, the oxygen discrepancy.

On the assumption that all of the anthracene is oxidized by peroxides incapable of continuing the autoxidation chain, the absorption of oxygen in the presence of anthracene can be expressed by the differential equations

$$\mathrm{d}O/\mathrm{d}t = k_0k_1/(k_2 + k_3A) \qquad (1)$$

$$-\mathrm{d}A/\mathrm{d}t = k_4PA, \text{ and} \qquad (7)$$

$$\frac{\mathrm{d}P}{\mathrm{d}t} = \frac{k_0k_1}{k_2 + k_3A} - f(P,A,B) \qquad (8)$$

in which P is the concentration of peroxides, and $f(P,A,B)$ is a function of peroxide, anthracene and benzoic acid concentrations, and represents the rate at which peroxides are used up.

---

(3) Almquist and Branch, THIS JOURNAL, 54, 2293 (1933).

A rough test of equation (7) may be obtained by measurements of the peroxide concentrations and rates of absorption of oxygen during inhibition. Such measurements are shown in Fig. 4.

Equations (1) and (7) can be combined to give

$$\frac{d^2O}{dt^2} \Big/ P\,\frac{dO}{dt}\left(1 - \frac{k_2}{k_0k_1}\,\frac{dO}{dt} = k_4\right) \tag{9}$$

k_0k_1/k_2 is the normal rate of absorption of oxygen and is about one cc. per minute.

The approximate constancy of k_4 is shown in Table IV. The values given in this table are derived from the curves shown in Fig. 4.

				Average 0.15

In Fig. 4 and Table IV we have used the equivalent of one cc. of oxygen as a concentration unit. Throughout all our experiments 2.25 cc. of benzaldehyde was used, and the oxygen was measured at 25° and one atmosphere. One cc. of oxygen corresponds to 0.0182 mole per liter. The rate constant, k_4, is therefore about 8.2 in the more usual units liters per mole per minute.

Inspection of Fig. 4 shows that an amount of benzoic acid equivalent to 1 cc. of oxygen, that is, 0.0182 *M*, is formed before the anthracene is all used up. The initial anthracene was 0.000125 *M*. It is therefore apparent that nearly all of the peroxide formed is eventually reduced by benzaldehyde rather than by anthracene. As a large quantity of benzoic acid was present at the start (0.444 *M*), the main reduction of the peroxides occurs at a constant rate, and the function ($f(P,A,B)$ of equation (8) is proportional to P. Although this simplification is insufficient to permit the expression of oxygen absorbed in terms of the time and the initial concentration of anthracene, it is obvious that the solution of equations (1), (7) and (8), with the above simplifications will give the time to absorb a chosen volume of oxygen as approximately a linear function of the initial concentration of anthracene. This follows, because in by far the greater part of the inhibition period, dP/dt is very small. But as has already been mentioned this time is a higher order function of the initial concentration of anthracene. Further we have observed that this phenomenon is more marked with high than with low concentrations of benzoic acid. Both of these observations are shown in Table I.

The most natural resolution of this paradox is that the peroxide is not a single substance, but is a mixture of small quantities of more active with larger quantities of less active peroxides. A large fraction of the more active peroxides is reduced by anthracene. Their concentration is a quadratic function of the reciprocal of the concentration of anthracene, for they are formed more slowly and are used up more rapidly at high than at low concentrations of anthracene. Hence $-\mathrm{d}A/\mathrm{d}t$ is a decreasing function of A, and the time taken to absorb 5 cc. of oxygen increases more than proportionally with increase in the concentration of anthracene.

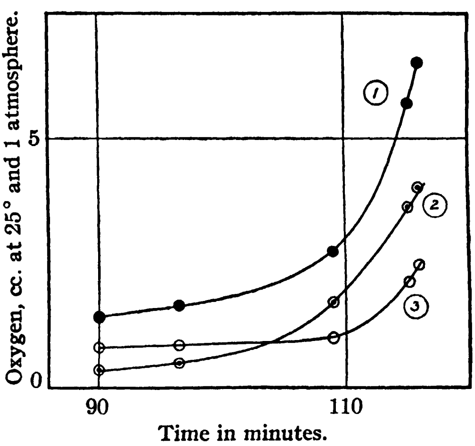

Fig. 4.—The variation with time of the distribution of absorbed oxygen during an induction period: 1, the total oxygen absorbed; 2, the oxygen as peroxides; 3, the oxygen as benzoic acid.

That this phenomenon is more marked with high than with low concentrations of benzoic acid indicates that the rate of oxidation of anthracene relative to that of combination with benzoic acid is greater for the more active than for the less active peroxides. When the concentration of benzoic acid is low, most of the induced reaction occurs through the less effective but more abundant peroxides, and the rate of oxidation of anthracene is approximately independent of its concentration. But when the concentration of benzoic acid is high a greater fraction of the induced reaction is carried by the more effective peroxides, and the decrease in the rate of oxidation of anthracene with increase in its concentration is marked.

Bäckström and Beatty's[2] evidence of an equivalence between anthracene oxidized and benzoic acid formed at high concentrations of anthracene shows that anthracene not only is oxidized by peroxide molecules of insufficient energy to propagate the autoxidation chain, but also is oxidized by peroxide molecules that are links in this chain. It must therefore be assumed that anthracene is oxidized (1) in the act of inhibition, (2) by non-chain-continuing peroxides that react with anthracene in preference to benzoic acid and (3) by similar peroxides that react with benzoic acid in preference to anthracene. At very high concentrations of anthracene, non-chain continuing peroxides are rare and the first mechanism predominates. At low concentrations of anthracene the other two mechanisms predominate, their relative effectiveness being largely determined by the concentration of benzoic acid. This theory of the combined action of chain-continuing and non-chain-continuing peroxides has been sponsored by Stephens[4] for the induced oxidation of inhibitors in general.

Experimental Part

In these experiments the benzaldehyde and benzoic acid must be very pure. The benzaldehyde was purified by repeated fractional distillations in an atmosphere of carbon dioxide and was kept in the dark under an excess pressure of this gas. The benzoic acid was purified by repeated crystallizations from water. The standards of purity were the absence of all signs of an induction period in the absence of deliberately added inhibitors, and the ability to obtain within ten per cent. of the normal rate of absorption of oxygen at the end of an inhibition period produced by an inhibitor. The anthracene and other inhibitors were ordinary C. P. chemicals. They were added immediately before an experiment, for, even with the greatest care, it was found that solutions of anthracene in benzaldehyde lost some anthracene when kept.

The reactions were all carried out in the dark, in the same vessel and with uniform shaking. The change in the volume of oxygen was measured

in a constant pressure gas buret connected to the reaction vessel. Reaction vessel and gas buret were thermostated at 25°.

Peroxide and benzoic acid concentrations were measured by stopping the reaction and analyzing for peroxides with potassium iodide and sodium thiosulfate, and for benzoic acid by acidimetry. Curves in which the concentrations of these substances are shown are compounded from a series of experiments stopped at different times. A curve for the absorption of oxygen can be obtained in a single experiment.

(5) The rate of reduction of peroxides by benzaldehyde was found to vary somewhat in different preparations of benzaldehyde. The rate constant 0.13 reciprocal minutes given in Table VII checks that (0.14) obtained by dividing d*O*/d*t* (1 cc. per minute) by the steady state concentration of peroxides (7.2 cc.). In another preparation of benzaldehyde Almquist and Branch[3] obtained 0.18 reciprocal minutes by dividing the rate of formation of benzoic acid by the peroxide concentration, and in the same experiment d*O*/d*t* divided by the steady-state concentration of peroxides was 0.17 reciprocal minutes. Apparently the reaction is affected by traces of impurities, probably water or metallic salts. Its rate is quadrupled by 0.002 *M* $FeCl_3$.

experiments and analyses need not be described in greater detail here, for a fuller account of them can be found in the earlier paper by Almquist and Branch.[3]

The experimental results from which the curves in Figs. 1, 2, 3 and 4 are shown in the appended Tables V, VI, VII and VIII. The additional results shown in Tables I, II and III are obtained from experimental results so similar to those shown in Table V that they need not be described in detail.

Summary

Measurements of the absorption of oxygen by benzaldehyde in the presence of benzoic acid and small concentrations of anthracene and some other inhibitors were made.

It is pointed out that the results obtained are not in agreement with the theory that the induced oxidation of anthracene in benzaldehyde occurs only in the act of inhibition.

It is shown by direct experiment that anthracene is oxidized by peroxides formed during the autoxidation of benzaldehyde. The rate of this reaction is first order with respect to each of the reactants. The rate constant has been measured.

The effect of benzoic acid on the induced oxidations has been explained on the basis of competitive reductions of the peroxides by the inhibitor and by benzaldehyde with preliminary combination with benzoic acid.

In order to explain the way in which the absorption of oxygen depends on the initial concentrations of anthracene and benzoic acid, it has been assumed that the peroxides responsible for the induced oxidation of anthracene are a mixture of substances or states having different specific reactivities toward anthracene, benzoic acid and benzaldehyde.

Heat Capacities of Cis and Trans Dichloroethylenes

BY A. R. OLSON AND F. W. BRITTAIN

In an investigation of *cis-trans* reactions which is in progress in this Laboratory, the heat capacities of the two forms of gaseous dichloroethylene were needed. No data for these substances were found in the literature, and so we determined them by the velocity of sound method. Eucken and Mücke[1] and Kneser[2] have discussed objections to the use of high frequency sound waves for heat capacity determinations. As will be seen later, these objections, apparently, do not apply to the dichloroethylenes in the temperature range in which we worked.

Briefly the method consists in determining the wave length of sound waves in the gas to be investigated. These waves are produced by a quartz crystal which is responding to an alternating current of known frequency. For an ideal gas the equation connecting heat capacity with the velocity of sound, W, is

$$C_v = \frac{R}{(MW^2/RT) - 1} = \frac{R}{\gamma - 1} \quad (1)$$

For a gas obeying van der Waals equation we can write

$$C_v = R/(\gamma - 1 + \phi) \quad (2)$$

in which

$$\phi = \frac{2aP}{(RT)^2} - \gamma\frac{2bP}{RT} \quad (3)$$

if we neglect higher order terms. Since the correction due to first order terms is small, this procedure is justified.

The van der Waals constants a and b have not been determined, and so they were estimated by two different methods. In the first method the average effect of substituting a chlorine for a hydrogen was determined for six substances for which the a's and b's were known, and then twice this correction was made in the constant for ethylene. In the second method, the average percentage change in the constants due to replacing two hydrogens bound to carbon by a carbon–carbon double bond was determined for five substances, and this reduction was made in the constants for ethylene dichloride. By the first method $a = 0.0319$ and $b = 0.00455$ and by the second method $a = 0.0303$ and $b = 0.00437$. The average values, $a = 0.031$ and $b = 0.0045$ are probably accurate to about 10%. This uncertainty in a and b corresponds to an uncertainty of 0.05 calorie/deg. in the heat capacity and this is less than the average experimental error.

Apparatus.—Electrical circuits for sonic interferometers have been described so often in the literature[3] that the description of the circuit is here limited to the wiring diagram in Fig. 1. The variation of the current through the microammeter due to sonic interference was from 20 to 100 microamperes, depending on the distance separating the reflector from the crystal.

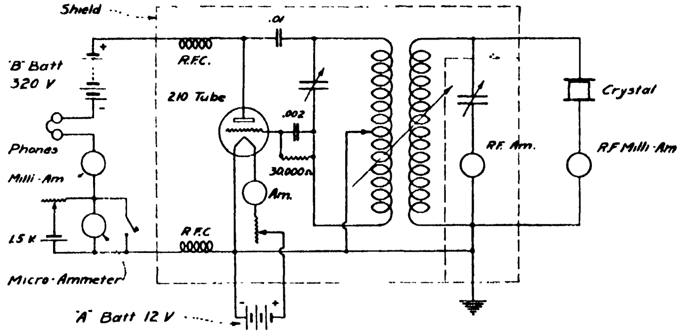

Fig. 1.—Wiring diagram for the sonic interferometer.

The quartz crystal was 28 × 23 × 22 mm. It was cut so that the 28 mm. axis was inclined about 18.5° away from the optic axis toward the mechanical axis, so as to get a vibration perpendicular to the face which was parallel to the reflector, as shown by Wright and Stuart.[4] The vibration frequency of the crystal was determined at various pressures and temperatures, not only directly by a General Radio standard wave meter, but also by checking by harmonic bracketing against several local broadcasting stations. The error in the frequency is estimated to be not more than 0.1%.

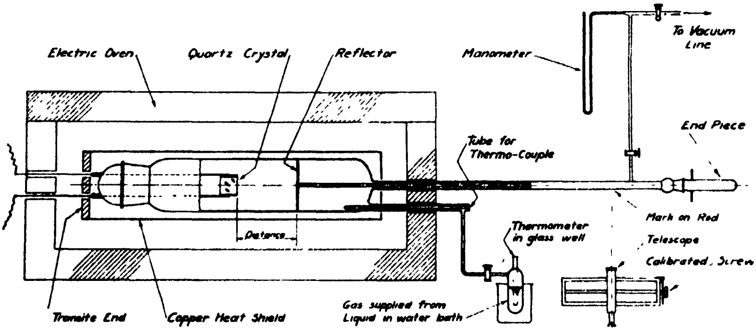

Fig. 2.—Assembly for measuring the velocity of sound.

The glass cylinder shown in Fig. 2 is about 70 mm. by 350 mm. The crystal mounting is depicted in Fig. 3. The reflector could be moved parallel to itself by turning the end piece. Positions of the reflector were read to 0.01 mm. The lubricant recommended by Meloche and Fredrick[5] was used on the joints exposed to the dichloroethylene. The gas pressure was determined by the temperature of liquid dichloroethylene

in the side-tube. The temperature of the gas in the cylinder was measured by a thermocouple. The temperature measurements are probably accurate to about 0.25°.

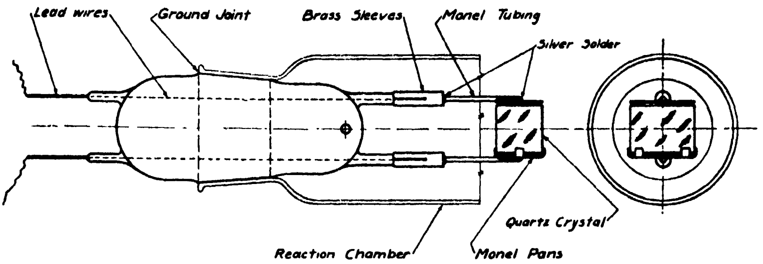

Fig. 3.—Mounting for quartz crystal.

The temperature of the gas between the oscillating crystal and the reflector was higher than the ambient gas due to the energy in the sound waves. This was checked not only by experiments on air at atmospheric pressure where all the data for computing the temperature from $w^2 = RT/M\ (C_p/C_v)$ are known, but also by inserting an alcohol thermometer in the path of the sound waves. For the crystal we used, a current through the crystal of 3.3 m. a. produced an increase of 0.3 degree in air at atmospheric pressure. By keeping the gas pressure and the current low enough, we were able to make this temperature correction unimportant.

Experimental Procedure

A new sample of gas was introduced into the reaction chamber for each run. The chamber was pumped out and filled with gas several times to eliminate air. The final pumping was run several hours at a pressure less than 10^{-3} mm. The pressure of the gas was taken as that corresponding to the temperature of the liquid and checked by the manometer. For the runs with the oven at room temperature the liquid was about

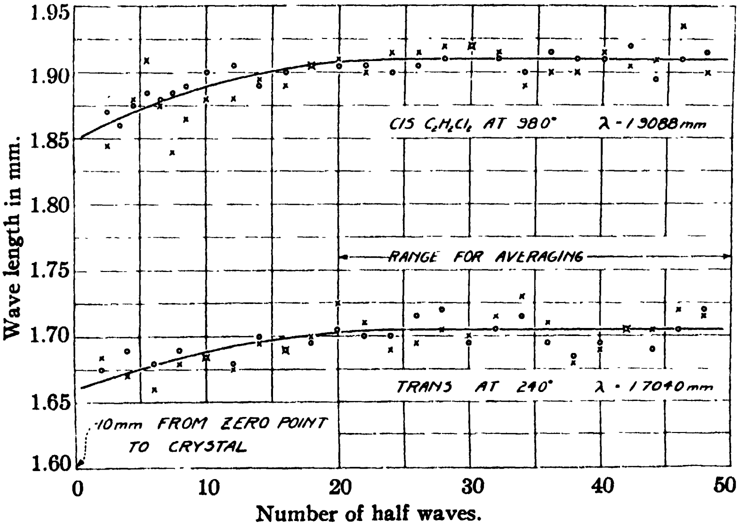

Fig. 4.—Typical curves of wave length as a function of the number of half waves separating the reflector from the crystal.

10° for the *cis* and at 0° for the *trans*. For runs at higher temperature the liquid was at room temperature for the *cis* and 8 to 10° for the *trans*. The oven, meanwhile, was heated to near the desired temperature and was allowed to stand for at least one hour to come to temperature equilibrium. The gas was allowed to stand in the reaction chamber with the crystal oscillating for at least half an hour before the run to ensure steady operation. For the runs, the reflector was set either 1 or 3 cm. away from the crystal and the first peak called the 0 or 20 half-wave position to correspond. The reflector was moved out and readings of distance taken for every other peak to the fiftieth peak and then repeated as the reflector was moved toward the crystal. The manometer, thermometers and other instruments were read before, at the middle and at the end of each run.

Typical readings of the wave length as a function of the number of half-wave lengths separating the reflector from the crystal are shown in Fig. 4. Due to the obvious trend in the wave length at small distances, only the sixteen readings between the twentieth and the fiftieth nodes were used for averaging. The average wave length was computed from $[(A + B \ldots N) - (a + b + \ldots n)]/N^2$ where $A, B \ldots N$ are the first eight readings and $a, b \ldots n$ are the second series of eight readings. From the two separate averages obtained as the reflector was moved in or out, a final average reading was computed for the runs. These final average wave lengths agreed within 0.1%.

Results and Conclusions

The data and the computed values of C_v are summarized in Tables I and II and are shown on curves on Figs. 5 and 6. It is interesting to note the decrease of 1 to 2% in the wave length close to the crystal which occurred consistently in all tests whereas Pierce and Reid[3] working with air and carbon dioxide found an increase.

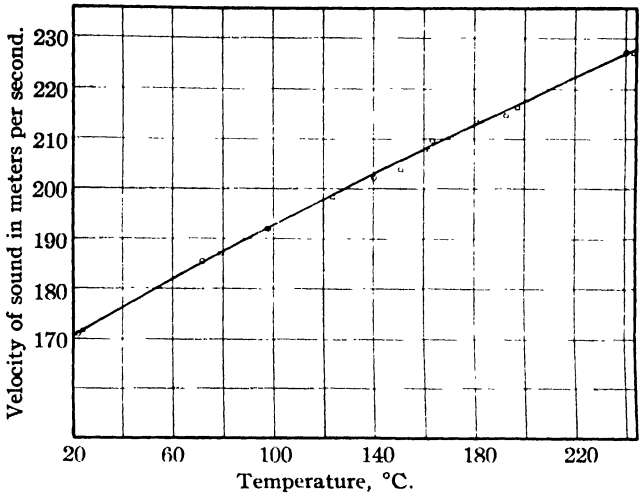

Fig. 5.—Velocity of sound in *cis*- and *trans*-dichlorethylene: ○, *cis*-dichloroethylene; □, *trans*-dichlorethylene.

The accuracy of the final results suffers from the nature of the equation, for the errors in measuring the velocity of sound are increased some fifteen times in computing C_v due to the fact that the velocity is squared and that γ (about 1.16) is so nearly equal to 1. Frequency and wave length were each measured to about 0.1%. This corresponds to an error of about 0.25 calorie in the heat capacity, agreeing with an average deviation of about 0.26 calorie for the individual experimental values.

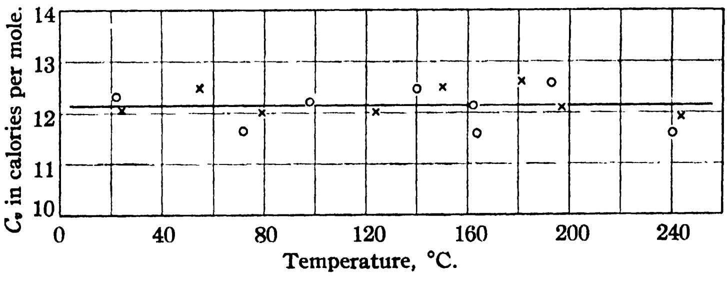

Fig. 6.—Heat capacity of *cis*- and *trans*-dichloroethylene: ○, *cis*-dichloroethylene; ×, *trans*-dichloroethylene.

Referring to Fig. 6, the data may be interpreted by assuming that C_v is the same for both gases and is constant over the whole range of temperatures with an average value of 12.14 ± 0.26 calories per mole.

Eucken and Mücke point out that with too high a frequency, the velocity of sound experiments on air and similar gases measures only a part of the vibrational energy. Kneser states that following a small and sudden change of pressure, each of the internal degrees of freedom, rotational and vibrational, requires a certain length of time to establish equilibrium with the translational degrees and that this time interval is a function of $h\nu/RT$. For a given temperature there is a critical frequency (or range of frequencies) below which the half period is relatively large and the particular internal degree is measured and above which the half period is too small for the degree to respond. For a given frequency and temperature, the internal degrees of freedom with relatively low $h\nu$ values will be measured and those with a relatively high $h\nu$ value will fail to respond. Due to the constancy of C_v over such a large temperature range, it appears to be quite likely that both forms of dichloroethylene have three vibration degrees of freedom of such low frequencies that they respond fully, and that the other nine vibrations have such high frequencies that they do not contribute appreciably to the heat capacity below 250°.

Acknowledgment is made to Mr. N. W. Garden, who constructed part of the apparatus, and to Mr. W. Maroney, who prepared the pure samples.

The Activity Coefficients of Hydrochloric Acid in Aqueous Solutions Containing Either Sodium or Potassium Perchlorate

BY STUART J. BATES AND JOSEPH W. URMSTON

Recent investigations,[1] both theoretical and experimental, have emphasized the fact that except in very dilute solutions, activity coefficients of strong electrolytes cannot be accurately calculated from theoretical considerations alone.

The original Debye–Hückel development of the ion attraction theory showed that in dilute solution the activity coefficient is chiefly determined by the ionic strength. Its dependence upon other factors was later taken into account and more accurate formulas derived. These involve constants whose numerical values must be determined from the data themselves.[1d] One of these constants "A" is related to the ionic diameters. By making certain assumptions regarding its value in mixtures of electrolytes, relatively simple relations between activity coefficients have been obtained.[2] The question as to the validity of such assumptions and relations must be settled by experiment.

---

[1] (a) Debye and Hückel, *Physik. Z.*, **24**, 185 (1923); (b) Brönsted and La Mer, THIS JOURNAL, **46**, 555 (1924); (c) Noyes, *ibid.*, **46**, 1080, 1098 (1924); (d) Hückel, *Physik. Z.*, **26**, 93 (1925).

Of the electrolytes which have been investigated at various activities, hydrochloric acid has been the most carefully and extensively studied, both in its own pure solutions and in mixtures. However, previous investigators[3] of mixtures have restricted themselves to adding salts containing the chloride ion. In this paper, and in that by Murdoch and Barton which immediately follows, the effects of other types of electrolytes, including those which contain no ion in common with those of hydrochloric acid, are described.

The activity of hydrochloric acid and hence the mean activity of its ion in salt mixtures may be computed from measurements of the electromotive forces of cells of the type

$$H_2\ (1\ \text{atm.}),\ HCl\ (m_1) + \text{salt}\ (m_2),\ AgCl + Ag$$

The quantities concerned are related by the equation

$$E - E_0 = -(2RT/F)\ln m_1\alpha \tag{1}$$

Here E is the measured electromotive force, E_0 the molal electrode potential, α the geometric mean activity coefficient of the ions of hydrochloric acid (more briefly, the activity coefficient of hydrochloric acid).

An added salt other than a chloride to be suitable for experiments of this nature must not react with the constituents of the cell and must possess certain other properties. Thus (1) it should be the salt of a strong acid, (2) the silver salt of its acidic constituent should be soluble, (3) it should not be the salt of an acid, like nitric acid, which may act as an oxidizing agent in solution and (4) it should be quite soluble. These conditions greatly restrict the choice of salts. However, sodium perchlorate appears to fulfil them admirably. Hence this salt was employed. In addition, in order to compare the relative effects of potassium and sodium ions, measurements were made employing potassium perchlorate; this salt is satisfactory except that it is not as soluble as could be desired.

Experimental Procedure

The cells used consisted of three silver–silver chloride half cells and two hydrogen half cells, each of the latter containing two hydrogen electrodes. The half cells were connected through stopcocks.

The hydrogen electrodes were of platinum foil, first covered electrolytically with a thin coating of gold and then with one of platinum black. They were washed with nitric acid and then with many changes of water; they were kept in water until placed in the cell. The hydrogen electrodes prepared in this manner checked to 0.02 or 0.03 millivolt.

[2] Harned, THIS JOURNAL, **48**, 326 (1926).

[3] (a) Harned, *ibid.*, **38**, 1986 (1916); (b) Güntelberg, *Z. physik. Chem.*, **123**, 199 (1926); (c) Harned and Åkerlöf, *Physik. Z.*, **27**, 411 (1927); (d) Randall and Breckenridge, THIS JOURNAL, **49**, 1435 (1927).

Electrolytic silver and precipitated silver chloride prepared from dilute solutions according to the directions of Randall and Young[4] were used for the silver–silver chloride electrode. These electrodes checked one another to 0.1–0.2 mv. The final results for the cells at various concentrations showed an average deviation from the smooth curve of not more than 0.15 mv.

The cells were in an oil thermostat regulated to 25 ± 0.05°. The electromotive forces were measured by the aid of a type K Leeds and Northrup potentiometer using as a standard a Weston cell that was frequently checked against a cell recently certified by the Bureau of Standards.

The hydrochloric acid was obtained by diluting a c. p. acid to a density of 1.1 and distilling in an all-glass still, which had been repeatedly employed for this acid distillation. Only the middle portion of the distillate was used; it was diluted to the desired concentrations, and these were checked by the silver chloride gravimetric method. The sodium perchlorate was prepared by the addition of perchloric acid of c. p. grade to a c. p. sodium carbonate, the product was twice recrystallized from water. Potassium perchlorate (c. p.) was purified by three crystallizations from water. Conductivity water was used in the preparation of all solutions.

Several series of measurements were made. In each series the electromotive force of the cell containing a solution of hydrochloric acid only was first determined. Then to weighed quantities of this solution were added weighed amounts of the pure dry salt and the electromotive forces of the cells containing these solutions were measured. In this manner any uncertainty due to errors of a constant nature may be minimized.

(4) Randall and Young, THIS JOURNAL, 50, 989 (1928).

The experimental results are given in Table I. All concentrations are expressed as moles per 1000 g. of water.

The effect of added salt upon the activity coefficient of hydrochloric acid may be readily computed for each series of experiments from the relation

$$\ln \alpha/\alpha_0 = (F/2RT)\Delta E \tag{2}$$

Here ΔE is the difference between the electromotive force of the cell containing hydrochloric acid at the concentration m_1 and that of the cell containing hydrochloric acid at the concentration m_1 and in addition an added salt; α_0 is the activity coefficient of the acid in the former solution, α its coefficient in the mixture.

Randall and Young[4] have made a careful study of all available data from which the activity coefficients of hydrochloric acid in its own pure solutions may be computed and have given a set of consistent values for 25°. We have taken our values for the pure solutions (α_0) from their results and have then computed values for mixtures by means of the above equation. Such values interpolated to round values of the acid concentration and of ionic strength are given in Table II.

Discussion

These results will be considered here chiefly with reference to a relation which may be[2] obtained from the ion attraction theory with the aid of the assumption that the ionic diameters of all ions present in the solution are the same. This relation [see also Brönsted, THIS JOURNAL, **45**, 2898 (1923)] which applies to solutions of constant ionic strength is as follows

$$\log \alpha = \log \alpha_0 + k(\mu - m) \tag{3}$$

Here α and m are the activity coefficient and molal concentration, respectively, of an electrolyte in a mixture of ionic strength μ; α_0 is its activity coefficient in its own pure solution of ionic strength μ; and k is a constant characteristic of both electrolytes.

Heretofore this relation has been tested only with salts containing the common chloride ion. Harned[3a] found this relation to hold closely for hydrochloric acid in the presence of added potassium, sodium or lithium chlorides at ionic strengths of 0.1, 1.0 and 3.0 molal; Hawkins[5] has shown

(5) Hawkins, THIS JOURNAL, **54**, 4480 (1932).

that the range for these three added chlorides extends to 6 molal. It holds less closely for sodium and potassium hydroxides in their corresponding chloride solutions at high ionic strengths.[6] Güntelberg[3b] determined the activity coefficients of hydrogen chloride in solutions of added lithium, sodium, potassium and cesium chlorides at an ionic strength of 0.1 molal. His results agree very closely with the requirements of the above equation.

In Fig. 1 are plotted for the ionic strengths 0.1, 0.25, 0.5, 0.7 and 1.0 the logarithms of the activity coefficients of hydrochloric acid in sodium perchlorate mixtures against concentrations m of the acid. The relations are linear, thus satisfying the requirements of equation (3). All of the lines have the same slope, namely, k = 0.0244. None of the points deviate from the linear relation by an amount corresponding to as much as 0.20 mv. In the same figure are plotted the corresponding values which Harned[2] obtained in this range of ionic strengths for the effect of added sodium chloride upon hydrochloric acid. These points lie along the same straight lines, thus showing that added sodium chloride and added sodium perchlorate have the same effects upon the activity coefficient of hydrochloric acid.

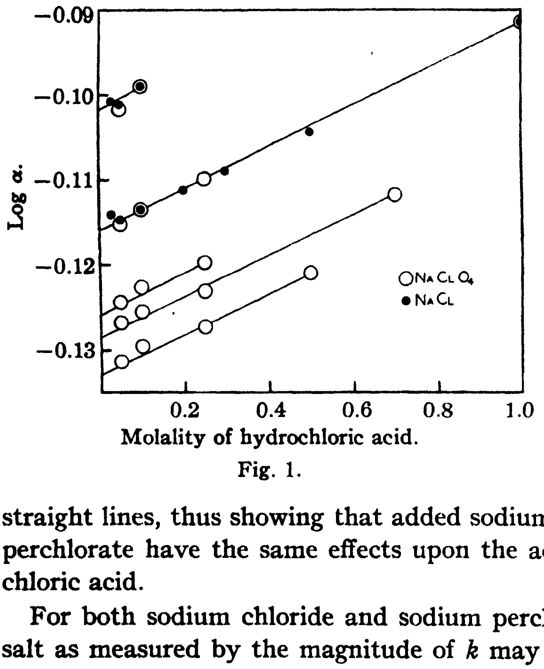

Fig. 1.

For both sodium chloride and sodium perchlorate the effects of added salt as measured by the magnitude of k may be somewhat greater at an ionic strength of 0.1 molal than at higher concentrations. Due in part to the small concentration range involved, the slope for this line is more uncertain[2] than that for the other series.

In agreement with the fact that added sodium chloride and sodium perchlorate have substantially the same effect upon the activity coefficients of hydrochloric acid, the few values obtained for the effect of added potassium perchlorate agree closely with those calculated upon the basis of the effect of added potassium chloride.[2] In each case the potassium salt has a greater effect than has the sodium salt.

It might be expected that because sodium chloride and sodium perchlorate have substantially the same effect upon hydrochloric acid, they would have the same effect upon other electrolytes. That this is not the

---

(6) Harned and Harris, THIS JOURNAL, 50, 2633 (1928).

case is shown by the results of Bozorth,[7] who determined the effect of added salts including sodium chloride and sodium perchlorate on the solubility of potassium perchlorate. At an ionic strength of 0.5 molal he found that the activity coefficient of potassium perchlorate was about 7% greater in the presence of added sodium chloride than it was in the presence of added sodium perchlorate. It is thus seen that these effects are very specific and hence in general predictions cannot be made with any degree of confidence.

Summary

The effect of added sodium perchlorate, an electrolyte without a common ion, upon the activity of hydrochloric acid at ionic strengths between 0.05 and 1.0 molal and at concentrations of acid from 0.05 to 0.25 molal has been determined by means of electromotive force measurements of the cell H_2, HCl (m_1) + $NaClO_4$ (m_2), AgCl + Ag.

The equation proposed by Harned for solutions of constant ionic strength μ, namely, $\log \alpha = \log \alpha_0 + k(\mu - m)$, holds well for hydrochloric acid in the presence of added sodium perchlorate. The value of the constant k is independent of the ionic strength.

Added sodium perchlorate has, within the range where comparisons are possible, quantitatively the same effect upon the activity coefficient of hydrochloric acid as does added sodium chloride. There is hence no essential difference upon the activity coefficient of hydrochloric acid, between the effect of a salt with a common ion and one without a common ion.

A few measurements were made employing potassium perchlorate as the added salt, but they could not be extensive because of its limited solubility. Within the concentration range investigated, potassium perchlorate has the same effect as has potassium chloride upon the activity of hydrochloric acid.

In general, however, all of these effects are quite specific.

The Activity Coefficients of Hydrochloric Acid in Aqueous Solutions Containing Either Sodium Dithionate or Perchloric Acid

BY PHILIP G. MURDOCH[1] AND ROBERT C. BARTON

The effect of added salts upon the activity of hydrochloric acid has been studied by a number of investigators.[2] All of these, except Bates and Urmston,[2d] have employed chlorides for the added salts. In the present investigation the influence of the added electrolytes sodium dithionate and perchloric acid was studied, that is, the effect of a negative bivalent ion and that of hydrogen ion were determined. These salts are among the relatively few (except chlorides) which are suitable for this purpose.

The electromotive forces of cells of the type H_2, $HCl(m_1)$ + salt (m_2), $AgCl + Ag$ were determined at 25°. Except where noted the experimental procedures were similar to those of Bates and Urmston.[2d]

The sodium dithionate used was prepared by recrystallizing a C. P. product three times from water. It gave no turbidity with silver nitrate. The salt crystallizes as $Na_2S_2O_6 \cdot 2H_2O$. The proportion of water was determined at intervals and always checked very closely with the calculated value.

The perchloric acid solutions were prepared from the 60% C. P. product of the G. Frederick Smith Corp. It had been redistilled *in vacuo* and was stated to contain not more than 0.004% non-volatile matter. The acid gave no test for chlorides, sulfates or lower oxy-acids.

All mixtures were made up by weight from stock solutions and from solid salt. All concentrations are expressed as moles per 1000 g. of water.

That dissolved air has an effect upon the potential of the calomel electrode in acid solution due to a reaction between mercury, chloride ion, hydrogen ion, and oxygen, has been clearly demonstrated by Randall and Young.[3] The similar effect on the silver–silver chloride electrode is less serious. Güntelberg[2b] found some influence and removed oxygen from his solutions by means of nitrogen. Randall and Young, however, discovered no measurable effect upon silver–silver chloride spiral[4] electrodes in 0.1 *M* hydrochloric acid.

The change in the potential of the silver–silver chloride electrode due to the presence of oxygen is associated with the removal of chloride ion from the solution in immediate contact with the electrode, and is proportional to the fractional change in the activity of the chloride ion. Hence, other factors remaining the same, it is especially noticeable at low chloride concentrations. The removal of the chloride is facilitated by high hydrogen-ion concentrations and therefore increases with increasing acid concentration. Thus with solutions 0.01 *M* in hydrochloric acid and 0.09 *M* in perchloric acid, a decrease of about 1 millivolt was observed when oxygen-free solution was substituted for one which had been in equilibrium with air. With solutions in which the chloride content was 0.1 *M* or greater, the effect was always less than 0.1 millivolt. Hence for those solutions in which the chloride concentration was 0.1 *M* or less, the Linhart type of cell, in which the whole solution is saturated with hydrogen, was employed. Hydrogen was bubbled through the cell for twenty-four hours before introducing the silver–silver chloride electrodes.

[4] Spiral electrodes may offer less silver surface and hence less opportunity for oxidation than do electrodes employing electrolytic silver crystals. The latter were used by Güntelberg and in this investigation.

Further evidence that a reaction occurs between silver and hydrochloric acid in the presence of air was obtained by shaking a piece of bright silver wire with 0.5 *M* hydrochloric acid for twenty-four hours. At the end of that time the surface of the metal was covered with a characteristic coating of silver chloride which darkened upon exposure to light.

[a] The changes in hydrochloric acid concentration result from the water of crystallization present in the sodium dithionate crystals added.

Experimental Results

The measured values of the electromotive forces at 25° and the activity coefficients are given in Table I. For solutions containing sodium dithionate the activity coefficients were computed with the aid of the values for pure hydrochloric acid solutions[5] α_0 by means of the following relation

$$\ln \alpha/\alpha_0 = (F/2RT)\Delta E \qquad (1)$$

Here ΔE is the difference between the electromotive force of the cell containing hydrochloric acid m_1 molal and that containing both hydrochloric acid m_1 molal and added dithionate.

In the case of the perchlorate mixtures such a direct comparison with the values for pure hydrochloric acid solutions is not possible. For such solutions the activity coefficients α were calculated from the equation

$$E - E_0 = -(RT/F)\ln(m_1 + m_2)m_1\alpha^2 \qquad (2)$$

Here m_1 and m_2 are the molal concentrations of the hydrochloric and perchloric acids, respectively; E is the measured electromotive force of the cell containing both acids; E_0 the molal electromotive force for the hydrogen silver–silver chloride cell. Here it is taken as 0.2221 volt.[6]

In Table II the data are shown interpolated to round values of hydrochloric acid and of added electrolyte.

Discussion

In general, the results of this and similar investigations must, for the present at any rate, be considered chiefly from the empirical standpoint. On account of the physical complexity of the problem[7] and of mathematical difficulties[8] the treatment of pure electrolytes is, except for very dilute solutions, incomplete and the situation is more complicated in the case of mixtures. However, brief reference will be made to certain relations between the results of this and of other investigations.

In many mixtures of constant ionic strength μ, the activity coefficient α of hydrochloric acid has been found to be related to the concentration m of

---

(5) Values which Randall and Young[3] have given for pure hydrochloric acid were used.

(6) Randall and Young.[3] Carmody [THIS JOURNAL, 54, 188 (1932)] has recently arrived at the value 0.2223. Since the values used for the activity coefficients of pure hydrochloric acid are those of Randall and Young, their value of E_0 is employed. The effect of any uncertainty in the values of these investigators is to change all activity coefficients by a constant factor.

(7) Bjerrum, *Trans. Faraday Soc.*, **23**, 445 (1927).

(8) Gronwall, La Mer and Sandved, *Physik. Z.*, **29**, 350 (1928).

the acid in the mixture and to the activity coefficient α_0 of pure hydrochloric acid at the same ionic strength by the equation.[2a]

$$\log \alpha = \log \alpha_0 + k(\mu - m) \qquad (3)$$

In Fig. 1 are plotted values of log α against those of m at various ionic strengths for the sodium dithionate and perchloric acid mixtures. The above equation demands a linear relation. It will be seen that this relation is closely followed by the dithionate mixtures and is approximately obeyed by the perchloric acid mixtures. The values for the latter mixtures, particularly in dilute solutions, are, however, subject to somewhat greater uncertainty so that for both added electrolytes equation (3) possibly holds within the experimental error. In the case of added sodium dithionate it would appear that k of equation (3) has the same value at different ionic strengths; however, the data are neither sufficiently numerous nor accurate to be certain of this.

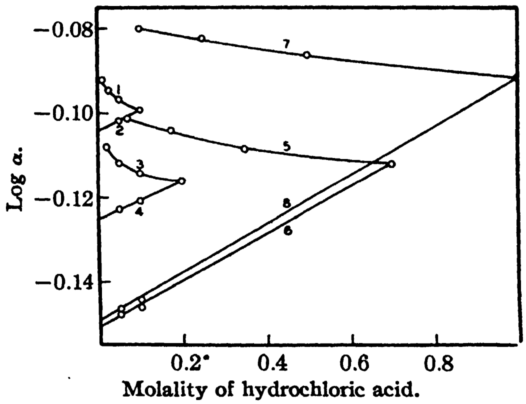

Fig. 1.—Added $HClO_4$: Curve 1, μ = 0.1; Curve 3, μ = 0.2; Curve 5, μ = 0.7; Curve 7, μ = 1.0. Added $Na_2S_2O_6$: Curve 2, μ = 0.1; Curve 4, μ = 0.2; Curve 6, μ = 0.7; Curve 8, μ = 1.0.

Equation (3) has been found to hold for dilute mixtures containing only univalent ions. The results of Randall and Breckenridge[2c] show that it is not followed by mixtures containing barium chloride or lanthanum chloride, but that the similar relation in which m, the concentration of the hydrogen ion constituent, is replaced by the geometric mean molality of the hydrogen and chloride ion constituents does hold. As these authors state, they give no derivation for this rule. Their relation does not hold for the data here presented for perchloric acid. Since equation (3) holds for sodium dithionate solutions, their rule does also, because for solutions containing no common ion the two relations are identical.

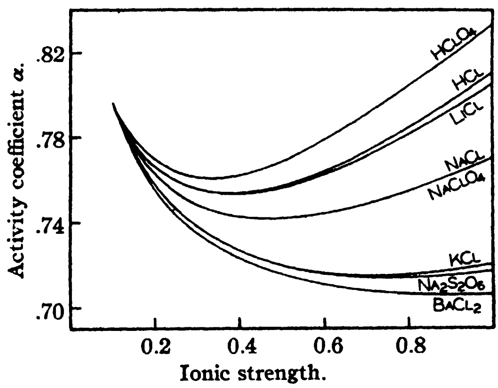

Fig. 2.—Effect of added salts upon 0.1 M HCl.

The comparative effect of increasing amounts of various salts upon the activity coefficient of hydrochloric acid is shown in Fig. 2. Here the activity coefficient of the acid, whose concentration is maintained constant at 0.1 *M*, is plotted against the ionic strength for the added electrolytes, lithium chloride,[2a] sodium chloride,[2a] potassium chloride,[2a] sodium perchlorate,[2d] barium chloride,[2c] sodium dithionate and perchloric acid. The figure shows that, as is to be expected, the minimum value for the activity coefficient is shifted most strongly to higher ionic strengths by those added salts which cause the greatest decrease in its value.

Of these added salts the activity coefficients of lithium chloride, sodium chloride, potassium chloride and barium chloride are known.[9] At a given ionic strength their activity coefficients decrease in the above order. Figure 2 shows that the effects of these salts on hydrochloric acid are in the same order. There is, however, no quantitative relation between the two sets of results. The comparative effects of sodium chloride and potassium chloride are somewhat anomalous since the activity coefficients of potassium chloride in its own pure solutions are but very slightly less than those of sodium chloride, while the activity coefficient of hydrochloric acid in the presence of the former is much less than in the presence of sodium chloride.

For those cases in which the activity coefficients of the salts in their own pure solutions are known, they are less, at the same ionic strength, than are those of hydrochloric acid in the mixture. From this it follows that the hydrogen ion has under certain conditions an unusually large tendency to escape from the solution. Thus, from the closely agreeing data of Harned[2a] and of Güntelberg,[2b] there may be found by extrapolation the activity product $\alpha_H\alpha_{Cl}$ in the solution 0.1 *f* NaCl + 0.0 *f* HCl. Taking the activity coefficient of 0.1 *f* HCl as 0.796 (Ref. 2) this product in 0.1 *f* NaCl is $(0.789)^2$. In this same solution the product $\alpha_{Na}\alpha_{Cl}$ has the value[10] $(0.778)^2$. Hence $\alpha_H/\alpha_{Na} = 1.03$[11] in 0.1 *f* NaCl. That is, the hydrogen-ion constituent has a greater tendency to be "salted out" from 0.1 *f* sodium chloride than has the sodium-ion constituent. This difference is associated with the fact that the electrical forces acting upon these two ions are not the same, though in both cases they are chiefly due to surrounding chloride ions. Thus the mean distances of the chloride ions will be different, for there are involved the diameters of the hydrogen and sodium ions, and the dielectric constant of the medium in their immediate neighborhood. In addition different proportions of these two ion constituents may exist as free ions. The fact that the hydrogen ion has a relatively large activity coefficient may be related to its simple structure. It is less deformable and less polarizable than other ions. The effect is to exert a greater repulsive force and the ion tends to escape from the solution.

(10) Scatchard, THIS JOURNAL, 47, 648 (1925).

(11) Due chiefly to uncertainties in the values for pure hydrochloric acid and pure sodium chloride solutions this figure may be about one per cent. in error.

We wish to acknowledge our indebtedness to Professor S. J. Bates of this Laboratory for much helpful advice and criticism during the course of this investigation.

Summary

The effects of added sodium dithionate and of added perchloric acid upon the activity coefficients of hydrochloric acid in aqueous solution were determined at 25° up to an ionic strength somewhat greater than unity.

The effects of these salts, which are of types not heretofore tested, are qualitatively the same as those of added chlorides of the alkali and alkaline earth elements. Thus, when added to a dilute solution of hydrochloric acid they cause its activity coefficient at first to decrease and then to increase with increasing ionic strength. The addition of perchloric acid increases the activity coefficient more than does that of any other electrolyte. In fact, the activity coefficient in these mixtures is greater than is that of pure hydrochloric acid at the same ionic strength.

The equation which has been found to hold for the effect of certain other electrolytes upon hydrochloric acid, namely, $\log \alpha = \log \alpha_0 + k(\mu - m)$ is closely followed by mixtures containing sodium dithionate and perchloric acid.

The Rate of Addition of Methyl Esters to Trimethylamine[1]

BY LOUIS P. HAMMETT AND HELMUTH L. PFLUGER

We have found that the rate of methylation of trimethylamine to tetramethylammonium ion by the methyl ester of a carboxylic acid is determined by the strength of the acid in a fashion which is without parallel in recorded ester reactions but is very similar to the general acid catalysis equation of Brönsted.[2] The reaction in question: $RCOOCH_3 + N(CH_3)_3 \longrightarrow RCOO' + N(CH_3)_4^+$, is of the same type as those upon which depend the familiar preparative use of the esters of strong acids as alkylating agents; in fact, now that the work of Hantzsch[3] has shown that those acids which are strong, and of equal strength, in aqueous solution are of very different inherent strengths, it becomes apparent that the useful alkylating agents are precisely the esters of the strongest acids, the sulfates, the sulfonates, and, in the order of the strength of the corresponding acids, the halides. That carboxylic esters can accomplish a similar alkylation of tertiary amines was shown by Willstätter and Kahn,[4] who worked without solvent, and merely demonstrated the formation of a large yield of tetraalkylammonium salt. We have found that the reaction goes cleanly and at a suitable rate for measurement in methyl alcoholic solution at 100°.

Materials and Method

Methyl alcohol was synthetic methanol from the Commercial Solvents Corporation. It was dried by the method of Lund and Bjerrum[5] using magnesium in the presence of iodine, and distilled through a bulb stillhead in an all-glass apparatus, retaining only the first two-thirds of the distillate. The product had a density of 0.78691 at 25°, which was not altered by repetition of the treatment. We also tried the method of drying with aluminum amalgam recommended by Hartley and Raikes,[6] but found the codistillation of mercury with the alcohol troublesome.

Trimethylamine was purchased as a 33% methyl alcohol solution and diluted directly with the purified methyl alcohol. Qualitative tests for primary and secondary amines were negative.

Esters were, in general, purified by extraction of an ether solution with aqueous sodium carbonate, drying over anhydrous sodium sulfate, and distilling through a Vigreux stillhead in an all-glass apparatus, retaining a portion of constant boiling point. *Methyl acetate* was extracted with calcium chloride brine without the use of ether, and then dried and distilled. Boiling points and saponification values were as follows: acetate, 58.9°, 99.6%; benzoate, 198°, 100.2%; *o*-toluate, 212.8°, 99.6%; *p*-toluate, 221°, 99.6%; *o*-chlorobenzoate, 235°, 99.7%; phthalate, 282.3°, 99.2%; *o*-nitrobenzoate, 288°, 99.5%. Free acid was found to be less than 0.01% in all cases except lactate. The *methyl lactate* purchased was a "practical" product and very impure, much of it distilling below 100°. A portion with a constant boiling point of 144.5° after two distillations was used for the velocity measurements. It was still impure, and probably contained a formic ester, as shown by a saponification value 3.75% too high, and by a direct test for formic acid with mercuric oxide in aqueous solution. *Methyl p-nitrobenzoate* was recrystallized from methyl alcohol and melted at 96.5° (corr.).

All materials were kept after purification in stoppered bottles in desiccators containing phosphorus pentoxide.

Method.—The reaction was followed quantitatively by determining the concentration of trimethylamine which remained after definite intervals of time. This was accomplished by steam-distilling the trimethylamine into standard acid and back-titrating with standard alkali. The reaction solutions were prepared by weighing out a suitable amount of ester either directly in a 50-cc. volumetric flask or by use of a small Bailey weight buret, then diluting to the mark with an approximately 0.2 molar solution of trimethylamine in methyl alcohol; 5 cc. of the mixed solution was pipetted into a 50-cc. volumetric flask half full of water (or methyl alcohol, if the ester was insoluble in water) to which 1 cc. of approximately 0.2 *N* hydrochloric acid had previously been added, and the flask was then filled with water up to the mark. This solution was used for the determination of the initial concentration of trimethylamine. The remainder of the reaction mixture was introduced into clean and dry Pyrex ampoules of 8 cc. capacity with the aid of a funnel drawn to a capillary, a small space being left in the ampoule for

expansion of the alcohol upon introduction into the hot bath. The ampoules, cooled by ice, were sealed and introduced into an oil thermostat which operated at 100 ± 0.03°. The time was recorded to the nearest minute.

When an ampoule was removed from the thermostat it was placed immediately in ice and the time was recorded. After cleaning it was opened, its contents were shaken into a small beaker, and 5 cc. was pipetted into an acid solution and diluted to 50 cc. exactly as with the initial reaction mixture.

For the determination of trimethylamine, the micro-Kjeldahl distillation method of Pregl[7] was used. Duplicate determinations were made on each ampoule and on the initial reaction mixture, using for each determination 10 cc. of the solutions diluted as above described. Twenty cc. of standard 0.01 *N* hydrochloric acid diluted to 50 cc. was contained in the receiver. After seven minutes distillation with the condenser immersed below the surface of the acid, followed by four minutes with the tip above the acid solution, the acid was boiled to remove carbon dioxide, and titrated with 0.01 *N* sodium hydroxide from a microburet, using methyl red indicator and a daylight lamp.

Precision.—That the reaction actually produced tetramethylammonium ion in large quantities was demonstrated with all the esters by qualitative test with the potassium bismuth iodide reagent of Kraut. This gives a red precipitate with both trimethylammonium and tetramethylammonium ions, and was therefore applied to a solution which had first been made alkaline and heated to remove the former. It is as a matter of fact difficult to imagine any reaction other than the formation of tetramethylammonium ion by which the quantity of trimethylamine measured by our method of analysis can decrease.

In the case of the nitro compounds a titanous chloride titration showed that no reduction of the nitro group by the alkaline alcoholic solution occurred, and colorimetric tests showed that only traces of nitrite ion were produced by splitting-off of the nitro group during the course of the reaction. In the case of the chlorobenzoate, no chloride ion could be found in the reaction mixture.

In further support of the unique course of the reaction is the failure to observe drifts in the bimolecular constants in nearly all of the reactions studied.

Two successive analyses of the same solution always agreed within three parts per thousand, and usually much better than this. Suitable experiments demonstrated that, within this precision, the operation of introduction into the ampoule and removal from it produced no errors; the distillation method gave figures in agreement with direct titration of a trimethylamine solution; there is no disappearance of trimethylamine when a methyl alcoholic solution is heated at 100° for one month.

Table I contains the detailed experimental data for two esters, methyl acetate and methyl benzoate. Except for the two nitrobenzoates, the precision and freedom from drift here exhibited is typical, as may be seen from the average deviations included in Table III. In the case of *p*-nitrobenzoate, the much larger and entirely irregular scatter of the results probably arises from the difficulty of manipulation without loss of solutions in a volatile solvent of this not very soluble substance. In the case of *o*-nitrobenzoate, and in this case only, was there the sort of recognizable drift of the constants apparent in Table II. The constants for methyl

lactate also show a drift if the actual initial concentrations of ester and amine are used in the calculation, a fact which we attribute to the impurity already mentioned. If, however, those concentrations found to exist after some five or ten per cent. of the ester has reacted are used as a starting point, the excellent agreement indicated by the average deviation shown is obtained.

Conclusions

The mean values of the rate constants of the nine carboxylic esters investigated in this research are arranged in Table III in the order of their magnitude. There are also included the dissociation constants[8] of the corresponding acids at 25°, and those reported by Schaller[9] for benzoic acid and its derivatives at 99°, and by Noyes[10] for acetic acid at 100°. These ionization constants are, of course, the values obtaining in aqueous solution.

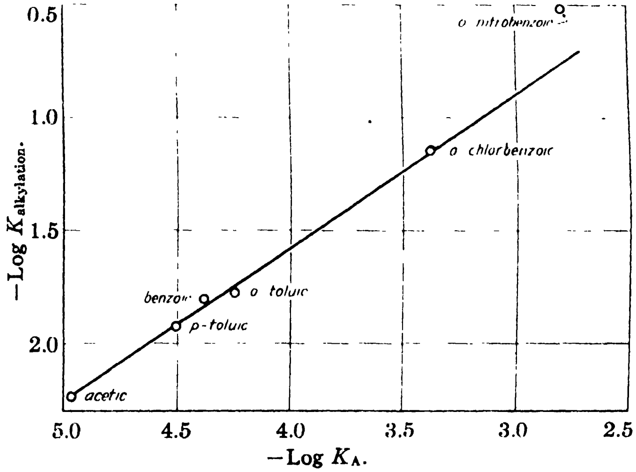

Fig. 1.

It is obvious that the rate of methylation of trimethylamine by these esters increases with increasing strength of the corresponding acid. But the relationship between reaction rate and acid strength is more than qualitative. Figure 1 contains a plot of the logarithm of the rate constant against the logarithm of the dissociation constant of the corresponding acid at either 100 or 99°, for all of the esters studied for whose acids dissociation constants at this temperature are available. The straight line whose equation is $\log k_v = 1.10 + 0.67 \log K_A$, where k_v is the velocity constant of the alkylation reaction, and K_A is the acid ionization con-

---

(8) Where no specific references are given, the dissociation constants have been obtained from the "International Critical Tables." Attention is called, however, to an error in the order of magnitude given in these tables for the constant of benzoic acid.

(9) Schaller, *Z. physik. Chem.*, **25**, 497 (1898).

(10) Noyes, THIS JOURNAL, **30**, 335 (1908).

stant, fits these data excellently except in the case of *o*-nitrobenzoate. The deviation of almost 0.3 unit in this case requires further investigation.

In Fig. 2 the alkylation constants at 100° have been plotted against acid dissociation constants at 25°. This seems a more reasonable procedure than the estimation of temperature coefficients which are at present unknown. It is clear that there is a very definite advantage in the comparison of the alkylation velocity at 100° with the ionization constant of the acid at the same temperature, especially when ortho substituted benzoic acids are concerned. The fact that the latter have especially large temperature coefficients of ionization has been pointed out by Smallwood[11] and given a theoretical derivation.

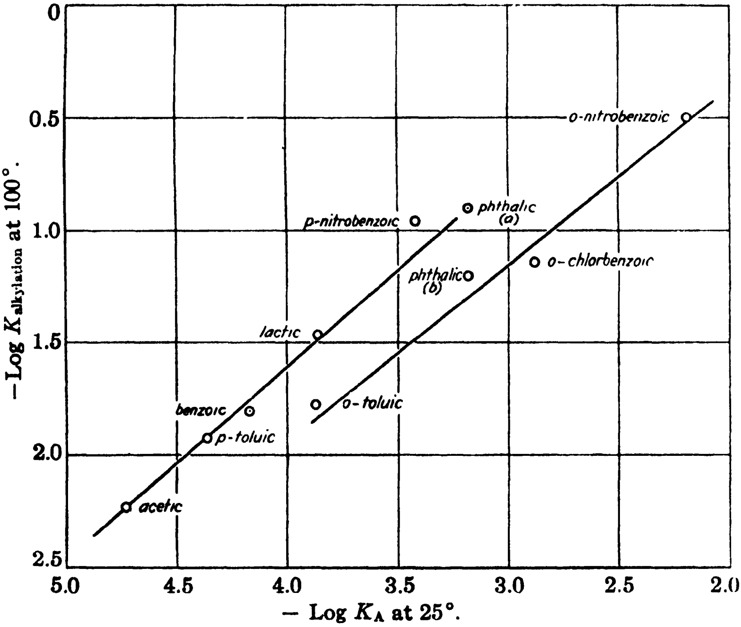

Fig. 2.

The acid with whose ionization constant the alkylation velocity of dimethyl phthalate is to be compared is of course the monomethyl ester of phthalic acid, and it is this constant which is listed in Table III. If the alkylation rate is plotted against this, the point (*a*) in Fig. 2 is obtained. Since, however, the dimethyl ester has twice the probability of reacting that a monomethyl ester would have, it is reasonable to divide the rate constant by two for comparison with the esters of monobasic acids. If this is done, point (*b*), which is in reasonable agreement with the other ortho substituted esters, is obtained.

We shall report later on the behavior of phenolic esters which do methyl-

---

(11) Smallwood, THIS JOURNAL, 54, 3048 (1932).

ate trimethylamine, but do not exhibit the same relation between rate and acid strength as that found for carboxylic esters, and upon the closely related problem inherent in the fact that we have here compared velocities in methyl alcohol solution with acid strengths in aqueous solution. This relation appears in the fact that carboxylic and phenolic acids are very differently affected by a change in solvent.[12]

Discussion

Because there is no universally valid relation between the rate of a chemical reaction and the equilibrium constant of the same or closely related reactions,[13] and because there is indeed no obvious reason to expect it, the existence of a simple and unique relation in this case presents a striking contrast which throws light on a number of important problems of reaction mechanism.

If one attempts to relate the velocity of the reaction of an ester with hydroxyl ion, *i. e.*, its alkaline hydrolysis, to the strength of the corresponding acid in the same way as we have done with the velocity of the reaction with trimethylamine, one obtains the complete lack of functional relationship exhibited by Fig. 3. The data[14] necessary are included in Table III. There is nevertheless this regularity in the large amount of existing data on hydrolysis velocities: that any substitution, of whatever electrochemical nature, in the immediate neighborhood of the carboxyl group tends to decrease the hydrolysis rate.[15] Whether the mechanism implied by the usual name "steric hindrance" is correct or not, the facts are that ethyl benzoate hydrolyzes only one-fourth as fast as ethyl acetate, though benzoic acid is almost four times as strong as acetic acid; and that alpha substituted aliphatic esters and ortho substituted aromatic esters hydrolyze less rapidly than unsubstituted esters of the same strength or esters containing the same substituent in a position further removed from the carboxyl group.

An important difference in principle between the reaction of an ester with a tertiary amine and its reaction with hydroxyl ion appears in the fact that the ester must in the first case break thus, $R_1COO\vdots R_2$, at the dotted line, both oxygens going with the acid radical, whereas the hydrolysis may go by two quite different mechanisms

$$R_1COO\vdots R_2 + OH' \longrightarrow R_2OH + R_1COO' \qquad (I)$$

$$R_1CO\vdots OR_2 + OH' \longrightarrow R_1COOH + {}'OR_2 \qquad (II)$$

(13) Adkins and Adams, THIS JOURNAL, **47**, 1368 (1925); Conant, *Ind. Eng. Chem.*, **24**, 470 (1932).

(14) These data are for the hydrolysis of ethyl esters, and are taken from Olsson's tables in which *k* for ethyl acetate is arbitrarily set at 100 [Olsson, *Z. physik. Chem.*, **133**, 233 (1928)] or calculated to the same scale from Kindler's tables [*Ann.*, **450**, 1 (1926); **452**, 90 (1927); **464**, 278 (1928)]. The use of ethyl esters is entirely justified by the well-demonstrated constancy of the ratio of the hydrolysis constants of ethyl and methyl esters [see Olsson, p. 240) and the wider range of data available for the ethyl esters.

(15) See for instance Kindler, *Ann.*, **464**, 278 (1928).

In the first case, the reaction may be called an alkylation of the hydroxyl ion, and in the second case an acylation, the acylation of ammonia to acetamide by methyl acetate being entirely analogous. It has been a much discussed problem for some thirty years whether the one or the other or both of these mechanisms agrees more closely with the facts.[16] If the hydrolysis mechanism were the alkylation represented by equation I, it is inconceivable that it should be more subject to steric hindrance than is the alkylation of trimethylamine. The existence of steric effects in the hydrolysis compared with their complete absence in the amine reaction is therefore strong evidence that the hydrolysis is an acylation proceeding according to equation II, the break occurring at a point in the molecule nearer the hindering groups than would be the case with the alkylation.

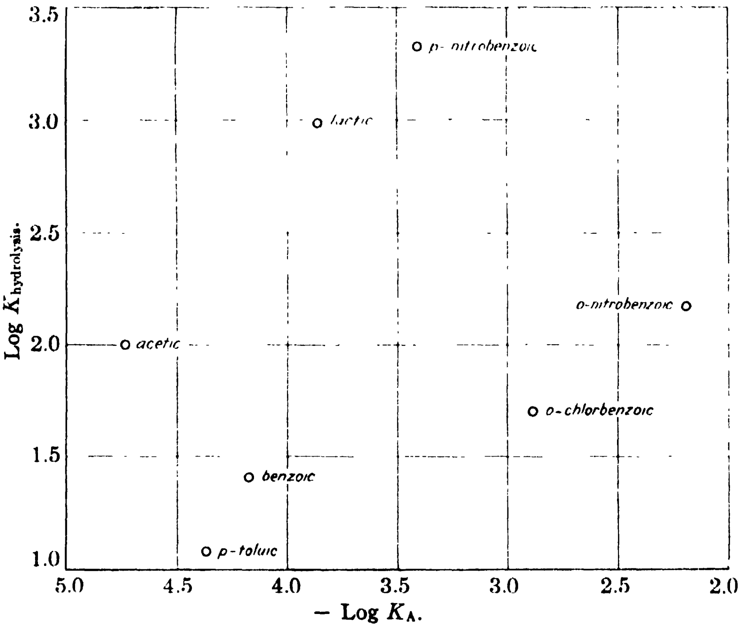

Fig. 3.

The previously existing evidence favors this mechanism for the hydrolysis of carboxylic esters, but it is directly applicable only to esters of secondary and tertiary alcohols. Holmberg[17] in 1912 pointed out that a Walden inversion can occur in the hydrolysis of an optically active alcohol whose activity depends upon an asymmetric carbinol carbon only if the hydrolysis is an alkylation, and follows mechanism I. Such an inversion has never been observed in the esterification and subsequent hydrolysis of a carboxylic ester.[16,17,18] On the other hand, the existence of an inversion

(18) Fischer, *Ann.*, **394**, 360 (1912); Verkade, *ibid.*, **477**, 287, 297 (1930).

in the hydrolysis of *p*-toluene sulfonic esters[19] of active alcohols proves that these do hydrolyze by mechanism I, a reasonable result because these esters of strong acids are in general active alkylating agents.[20] In further agreement is the fact that steric hindrances due to ortho substitution do not appear in the hydrolysis of substituted benzene sulfonic esters.[21]

With respect to detailed mechanism, it is profitable to consider the amine reaction as a substitution of trimethylamine for acetate ion, both amine and ion being bases in the Brönsted sense or molecules with lone electron pairs in the Lewis picture. Of the two widely discussed mechanisms for substitution reactions, the one dependent upon a preliminary dissociation of one reactant is here impossible. It would require either that the rate be independent of nature and concentration of the base or that it be proportional directly to the dissociation constant and inversely to the concentration of the acid ion produced. The hypothesis of a preliminary addition reaction on the other hand can be reconciled with the present result only by supposing that the rate of the addition is dependent upon the strength of a linkage which is to be broken in a further reaction of the addition compound. Recently, however, a theory of simultaneous addition and dissociation has been proposed on quantum mechanical grounds by London,[22] given quantitative application to simple reactions by Eyring and Polanyi,[23] and by Eyring and others,[24] and utilized qualitatively for more complex reactions by Polanyi[25] and others and by Olson.[26] Applied to the methylation of trimethylamine, one obtains the picture shown, in which the arrows represent the direction of motion. The reaction takes place by the approach of the nitrogen of the pyramidal trimethylamine molecule to the carbon of the methyl group on the side directly opposite to the oxygen atom. Simultaneously the oxygen and the accompanying acid radical recede from the carbon. If the kinetic energy of the approaching trimethylamine exceeds a certain minimum, the activation energy of the reaction, there is complete ejection of the acid ion, attachment of the trimethylamine, and rearrangement of the hydrogens on the methyl to new positions of equilibrium. The activation energy is dependent upon the energies of both the broken bond and the newly formed one, increases very rapidly with any deviation from linearity of ap-

proach,[23,24] and determines the reaction velocity provided steric factors are constant. One need only suppose that the energy of the bond between alkyl and acid radical is related to the strength of the corresponding acid to obtain a reasonable account of the existence if not of the exact form of a relation between velocity and acid strength. The equally probable dependence upon the strength of the reacting base is much more likely to be complicated by steric effects, and both base strength and spatial configuration are apparently factors in determining the rate of addition of different tertiary amines to a single alkyl halide.[27]

In further agreement with the demonstrated properties of the alkylation reaction, a Walden inversion must take place when the carbinol carbon is asymmetric[25,26] and variations in shape or size of the radical R can have no effect as such upon the velocity of a reaction which takes place at a point in the molecule so widely separated from R and so completely shielded from it.

The formal identity of the relation here found between acid strength and methylation rate with that found by Brönsted[2] between acid strength and the rate of a reaction subject to general acid catalysis suggests a fundamental similarity in the two reactions. It is therefore probable that the rate-determining step in the catalysis is a transfer of hydrogen ion from the acid HA to the weakly basic substrate S, entirely analogous to the transfer of methyl in the alkylation reaction $HA + S \rightleftarrows SH^+ + A'$, and that the further reaction of the ion SH^+ is by comparison extremely rapid. This is the interpretation of the catalysis suggested by Pedersen,[28] and it may be added that the mechanism of reaction just discussed casts considerable doubt upon the possibility of further dissection of the reaction, for instance, into the formation of an addition compound (HA, S), and its subsequent further reaction. Those predictions of a dependence upon base strength as well as upon acid strength and upon steric properties which were made for the alkylation reaction should be equally applicable to both acid and basic catalysis and should furnish a test of the usefulness of the interpretation.

Summary

It has been found that the rate of the alkylation of trimethylamine to tetramethylammonium ion by the methyl ester of a carboxylic acid is related to the strength of the acid by an equation of the same form as that which connects the rate of a reaction subject to general acid catalysis with the strength of the catalyst acid.

The complete absence of steric hindrances in this reaction compared with its predominance in ester hydrolysis shows that the mechanisms of the two reactions are different.

[28] Pedersen, THIS JOURNAL, **53**, 18 (1931).

It is probable that the rate-determining step in the general acid and basic catalysis of Brönsted is a transfer of hydrogen ion from acid catalyst to substrate similar to the transfer of methyl in the alkylation reaction.

These results are in agreement with the theory of simultaneous addition and dissociation in substitution reactions.

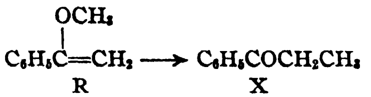
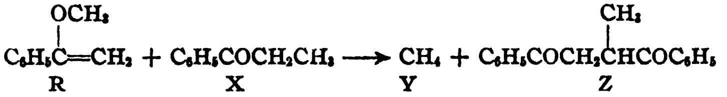
The Kinetics of the Rearrangement of α-Methoxystyrene[1]

BY F. H. MACDOUGALL, WALTER M. LAUER AND MARVIN A. SPIELMAN[2]

Claisen[3] has shown that α-methoxystyrene undergoes on heating a molecular rearrangement with the formation of propiophenone. A recent investigation[4] of the process has revealed an unusual type of side reaction. The unchanged starting material (R) reacts with the rearrangement product (X); a molecule of methane (Y) is eliminated and 1,2-dibenzoylpropane (Z) results.



$$\underset{R}{C_6H_5\overset{\overset{OCH_3}{|}}{C}{=}CH_2} \longrightarrow \underset{X}{C_6H_5COCH_2CH_3} \qquad I$$



$$\underset{R}{C_6H_5\overset{\overset{OCH_3}{|}}{C}{=}CH_2} + \underset{X}{C_6H_5COCH_2CH_3} \longrightarrow \underset{Y}{CH_4} + \underset{Z}{C_6H_5COCH_2\overset{\overset{CH_3}{|}}{C}HCOC_6H_5} \qquad II$$

In connection with a study of the mechanism of this type of molecular rearrangement, it became desirable to know the order of the reaction and to gain as much information as possible about the unique condensation reaction (II). While the mixture of compounds resulting from reactions I and II does not lend itself to highly precise methods of analysis, nevertheless a technique was developed whereby its composition could be determined with a fair degree of accuracy.

Experimental Methods

The thermostat was an upright Pyrex tube, 16 × 40 cm. rounded at the lower end and closed at the top with an asbestos cover. The lower two-thirds was wrapped with an asbestos jacket. Within was suspended a cylindrical aluminum block, 4.5 × 9 cm., in which were drilled five holes. An 8 mm. hole through the center bore a glass supporting rod and symmetrically disposed about it were four cylindrical holes. The diameter of these was 10 mm. except near the bottom where the bore was smaller. Three of these holes held the sample tubes; the fourth hole held a thermometer. A constant temperature was maintained by boiling about 50 cc. of an appropriate liquid at such a rate that the vapor condensed well above the aluminum block at a marked position above the insulating jacket. The following liquids were used: diphenyl ether, b. p. 260.0 ± 0.3°; isosafral, b. p. 249.5 ± 0.4°; quinoline, b. p. 235.6 ± 0.5°; and methyl salicylate, b. p. 222.8 ± 0.6°. Temperature measurements were made with Anschütz standard thermometers which were checked against instruments having Bureau of Standards calibrations.

[4] Lauer and Spielman, THIS JOURNAL, **55**, in press (1933).

Samples (about 0.8 g.) of freshly distilled, analytically pure α-methoxystyrene were weighed out into 8-cm. lengths of 8-mm. glass tubing sealed at one end. These were filled with nitrogen, loosely stoppered and drawn out to 8-cm. capillaries which were sealed after room temperature was reached. The liquid occupied about 80% of the volume of the reaction vessels. Calculation shows that, even at the highest temperature employed less than one per cent. of the material is in the gas phase. The tip was formed into a hook through which a light wire was passed to facilitate handling. After they were removed from the thermostat, they were cooled and unsealed in a closed system connected to a gas buret. Heating with a boiling water-bath served to expel the dissolved methane. After cooling to room temperature, the volume of gas was determined over mercury. The heating with the water-bath and the subsequent cooling were repeated until constant values were obtained for the volume of gas.

The residual liquid was then removed and analyzed for the methoxyl group by the Zeisel method, using the elegant volumetric modification of the method described by Viebock and Schwappach.[5] In these determinations, check analyses were made and only those were used which agreed to within 0.2% OCH_3. The percentages of α-methoxystyrene so obtained are probably correct to within one per cent. In the measurement of the methane, gas buret readings could be duplicated to 0.01 cc. after heating and cooling, but the total volume of methane was in general small and there was always the danger that some of the methane might have been retained in the organic liquid.

We see from reaction equations I and II that, so long as all the methane formed remains in the liquid, there is no change in the total number of molecules. The composition of the reaction mixture is expressed in mole fractions assuming all the methane to be dissolved. Since in general the amount of methane formed is small, this procedure is sufficiently accurate.

Since some time is required to heat the reacting substance to the temperature selected for the experiment, a time correction is necessary. This was determined graphically by plotting values of $1/R$ against the time and extrapolating back to a value of R equal to 1. The time correction was found to be three minutes. Accordingly all time values have been diminished by this amount.

For fuller details about experimental methods, the paper by Lauer and Spielman[4] may be consulted.

Kinetic Equations.—Let R, X and Y be the mole fractions of α-methoxystyrene, propiophenone and methane, respectively, in the reaction mixture at any time t. We shall show that reactions I and II are of the second order. On this basis, we have the following set of equations:

$$\mathrm{d}R/\mathrm{d}t = -k_1R^2 - k_2RX \qquad (1) \qquad \mathrm{d}Y/\mathrm{d}t = k_2RX \qquad (3)$$

$$\mathrm{d}X/\mathrm{d}t = k_1R^2 - k_2RX \qquad (2) \qquad 1 = R + X + 2Y \qquad (4)$$

Of the equations (1), (2) and (3), only two are independent, because of the

---

(5) Viebock and Schwappach, *Ber.*, **63**, 2818 (1930).

relation expressed in equation (4). It will be convenient to make the substitutions

$$u = k_1t \qquad (5) \qquad c = k_2/k_1 \qquad (6)$$

Equations (1), (2) and (3) become

$$\mathrm{d}R/\mathrm{d}u = -R^2 - cRX \qquad (7) \qquad \mathrm{d}Y/\mathrm{d}u = cRX \qquad (9)$$

$$\mathrm{d}X/\mathrm{d}u = R^2 - cRX \qquad (8)$$

R, X and Y are functions of u (or t) but cannot be expressed in terms of any simple function of u containing a finite number of terms. They can, however, be represented by infinite power series. The coefficients of the powers of u in the various series can be found by assuming an expansion $R = a_0 + a_1u + a_2u^2\ldots$ and $X = b_0 + b_1u + b_2u^2\ldots$ Substitution of these expressions in (7) and (8) leads to a knowledge of the coefficients. A less tedious method employs Maclaurin's theorem. If we denote the value of a function for $u = 0$ by the subscript zero, we have

$$R = R_0 + u(\mathrm{d}R/\mathrm{d}u)_0 + u^2/2!\,(\mathrm{d}^2R/\mathrm{d}u^2)_0 + u^3/3!\,(\mathrm{d}^3R/\mathrm{d}u^3)_0 + \ldots \qquad (10)$$

$$X = X_0 + u(\mathrm{d}X/\mathrm{d}u)_0 + u^2/2!\,(\mathrm{d}^2X/\mathrm{d}u)_0 + u^3/3!\,(\mathrm{d}^3X/\mathrm{d}u^3)_0 + \ldots \qquad (11)$$

Restricting ourselves to the case in which we start our reaction with pure α-methoxystyrene, we readily obtain from (4) and by repeated differentiation of (7) and (8) the results

$$R_0 = 1;\ (\mathrm{d}R/\mathrm{d}u)_0 = -1;\ (\mathrm{d}^2R/\mathrm{d}u^2)_0 = 2 - c;\ (\mathrm{d}^3R/\mathrm{d}u^3)_0 = -6 + 6c + c^2;$$
$$(\mathrm{d}^4R/\mathrm{d}u^4)_0 = 24 - 36c - 4c^2 - c^3;\quad (\mathrm{d}^5R/\mathrm{d}u^5)_0 = -120 + 240c - 6c^2 - 4c^3 + c^4;$$
$$X_0 = 0;\ (\mathrm{d}X/\mathrm{d}u)_0 = 1;\ (\mathrm{d}^2X/\mathrm{d}u^2)_0 = -2 - c;\ (\mathrm{d}^3X/\mathrm{d}u^3)_0 = 6 + 2c + c^2$$
$$(\mathrm{d}^4X/\mathrm{d}u^4)_0 = -24 - c^3;\ (\mathrm{d}^5X/\mathrm{d}u^5)_0 = 120 - 48c - 26c^2 - 8c^3 + c^4$$

Similar procedures enable us to express in a power series in u any function of R or X, *e. g.*, $1/R$ and $1/(R+Y)$. We thus obtain the expansions

$$1/R = 1 + u + \frac{c}{2}u^2 - \frac{c^2}{6}u^3 + \frac{2c^2 + c^3}{24}u^4 - \frac{4c^2 + 6c^3 + c^4}{120}u^5 + \ldots \qquad (12)$$

$$1/(R + Y) = 1 + u - \frac{c}{3}u^3 + \frac{2c + 2c^2}{24}u^4 \ldots \qquad (13)$$

$$R = 1 - u + \frac{2 - c}{2}u^2 - \frac{6 - 6c - c^2}{6}u^3 + \frac{24 - 36c - 4c^2 - c^3}{24}u^4 + \ldots \qquad (14)$$

$$X = u - \frac{2 + c}{2}u^2 + \frac{6 + 2c + c^2}{6}u^3 - \frac{24 + c^3}{24}u^4 \ldots \qquad (15)$$

$$Y = \frac{c}{2}u^2 - \frac{4c + c^2}{6}u^3 + \frac{18c + 2c^2 + c^3}{24}u^4 \ldots \qquad (15a)$$

It will be shown that the value of $c = k_2/k_1$ is about 1/8. If we plot $1/R$ and $1/(R+Y)$ against u (or t), we shall obtain in the first place a curve which approximates to a straight line for small values of u but curves upward for larger values of u. In the second place (for the $1/(R+Y)$ curve), the curve will be more nearly straight over a greater range of u but should be slightly concave to the u axis. In Fig. 1 are plotted values of $1/R$ and $1/(R+Y)$ against t for the reaction at 260°. It will be seen that the curves for $1/R$ and $1/(R+Y)$ exhibit the predicted behavior. Figure 2 gives a graphic picture of the rate of formation of methane.

Equations (14) and (15) represent the values of R and of X, respectively, only for values of u less than unity. In all our experiments, the study of the reaction was extended to times for which u was greater than 2. These equations therefore can be applied only in the earlier stages of the reaction.

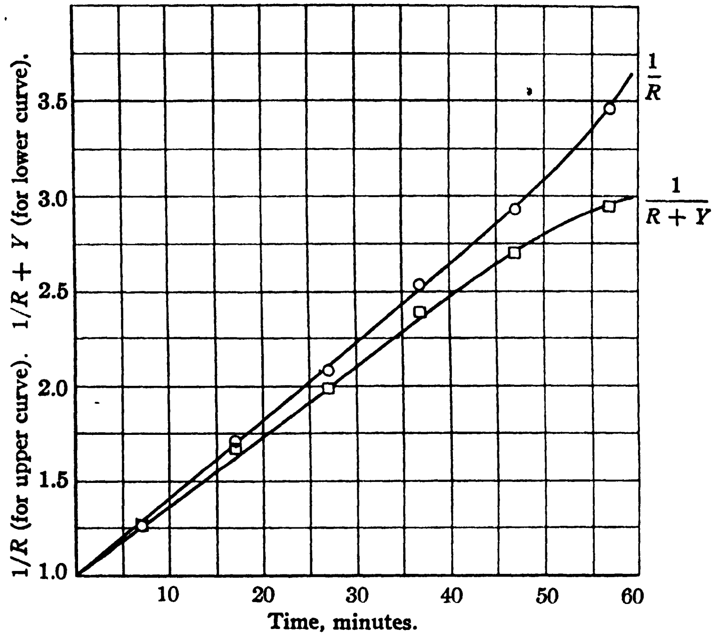

Fig. 1.—Decomposition of α-methoxystyrene at 260.0°.

In order to be able to determine the best values of k_1 and k_2 using all the data for a run at a given temperature it seemed desirable to express R and X in a power series such that the series would be convergent and have a definite finite limit for all values of the variable. This was accomplished in the following way. Introducing the new variable V defined by the equation

$$V = u/(1 + u) \tag{16}$$

we see that $V = 0$ for $u = 0$ and that $V < 1$ for all finite values of u (or t). On substitution, the fundamental equations (7) and (8) become

$$(1 - V)^2 \, \mathrm{d}R/\mathrm{d}V = -R^2 - cRX \tag{17}$$

$$(1 - V)^2 \, \mathrm{d}X/\mathrm{d}V = R^2 - cRX \tag{18}$$

Applying Maclaurin's theorem, we can express R and X and any function of them in a power series in V. We obtain

$$R = 1 - V - \frac{c}{2} V^2 + \frac{c^2}{6} V^3 + \frac{c^2}{3}\left(1 - \frac{c}{8}\right) V^4 + \frac{17}{60} c^2 \left(1 - \frac{12}{17} c + \frac{c^2}{34}\right) V^5 + \dots \tag{19}$$

$$X = V - \frac{c}{2}V^2 - \frac{2}{3}c\left(1 - \frac{c}{4}\right)V^3 - \frac{c}{2}\left(1 - c + \frac{c^2}{12}\right)V^4 - \frac{2}{5}c\left(1 - \frac{47}{24}c + \frac{7}{12}c^2 - \frac{c^3}{48}\right)V^5 \ldots \tag{20}$$

$$Y = \frac{c}{2}V^2 + \frac{c}{3}\left(1 - \frac{c}{2}\right)V^3 + \frac{c}{4}\left(1 - \frac{5}{3}c + \frac{c^2}{6}\right)V^4 + \frac{c}{5}\left(1 - \frac{8}{3}c + \frac{13}{12}c^2 - \frac{c^3}{24}\right)V^5 \ldots \tag{21}$$

$$X + Y = \frac{1 - R + X}{2} = V - \frac{c}{3}V^3 - \frac{c}{4}\left(1 - \frac{c}{3}\right)V^4 + \frac{c}{5}\left(1 - \frac{5}{4}c + \frac{1}{12}c^2\right)V^5 \tag{22}$$

The greatest value of V met with in our experiments was about two-thirds. Moreover, the value of c was found to be of the order of one-eighth. Accordingly we proceeded as follows. Assuming an approximate value of c and using the experimentally determined values of X and Y for a given time t, an approximate value of V was easily calculated by means of equation (22). Substituting this value of V in equation (19), a more accurate value of c was determined. Using this value of c in equation (22), there resulted a more accurate value of V and on substitution once more in equation (19), we obtained a final value of c. This procedure was gone through for all the data of a run at a given temperature. From the values of V thus obtained for the various times t, equation (16) gave the cor-

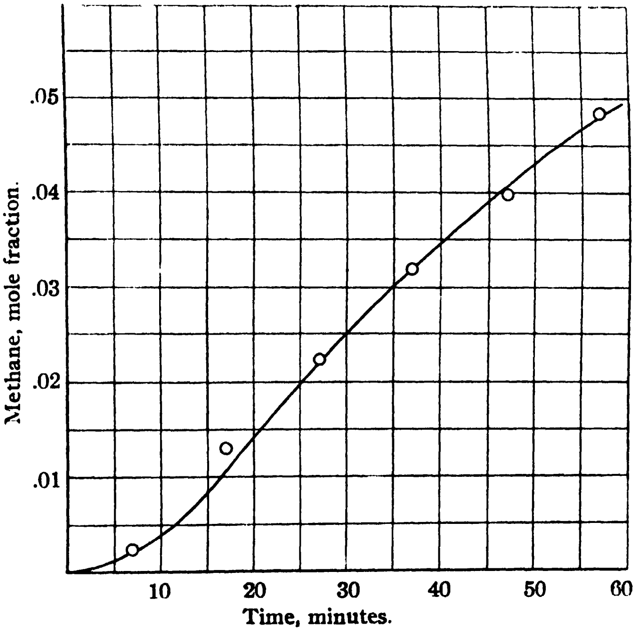

Fig. 2.—Condensation reaction at 260.0°.

responding values of u and hence the values of k_1 (equation (5)). In Table I are given the results of these calculations applied to the data obtained at 260°.

0.00473. The agreement between calculated and observed values is very satisfactory.

Tables III and IV give the results obtained from the experiments at 249.5 and 235.6°.

Experiments at 222.8 °C.—At the temperature 222.8° a run was made starting with approximately equivalent amounts of α-methoxystyrene and propiophenone. Representing by a the mole fraction of α-methoxystyrene at the beginning of the reaction, we obtain as solutions in series of equations (17) and (18)

$$\begin{aligned} R/a = {} & 1 - [a + (1-a)c]V - \left[a - a^2 + \left(\frac{2 - 5a + 4a^2}{2}\right)c - \right. \\ & \left.\left(\frac{1-a}{2}\right)c^2\right]V^2 - \left[a(1-a)^2 + (1 - 4a + 6a^2 - 3a^3)c - \right. \\ & \left. \frac{(6 - 13a + 14a^2 - 6a^3)}{6}c^2 + \frac{(1 + a - 4a^2 + 2a^3)}{6}c^3\right]V^3 + \dots \end{aligned}$$

$$\begin{aligned} X/a = {} & \frac{1-a}{a} + [a - (1-a)c]V + \left[a - a^2 - \left(\frac{2-a}{2}\right)c + \right. \\ & \left.\left(\frac{1-a}{2}\right)c^2\right]V^2 + \left[a(1-a)^2 - \left(\frac{3 - 4a^2 + 3a^3}{3}\right)c + \right. \\ & \left.\left(\frac{6 - 5a + 2a^2 - 2a^3}{6}\right)c^2 - \left(\frac{1 + a - 4a^2 + 2a^3}{6}\right)c^3\right]V^3 + \dots \end{aligned}$$

$$\begin{aligned} Y/a = {} & (1-a)cV + \left[\left(\frac{2 - 3a + 2a^2}{3}\right)c - \left(\frac{1-a}{2}\right)c^2\right]V^2 + \\ & \left[\left(\frac{3 - 6a + 7a^2 - 3a^3}{3}\right)c - \left(\frac{6 - 9a + 8a^2 - 4a^3}{6}\right)c^2 + \right. \\ & \left.\left(\frac{1 + a - 4a^2 + 2a^3}{6}\right)c^3\right]V^3 + \dots \end{aligned}$$

Unfortunately these series do not converge rapidly when the value of V is as great as one-half so that the use of the first four terms of each series gives only an approximate value of the function represented. Moreover, the reactions do not seem to go so smoothly at 222.8° as at the higher temperatures. Nevertheless, it was possible to get some idea as to the magnitude of k_1 and k_2. The experimental data are given in Table V. It will perhaps be sufficient to state that these data lead to values of k_1 lying between 0.004 and 0.005 and a value of k_2 in the neighborhood of 0.0005. Table VI contains a summary of the results at the three higher temperatures.

TABLE V

REACTION AT 222.8°

t (corr.), min.	0	57	117	177	237	297

Energy of Activation.—The quantity A in the Arrhenius equation

$$d \log_e k/dT = A/RT^2$$

is usually interpreted as the energy of activation. This equation in integrated form is

$$A = \frac{2.303\,RT_1T_2}{T_2 - T_1}\left(\log_{10}\frac{k_{T_2}}{k_{T_1}}\right)$$

Since the ratio of k_2 to k_1 has been found to be practically constant from 235 to 260°, it follows that both reactions have the same energy of activation. From the values of k_1 at 260 and 249.5°, we find $A = 36{,}700$ calories; from the data at 260 and 235.6° we find $A = 32{,}300$ calories. The energy of activation is thus found to be about 34,000 calories.

Kinetic Mechanism of Rearrangement.—Since Reaction I is found to be of the second order with respect to R, we may suppose that when two molecules of R encounter each other under appropriate energy conditions, an activation complex is formed which, on the one hand, can break down re-forming two molecules of R and, on the other hand, can break down forming either one molecule of R and one molecule of X or two molecules of X. If the rate at which the complex breaks up forming $R + X$ (or $2X$) is not too great, the concentration of the complex will be maintained at its equilibrium value with respect to R. Under these circumstances the velocity of Reaction I will be proportional to the square of the concentration of R. Reaction I will still be one of the second order even if the complex is not in equilibrium with R but decomposes solely into $R + X$ (or $2X$), provided that the concentration, C, of the complex is always so minute that dC/dt is negligibly small in comparison with the rate of formation of the complex or its rate of decomposition. Reaction I may then be represented by the scheme

$$2R \rightleftarrows \text{(complex)} \longrightarrow R + X \qquad \text{I(a)}$$

or

$$2R \rightleftarrows \text{(complex)} \longrightarrow 2X \qquad \text{I(b)}$$

Reaction II is a typical bimolecular process given by the scheme

$$R + \mathrm{X} \rightleftarrows \text{(complex)} \longrightarrow Y + Z \qquad \text{II}$$

Summary

1. The rearrangement of α-methoxystyrene to propiophenone is accompanied by an unusual type of side reaction in which the methoxystyrene and propiophenone react to form methane and 1,2-dibenzoylpropane.

2. The kinetics of these reactions was investigated at the temperatures, 260, 249.5, 235.6 and 222.8°.

3. Both reactions were found to be of the second order.

4. The differential equations describing the reactions were integrated in the form of infinite series.

5. The ratio of k_2 to k_1 remains virtually unchanged in the range 235–260°.

6. Both reactions have equal energies of activation, the value of which is 34,000 calories.

Cohen and Preisler[3] that such a concentration effect is due to a reversible aggregation of a dye.

In the potential maesurements we encountered much the same sort of difficulties that were discussed in the previous paper. In particular it may be said that there remains an element of selection in using the minimal potentials attained after each addition of reducing agent. However, we now have to report the following significant fact. A phosphate was made with resublimed phosphorus pentoxide and potassium hydroxide prepared electrolytically by use of a mercury diaphragm. When the oxidation–reduction systems were placed in buffers made with this material, the usual reversal of potential drift was almost or entirely eliminated; the attainment of a steady potential was slower, and in all cases the amount of reducing agent used before the dye was attacked was appreciably smaller. Spectrograms failed to reveal the difference between this phosphate and the previously used phosphate, which had been prepared from recrystallized U. S. P. phosphoric acid and electrolytic sodium hydroxide. A limited series of titrations made with the "purified" buffer components and involving no reversal of potential drift gave the same constants as titrations in which minimal potentials were used.

Other aspects of electrode behavior, the special precautions, the more general methods and the standards of reference have been adequately described in previous papers.

In accordance with the scheme outlined by Clark and Cohen[4] we may derive for systems I–V the following equation relating electrode potential E_h (referred to the hydrogen standard), concentration of total reductant $[S_R]$, concentration of total oxidant $[S_O]$, hydrion activity (H^+) and apparent dissociation constants of reductant, K'_{r_1} and K'_{r_2}. E_0 is implicitly a function of the activity coefficients of the species involved and can be considered a "normal potential" only when the environment is constant.

$$E_h = E_0 - \frac{RT}{2F} \ln \frac{[S_R]}{[S_O]} + \frac{RT}{2F} \ln [K'_{r1}K'_{r2} + K'_{r1}(H^+) + (H^+)^2] \qquad (1)$$

The oxidants of systems I–V possess the highly polar group $=NR_2^+$ throughout the range of P_H considered. Therefore the dissociation constants of the oxidants may be neglected.

Equation (1) applies when no association takes place. In the case of system VI there is evidence of association of the dye in aqueous solution. This was tested by a comparison of spectrophotometric data, potentiometric measurements and the distribution coefficient for the partition of the rosindone between water and amyl alcohol.

Let it be assumed that the unimolecular species OX^- is distributed between water and amyl alcohol in accordance with:

---

(3) Cohen and Preisler, Public Health Reports, Supplement 92 (1931).

(4) Clark and Cohen, *Public Health Reports*, **38**, 666 (1923).

$$\frac{[\mathrm{OX}^-]_{\mathrm{alc.}}}{[\mathrm{OX}^-]_{\mathrm{w}}} = \frac{\gamma_{\mathrm{OX}^- \text{ in w}}}{\gamma_{\mathrm{OX}^- \text{ in alc.}}} = k' \qquad (2)$$

Assuming a limited range of conditions we may replace the ratio of activity coefficients by the usual distribution coefficient, k'. The same sort of approximation is used in (3). In water let there be equilibrium between unimolecular and bimolecular forms.

$$\frac{[\mathrm{OX}^-]_{\mathrm{w}}^2}{[\mathrm{OX}_2^{--}]_{\mathrm{w}}} = K\,\frac{\gamma_{\mathrm{OX}_2^{--}}}{\gamma_{\mathrm{OX}^-}^2} = K' \qquad (3)$$

Let $C_{\mathrm{alc.}}$ and C_{w} be the total concentrations of dye in alcohol and water phases, respectively. Then

$$\frac{K'}{2} = \frac{C_{\mathrm{alc.}}^2}{(k')^2 C_{\mathrm{w}} - k' C_{\mathrm{alc}}} \qquad (4)$$

In applying this equation it will be assumed that the two solvents do not change their mutual solubilities as the concentration of the dye in each phase changes and, for the purposes of approximation, changes in activity coefficients will be neglected. We shall also neglect higher polymers the consideration of which would greatly complicate the equation.

In the case of the potentiometric measurements with the rosindone, equation (3) must be combined with the ordinary, basic equation similar to (1). There is then obtained equation (5).

$$E_{\mathrm{h}} = E_0 - \frac{RT}{2F} \ln \frac{[\mathrm{S_R}]}{[\mathrm{S_O}]} \frac{K' + \sqrt{K'^2 + 8K'[S_O]}}{2K'} + \frac{RT}{2F} \ln [K'_{r_1}K'_{r_2}(\mathrm{H}^+) + K'_{r_1}(\mathrm{H}^+)^2 + (\mathrm{H}^+)^3] \qquad (5)$$

K'_{r_1} and K'_{r_2} are the apparent dissociation constants of the phenolic and substituted ammonium groups of the reductant,  $\mathrm{R}\begin{cases}\mathrm{SO_3^-}\\ \mathrm{OH}\\ \mathrm{NR_2H^+}\end{cases}$. The sulfonic acid is assumed to be completely dissociated in solutions of oxidant and reductant. The range of experimental conditions was such that no change in the dissociation of the oxidant was observed.

Experimental

Neutral Blue (Rowe 832).—The sample was recrystallized from ethylene dibromide. The aqueous solution had a minimal transmittance at $m\mu = 560$. Table I gives the results of a typical titration and Table II gives data sufficient to establish the relation of E_0' to P_{H} in acid solutions. Titrations in buffer solutions of P_{H} values higher than 4.2 were not satisfactory because of the very low solubility of the reductant.

Isorosindulines Nos. 1, 2 and 3.—These three dyes are very similar to neutral blue in structure and in behavior. The very limited solubility of each of the reductants precludes accurate measurements in solutions of P_{H} value greater than 4.5 or 5.0. The effects of substituents would have to be considered in connection with dissociation constants which could not be measured because of this limited solubility. Therefore it suffices to state the data of Table III which shows the slight over-all effect of substitution. The concentration effect was not studied.

Induline Scarlet (Rowe 827).—The commercial product was purified as follows. It was precipitated from hot aqueous solution by salting it out with potassium chloride. The material was then dissolved in glacial acetic acid, from which it precipitated on addition of ether. Finally, after being salted out of the aqueous solution a second and a third time with minimal quantities of potassium chloride, beautiful, clean crystals were obtained. These were washed cautiously with water.

Anal. (Kjeldahl) Calcd. for $C_{19}H_{18}N_3Cl$: N, 12.98. Found: N, 13.03, 12.82.

In dilute, aqueous acetate buffer the minimal transmittance was at mμ = 500. No concentration effect was observed by means of the spectrophotometer in concentrations as high as 1 × 10^{-3} molar.

Titrations with chromous acetate in hydrochloric acid and acid phosphate buffers were unsatisfactory because of drifting potentials. In acid citrate buffers and in neutral and alkaline buffers satisfactory data were obtained with deviations from the theoretical comparable with those of Table I. Table IV summarizes the data.

TABLE IV

INDULINE SCARLET (ROWE 827)

Relation of E_0' to P_H at 30°. Determined by separate titrations with chromous acetate. Values used in calculations $E_0 = 0.0472$. $K_r' = 3.13 \times 10^{-5}$ ($pK_r' = 4.51$) $E_0' = E_0 + 0.03006 \log [K_r'(H^+) + (H^+)^2]$. Total concentration of dye: 3×10^{-5} *M* (approx.)

Sulfonated Rosindone.[5]—The dye was purified as follows. The ampholyte was precipitated from the aqueous solution of the sodium salt by cautious addition of dilute acetic acid. After a day and a half the material had become crystalline. These crystals were filtered and were repeatedly washed with large amounts of distilled water.

Anal. Calcd. for $C_{27}H_{25}O_4N_3S$: N, 8.62; S, 6.58. Calcd. for $C_{27}H_{25}O_4N_3S \cdot H_2O$: N, 8.32; S, 6.35; N/S, 3.00. Found: N, 8.37, 8.45; S, 6.39, 6.38; N/S, 3.01.

The spectrophotometric examination of this dye showed two absorption bands in water, in aqueous buffer solutions, in ethyl alcohol and in amyl alcohol. In the non-aqueous solvents the bands were narrow, the peaks sharp and there was no shift of the wave length at these peaks as the concentration of the dye was changed. In water and in aqueous buffer solutions, on the other hand, the bands were comparatively broad and both the extinction coefficients at one wave length and the wave lengths of the peaks

[a] Molecular extinction coefficient = $1/lm \log 1/T$ where l is length of solution in centimeters, m is concentration in mole/liter, and T is transmittance. [b] The actual concentration is slightly less than this value since the dyestuff did not dissolve completely in the original stock solution. The 0.00001 *M* solution was prepared by diluting the 0.001 *M* solution 100 fold. [c] These values may be in error since they are at the limit of the precision of the instrument. [d] These values are estimated since the absorption bands overlap.

---

(5) Dr. Carleton tells us that the position of the sulfonic acid group is unknown but that it may be in the position indicated in formula VI.

varied with the concentration of the dye. In all these solvents the absorption bands changed but little with moderate alteration of the salt concentration. Table V summarizes some typical results.

These results suggest that the species present in the alcohol solutions do not change their nature with change in concentration of the dye and that in aqueous solutions such a change does occur.

To test the assumption that association occurs in aqueous solution, a series of experiments upon the distribution of the dye between two solvents was made. Amyl alcohol was the only solvent found which possesses properties satisfactory for the purpose. The results of one of the distribution experiments are given in Table VI where calculations made with equation (4) are summarized. The value of k' was determined from two sets of data in which K' could be eliminated. The agreement in the calculated values of the constant is somewhat misleading since the errors in determining the concentration of the dye in the more dilute solutions would not permit the suggested accuracy. Nevertheless the demand of equation (4) seems to have been met. Visually, the effect is striking. With very small concentrations of the dye, most of the dye is seen in the alcohol layer, while with large concentration the relation is reversed.

TABLE VI

SULFONATED ROSINDONE

Distribution of dye between amyl alcohol and water at room temperature (22° approx.).
$k' = 10$

C_{alc} mole/liter	C_{water} mole/liter	K'	C_{alc} mole/liter	C_{water} mole/liter	K'
0.0003	0.0007	2.6×10^{-6}	0.00008	0.00007	2.0×10^{-6}
.00022	.00048	2.2×10^{-6}	.000065	.000035	2.8×10^{-6}
.00018	.00032	2.2×10^{-6}	.00005	.00002	2.8×10^{-6}
.00014	.00016	2.6×10^{-6}	.00003	.000007	4.4×10^{-6}
.00011	.00009	3.0×10^{-6}	.000015	.000003	3.0×10^{-6}

A somewhat different distribution coefficient would obviously obtain were the aqueous phase a buffer solution. An experiment was made on the distribution of the dye between amyl alcohol and an aqueous solution buffered with the borate–boric acid–potassium chloride system. This gave an association constant approximately the same as that found by the potentiometric measurements with the same buffer solution.

According to equation (5), which involves the apparent polymeric dissociation constant, K', the "titration curve" relating electrode potential to percentage reduction *at constant* (H^+) should be asymmetric. This was found to be the case. However, accurate evaluations of the characteristics of the curve were difficult for the following reason.

Since an appreciable amount[6] of reducing agent, d, is used by the slight impurities of the buffer solution, it is necessary to correct y, the ml. of

---

(6) Equivalent to about 2×10^{-6} normal.

reducing agent used at any given stage, by applying this "*d*-correction" before further calculations are made. Ordinarily this "*d*-correction" as well as the total amount, *A*, of reducing agent can be found by the method of Reed and Berkson.[7] In the present instance the asymmetry of the titration curve prevents the application of this method. Therefore estimates of the "*d*" and "*A*" values had to be made by a graphic method which leaves a small element of judgment.

With $[S_O]$ and the ratio $[S_R]/[S_O]$ thus established, K' could be estimated from any two sets of data. In Table VII the value of K' so estimated is rounded to 1×10^{-5}. Its application leads to a fairly satisfactory agreement in the calculated values of E'_0, the potential at 50% reduction. This is the more satisfactory when it is considered that a titration of the dye at a concentration one-tenth that recorded in Table VII gave a value of E'_0 agreeing within 0.1 millivolt. A titration of the dye at ten times the concentration recorded in Table VII gave a value of E'_0 0.9 millivolt more positive. However, the corrections are here the more uncertain and the concentration of the dye is close to saturation in borate-potassium chloride buffers.

There remains the possibility that the dye is not homogeneous, that it consists of two or more monosulfonates and that the dissymmetry of a titration curve is of an origin comparable with that found by Sullivan, Cohen and Clark[8] in their titration of *mixtures* of the sulfonates of indigo. An asymmetry of only 4 millivolts in the titration curve was found in the most dilute solution measured. If this asymmetry be ascribed entirely to a mixture of two or more monosulfonates, then their E_0 values would be at the most 4 millivolts apart. The agreement in the value of the association constant calculated from the distribution experiment and from the potentiometric measurements indicates that the greater part of the asymmetry, if not all, is due to association. Consequently if there is present a mixture of monosulfonates, they have the same, or nearly the same, E_0 values and for our purposes we can neglect the possibility of mixtures and treat the oxidant as a homogeneous compound.

Calculations with the measurements of the rosindone in phosphate buffers yielded a value of K' considerably higher than the value for borate buffers; 5×10^{-5} for phosphate buffers instead of 1×10^{-5} for borate buffers. Accordingly the calculations of Table VIII, which summarize the results, are made with these distinct constants. In this table the apparent acid dissociation constants of the reductant, K'_{r_1} and K'_{r_2} are those estimated by the usual methods (see previous papers of this series).

Part of the difference between the values for K' in the two buffers may be ascribed to a difference in ionic strengths which affect the activities.

* The starred values were calculated by equation (5) giving E'_0 (corr.) directly. The other values were estimated graphically and the E'_0 (Found) was then corrected for [So], consequently not as much weight was placed on these values. The error introduced by graphical estimation was not sufficient to warrant the more laborious calculations.

However, in this, as in the previous investigation, our preliminary measurements indicate that moderate variation of ionic strength causes a second order effect. We believe that the salt effect is largely specific and comparable to that noted by Sullivan, Cohen and Clark[8] in the cases of the sulfonates of indigo which behaved differently in borate and in phosphate buffers.

Since association of the dye is doubtless a first step toward the formation of a precipitable aggregate, it is important to note that our approximate measurements of the solubilities of the dye in solutions containing various buffer and neutral salts indicate that the potentiometric measurements were conducted with solutions of the dye too dilute for precipitation.

Discussion

In Fig. 1 are shown the curves relating E'_0 to P_H for each of the systems studied. E'_0 is the potential at 50% reduction. In the figure only the experimental data for complete titrations are shown. Less accurate supplementary data, as, for instance, those obtained by the method of mixtures, indicate that the curves are properly extrapolated, provided no resolution of the titration curve comparable to that found by Michaelis[9] in the case of rosinduline 2G in very acid solutions appears. For purposes of orientation the curves for several other systems are shown in Fig. 1. Curve 2G is for rosinduline 2G (Rowe 830), drawn according to the first data of Michaelis.[10] Rosinduline 2G has a structure very similar to VI except that it has no substituted amino group.

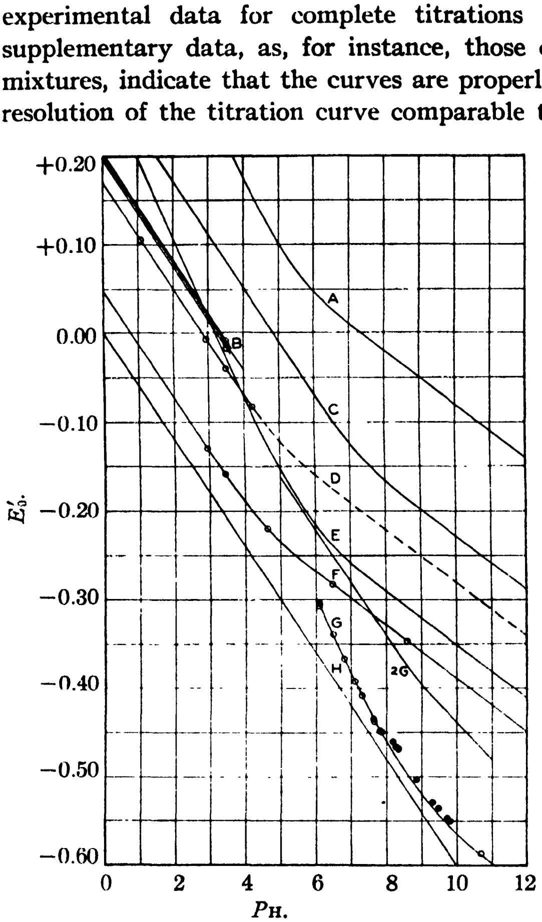

Fig. 1.—Relation of E_0' to PH (E_0'; potential in volts, referred to the hydrogen electrode standard, when dye is 50% reduced): A, methylene blue; B, the isorosindulines Nos. 1, 2 and 3; C, indigo disulfonate; D, neutral blue; E, dimethylphenosafranine; F, induline scarlet; G, sulfonated rosindone; O, in phosphate buffers; ●, in borate buffers; 2G, rosinduline 2G (after Michaelis); H, hydrogen electrode, 1 atm. hydrogen.

The system of induline scarlet and that of the rosindone nearly supplement one another as oxidation–reduction indicators with characteristic potentials near that of the hydrogen electrode under one atmosphere of hydrogen. In the case of the sulfonated rosindone at a concentration of total dye of $3 \times 10^{-5}M$, 90% reduction, and PH 7.0 the potential is that of the hydrogen electrode under one atmosphere of hydrogen. We are thus encouraged to believe that these dyes will be useful in certain biochemical studies which have been delayed for lack of such indicators; but we must add the caution that in practical applications the several peculiar properties of these systems will have to be considered.

Since the reductants of the isorosindulines, I–IV, are practically insoluble in buffers of PH values greater than about 4.5 or 5.0, these systems are of less biochemical interest. The effects of substitution are slight but appreciable. An analysis of such effects would require knowledge of the dissociation constants.

[9] Michaelis, *J. Biol. Chem.*, **92**, 211 (1931).

[10] Michaelis, *ibid.*, **91**, 369 (1931).

With regard to the postulate of a reversible association of the sulfonated rosindone it may be said that there is now a first order agreement between the results of the potentiometric measurements and the results of the study of the distribution coefficient between aqueous solutions and amyl alcohol. The purely qualitative spectrophotometric data admit the same explanation. Undoubtedly the following steps of aggregation should be considered: $2\mathrm{O_X} \rightleftharpoons \mathrm{O_{X_2}}$; $\mathrm{O_X} + \mathrm{O_{X_2}} \rightleftharpoons \mathrm{O_{X_3}}$, etc. But obviously the resulting equations would be complex and would involve too many constants for a practical test. Therefore only the first order approximation can be sought with the assumptions used. The calculations suggest that if the number of molecules in the predominant aggregate present in the alcohol is X, the numbers present in the predominant aggregates of the aqueous phase are X and $2X$, the proportion depending upon the concentration. If X were other than unity the equation involving the electrode potential would be so seriously altered that it is doubtful whether the application of equation (5) would have led to the agreement found. Therefore the "internal evidence" seems to justify the assumptions made.

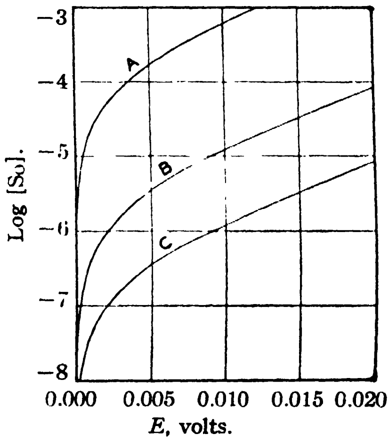

Fig. 2.—Effect of association of oxidant upon potential, K', the apparent polymeric dissociation constant: A, for $K' = 5 \times 10^{-4}$; B, for $K' = 1 \times 10^{-5}$; C, for $K' = 1 \times 10^{-6}$.

In the previous paper Stiehler, Chen and Clark[2] reported several very careful titrations of safranines. Their titration curves were analyzed by the method of Reed and Berkson and failed to show the dissymmetry predicted from the evidence of aggregation found by separate titrations at different concentrations. They noted, however, that the titrations which showed no asymmetry might have been made at unsuitable concentrations.

An examination of equation (5) will show that when the contribution of aggregation to the observed potential is plotted against log $[\mathrm{S_O}]$ there is obtained a family of curves with K' as a parameter (see Fig. 2). Curve A approximately represents the case of dimethylphenosafranine.[11] If, during a titration of this dye, the value of log $[\mathrm{S_O}]$ falls from -4.22 to -6.22, the contribution of declining association to the observed potentials should be about 2 millivolts. The resulting dissymmetry of the

---

(11) See Stiehler, Chen and Clark, Ref. 2, p. 897.

titration curve would escape visual inspection unless the value of the "*d*" correction were known. When such a curve is treated as if symmetrical by the method of Reed and Berkson, the "*d*" and "*A*" values are automatically adjusted so that the calculated values of E_0' appear constant within experimental error. In the earlier work on methylene blue[12] and on Nile blue[8] the element of judgment remained in the selection of "*A*" values and the slight dissymmetry of a titration curve was obscured.

Therefore the more reliable test of the "concentration effect" is that obtained when a fixed ratio of total oxidant and total reductant is used at different concentrations of the sum. Unfortunately there are limitations to the exploration of the entire course illustrated in Fig. 2. A test at dilutions great enough to bring about complete dissociation would involve measurements at concentrations of the order of millionth molar or less. This involves large experimental errors. Use of relatively high concentrations is precluded in some instances by limited solubilities and in all cases involves some uncertainty of correction for the effect of the oxidation–reduction system upon the buffer system. Therefore the empirical linear relation $\tilde{E} = E_0 + A \log C$ used in the previous paper[2] was legitimate as a first approximation applicable within narrow limits of concentration.[13] The better analysis in the case of the rosindone is made possible by the fortunate circumstance that the greatest change in association takes place within a range of concentration adapted to the potentiometric measurements (see curve B, Fig. 2).

Summary

The equilibrium potentials of six oxidation–reduction systems in which aposafranines are the oxidants have been determined at 30°.

Neutral blue (Rowe 832) and three other closely related isorosindulines have the following "normal potentials," E_0: Neutral blue, 0.170; Isorosinduline No. 1, 0.199; Isorosinduline No. 2, 0.195; Isorosinduline No. 3, 0.202. In acid solution $\Delta E_{\text{h}}/\Delta P_{\text{H}} = -0.0601$. The low solubilities of the free bases prevented measurements in neutral and alkaline solutions. A rough estimate of the dissociation constant of the neutral blue cation, treated as an acid, is 1×10^{-5}.

The system of which induline scarlet (Rowe 827) is the oxidant gave electrode potentials which may be described by the equation

$$E_{\text{h}} = 0.047 - 0.03006 \log [\text{S}_{\text{R}}]/[\text{S}_{\text{O}}] + 0.03006 \log [K_{\text{r}_1}'(\text{H}^+) + (\text{H}^+)^2]$$

K_{r_1}', the apparent first dissociation constant of the cation of the reductant is 3.1×10^{-5} ($pK_{\text{r}_1}' = 4.5$). At $P_{\text{H}} = 7.0$ and $[\text{S}_{\text{R}}]/[\text{S}_{\text{O}}] = 1$, E_{h}, $= -0.299$.

---

(12) Clark, Cohen and Gibbs, *Public Health Reports*, **40**, 1131 (1925).

(13) The first value of $\tilde{E}_0$ in Table III of the previous communication is brought nearer to the average by the full correction.

The system of which the sulfonated rosindone is the oxidant gave electrode potentials which may be described by the equation

$$E_h = E_0 - 0.03006 \log [S_R]/[S_O] - 0.03006 \log [K' + \sqrt{K_2' + 8K'[S_O]}]/2K' + 0.03006 \log [K'_{r_1}K'_{r_2}(H^+) + K'_{r_1}(H^+)^2 + (H^+)^3]$$

$K'_{r_1} = 3.2 \times 10^{-8}$ ($pK'_{r_1} = 7.5$); $K'_{r_2} = 3.2 \times 10^{-10}$ ($pK'_{r_2} = 9.5$). K' is the apparent dissociation constant for an equilibrium between uni- and bimolecular species. K' is approximately 5×10^{-5} when the dye is in phosphate buffers and 1×10^{-5} when the dye is in borate buffers. This specific salt effect is also reflected in the extrapolated values of E_0, 0.243 for phosphate and 0.251 for borate buffers.

Other evidences of a reversible association of the rosindone in aqueous or aqueous buffer solutions are: (1) the qualitative analysis of the changes in the spectrophotometric absorption curves which follow dilution; (2) the analysis of quantitative studies on the distribution of the dye between water and amyl alcohol. The values of K', estimated by the distribution studies, are in substantial agreement with those estimated by the potentiometric measurements.

When the sulfonated rosindone is 90% reduced, $P_H = 7.0$ (phosphate buffer) and total dye concentration is 3×10^{-5} M, the electrode potential is that of the hydrogen electrode under 1 atmosphere of hydrogen. This system gives potentials nearer that of the hydrogen electrode than any system previously reported in this series of papers on oxidation-reduction indicators.

The Homogeneous Thermal Polymerization of Isoprene

BY WILLIAM E. VAUGHAN[1]

In an earlier publication[2] there has been reported an investigation of the homogeneous thermal polymerization of 1,3-butadiene, and in that paper there has been given a brief review of the several similar reactions hitherto studied, together with a cursory survey of some of the theoretical aspects of the general problem of association processes. There is thus no need to repeat that material. Suffice it to say that Kassel's contention[3] that the formation of polyatomic molecules by a second-order association process is possible at a relatively large fraction of all collisions, is well supported by the experimental evidence thus far presented. It may also be mentioned that the data for the three reactions considered, namely, the hydrogenation of ethylene and the dimerizations of ethylene and of 1,3-butadiene, show that the ratio of the empirical second-order rate constant to that calculated from the collision frequency and the simple Maxwellian factor decreases for the reactions in the order named; this was interpreted as indicating that orientation of the properly activated particles at the moment of impact was highly important for the achievement of reaction, and that the more complex the molecules the more precise must be their mutual locations.

[3] Kassel, "Kinetics of Homogeneous Gas Reactions," Chemical Catalog Co., Inc., N. Y., 1932, pp. 44-47; also THIS JOURNAL, 53, 2143 (1931).

The present study is a continuation of the former, concerning itself with the 2-methyl derivative of 1,3-butadiene, which is known to form a dimer under certain conditions.

Experimental

The technique employed was essentially the same as that used previously. The furnace was electrically heated and its temperature manually maintained at constancy. Temperatures were determined by means of a calibrated thermometer. It is estimated that the temperature readings were accurate to ±1°. During the first several hours of all runs the variation of the temperature was within ±0.5°. The reaction cells, several of which were used, were all of 80 cc. capacity; they communicated through capillary tubing to the supply of isoprene and to a quartz spiral manometer. In those experiments where the pressure was sufficiently high so that isoprene would condense out in the tubing at the temperature of the room, the entire reaction system other than the cell, namely, the tubing and spiral manometer, was electrically heated to approximately 150°, and in such cases the reaction system was sealed off from the auxiliary trap used in conjunction with the storage vessel for the admittance of the isoprene. A mercury column served as an absolute manometer in combination with the quartz spiral which acted as a null instrument; the scale of the former was readable by means of a vernier with a precision of 0.1 mm. This figure likewise is a close estimate of the accuracy with which the fibers of the quartz spiral were adjustable.

The reactant was an Eastman Kodak Company product which was used without further chemical treatment. It was, however, fractionally distilled *in vacuo* several times, only the middle portion being preserved. In the course of the experiments two separate samples were utilized with no detectable difference in their behavior.

Data and Results

In the several runs performed observations were made of the pressures at various time intervals, chosen to correspond to approximately equal amounts of reaction. These data when plotted gave curves of the types shown in Fig. 1. The curves possessing a minimum are characteristic of all of the higher temperature experiments (above 371°), while the continuous downward trend of pressure with time shown by No. 26 of the figure is typical of rate measurements made at temperatures from 286.5 to 371°. It is these latter rates which are primarily of interest to the purposes of this study.

A number of reports[4] confirm the thermal dimerization of *liquid* isoprene,

Soc.*, **47**, 1928 (1915); (d) Aschan, *Ann.*, **439**, 221 (1924); *Ber.*, **57**, 1959 (1924); (e) Wagner-Jauregg, *ibid.*, **488**, 176 (1931); (f) Whitby and Crozier, *Canadian J. Research*, **6**, 203 (1932).

although there is some disagreement as to the nature of the dimer formed; the recent work indicates that the product is a monocyclic compound. Gapon[5] has investigated the kinetics of the polymerization of liquid isoprene at 100–150° and claims to have differentiated three second-order reactions that occur simultaneously; two dimers, dipentene and 1,3-dimethyl-1-vinylcyclohexene-3, are formed together with a complex polymer. These three processes are seemingly so clearly differentiated that he further gives as the activation energies for the three reactions, 22,400, 21,500 and 18,800 calories, respectively. In the light of the experimental difficulties involved, the precision of these results is very surprising.

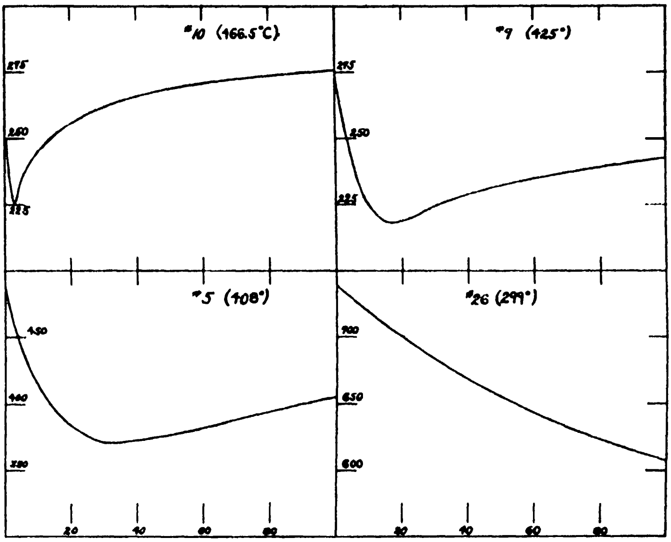

Fig. 1.—Pressure (mm.) *vs.* time (min.).

The above-mentioned results and the analogous study of butadiene obviously suggest a treatment of the pressure–time data by appplication of the integrated second-order reaction rate equation

$$k = \Delta p_{\mathrm{I}}/(\Delta t)(p_{\mathrm{I}_1})(p_{\mathrm{I}_2}) \qquad (1)$$

wherein Δp_{I} is the change in isoprene pressure in the interval Δt, $(t_2 - t_1)$, and p_{I_1} and p_{I_2} are the pressures of isoprene at the times t_1 and t_2. The results to which this leads are shown by Table I, which shows the rate constants, k, at various fractions of isoprene converted for Run No. 24, which was chosen as typical of the low temperature runs, and by Fig. 2, which shows a plot of such a set of data for a similar experiment.

The downward trend of k with time considered in relation to the behavior revealed in the higher temperature experiments, namely, that a pressure increase occurs after a certain pressure decrease, may be taken to indicate

the presence of a subsequent decomposition of the dimer, occurring along with the formation process. Certain runs were prolonged, such as No. 5 at 408°, and it was observed that the final pressure (attained after 1080 min.) was the same as the initial pressure; it would seem, then, that one molecule of the dimer decomposes to give two molecules of gaseous products. However, in the highest temperature experiments (for example, No. 10), the final pressure exceeded the initial, indicating still further decomposition. The products of the decomposition were probably unsaturated hydrocarbons, inasmuch as freezing down with liquid air caused the pressure to drop to an unreadable amount, indicating that no hydrogen is split out. The cool cell, after the furnace was removed following the termination of a run, contained droplets of a colorless liquid condensate which had a definitely turpentine-like odor, somewhat similar to that of limonene. This material rapidly decolorized a few drops of a very dilute permanganate solution, as does limonene. In none of the lower temperature experiments was any discoloration of the cell observed but at the higher temperatures a dark film appeared on the walls.

To secure a rate constant representative of the polymerization reaction alone, undisturbed by the decomposition, the data of each run were treated as shown in Fig. 2, the constant obtained by extrapolation to zero fraction converted being taken as the true rate of the association. The construction of the straight line through the divergent points can be none too precise and the constants are certainly liable to some error. The results obtained are listed in Table II.

It may be recalled that in the case of butadiene[6] the rate constant was obtained in a similar fashion; but the extrapolation was simpler, since the constants for the intervals were invariant until 60–70% conversion was approached, at which point the constants increased, due seemingly to further polymerization, in contrast to the present steady decrease of the constants from the onset of reaction. Table II shows that in the small pressure range utilized the rate is independent of pressure

20	286.5	408.5	.527	.42	2.44	Hexaphenylethane
21	286.5	312.0	.487	.42	2.44	Hexaphenylethane; packed
22	301.0	289.4	.586	.92	5.48	Hexaphenylethane; packed
23	300.0	412.4	.726	.81	4.83	
24	299.5	620.0	.798	.93	5.53	
25	297.0	615.0	.776	.70	4.15	
26	299.0	739.0	.470	.83	4.94	

It is to be further observed that in certain of the runs, such as No. 21, shown in Fig. 2, at the beginning of the reaction there was a brief period during which there was an abrupt decrease in the values of the constants to a point where they revealed the apparent linear relationship to the fraction of isoprene converted (as was utilized in determining the rate at zero percentage conversion). It was thought that this somewhat anomalous feature might be due to an extraneous reaction such as might be

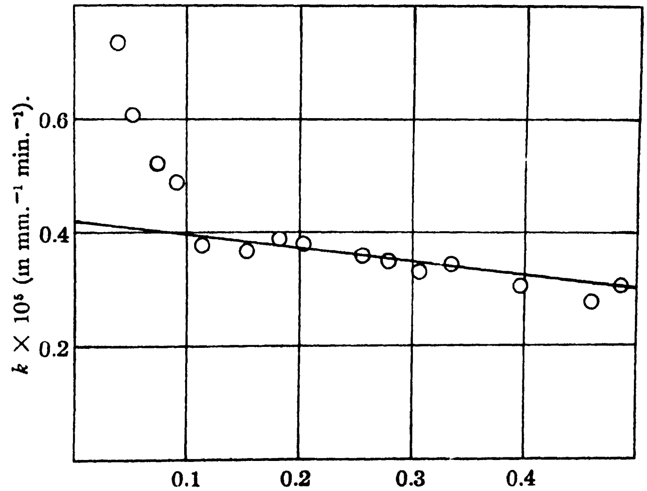

Fig. 2.—Run 21 (286.5°).

brought about by traces of peroxides in the gas, causing a catalyzed polymerization. Conant and Peterson[7] have proved in their very high pressure polymerizations of isoprene that traces of peroxides are extremely active catalysts in the process and that by treatment of the liquid reactant with hexaphenylethane the rate was reduced ten-fold. This procedure was tried in the cases of Runs 19 to 22, and this initial effect was diminished but not completely removed.

The reaction seemed to be essentially homogeneous, inasmuch as in a cell packed with lengths of Pyrex tubing so that the surface-volume ratio was increased five-fold, it proceeded with the same velocity as in the "empty" cell.

An effort was made to express quantitatively the data for the higher temperature experiments. Computation showed that in the earlier part of a given run the rate was well expressed by the simple second-order equation (1). Attempts were then made to express the total pressure over the whole range of the run as resulting from a concurrent bimolecular association and a first- or second-order decomposition of the dimer formed, but the complexity of the mathematical analysis coupled with the uncertainty of the premises led to the pigeon-holing of this phase of the problem pending further investigation.

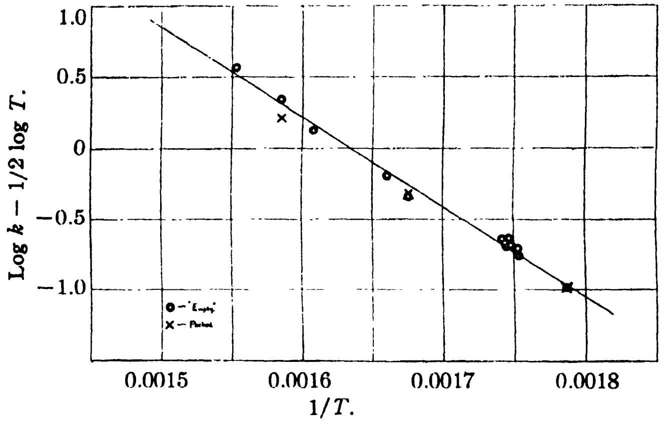

Fig. 3.

A plot of $\log_{10} k - 1/2 \log_{10} T$ *vs.* $1/T$ (k in cc. moles^{-1} sec.$^{-1}$), (in accord with the equation $k = AT^{1/2} e^{-E/RT}$), is shown in Fig. 3. The slope of the line corresponds to $E = 28{,}900$ calories and an equation expressing it is $k = 2.193(10^{10})\ T^{1/2} e^{-28{,}900/RT}$

Discussion of the Results

Following the method used previously[8] it is possible to determine the efficiency of molecule formation at collisions between properly activated

---

(7) Conant and Peterson, THIS JOURNAL, 54, 628 (1932).

(8) Ref. 2, p. 3873.

particles. For molecules possessing in one degree of freedom an energy of 28,900 calories per mole at 570°K. the Maxwellian factor is 7.83×10^{-12}. The total number of collisions per cc. in each second is given by[9] $Z = 2N^2\sigma^2\sqrt{\pi kT/m}$, wherein N is the number of molecules of diameter σ and mass m per cc. Evaluation of Z for C_5H_8 at a concentration of one mole per liter for a temperature of 570°K. on the assumption of a diameter of 5.0×10^{-8} cm. gives 8.57×10^{31}. If molecules of the dimer resulted on each collision of properly activated molecules, the rate of disappearance of isoprene should be calculable from $2Z$ times the exponential, since two molecules react at each successful impact; this product is 2.21 (units of moles/liter and sec.). The value of the experimentally determined constant at this temperature is 4.15×10^{-3}, expressed in the same units. The ratio of these two figures is 1:530. The significance of this figure as bearing upon the orientation of the particles on collision has been treated heretofore in the discussion of the reaction mechanism for the association of polyatomic molecules.

In Table III are summarized some data for the four second-order association reactions treated to date. In the last column are given the ratios which show conclusively the validity of Kassel's argument, based on theory, for the possibility of the occurrence of such processes with a reasonably high efficiency. That the ratios are not regularly decreasing with increasing complexity of the molecules involved, as might be required by the simple *a priori* picture of a "steric factor," is not unexpected, inasmuch as the "steric factor" may well be a predominating influence and yet be modified by other variables in such complex processes as the formation

of the dimer (or possibly mixture of dimers) encountered here, and that met with in the butadiene experiment.

Acknowledgment.—The author is pleased to acknowledge his indebtedness to the Gates Laboratory for the hospitality and facilities extended him, and to his associates there for aid during his stay in Pasadena.

Summary

The homogeneous thermal polymerization of isoprene has been investigated in the temperature range of 286.5 to 371° at pressures varying from 212 to 739 mm.; the principal process is interpreted as a bimolecular association reaction, the rate of which is expressible by $k = 2.19_3(10^{10}) T^{1/2}e^{-28,900/RT}$

Dielectric Constants: Ethanol–Diethyl Ether and Urea–Water Solutions between 0 and 50°

BY JEFFRIES WYMAN, JR.

The importance of a knowledge of the dielectric constant of the solvent as well as its change with temperature in the study of solutions is well known and requires no elaboration. The present paper is a report of routine measurements at a variety of temperatures on two sets of solvents of considerable use especially in organic and biological chemistry. The first set, consisting of mixtures of ethanol and diethyl ether, covers a range of dielectric constant from about 4 to 28. The second, comprising aqueous solutions of urea of concentrations running up to nearly 8 moles per liter, is characterized by dielectric constants greater than that of water, in fact approaching 108 at the upper limit. In this respect the urea–water solutions occupy an exceptional position and afford a convenient class of solvents of high dielectric constant. In fact, apart from certain ampholytes supposed to exist as zwitter ions and one or two compounds closely related to it, urea is the only substance known to form solutions of dielectric constant greater than that of water.[1] Existing data on the dielectric constant of both the above sets of liquids are somewhat incomplete and contain inconsistencies. The present results serve to extend the list of mixed solvents of accurately known dielectric properties such as those dealt with in recent papers by Åkerlöf[2] and Wyman.[3]

[1] See Devoto, *Gazz. chim. ital.*, **61**, 897 (1932); also Wyman and McMeekin, THIS JOURNAL, **55**, 908 (1933); **55**, 915 (1933).

[2] Åkerlöf, *ibid.*, **54**, 4125 (1932).

[3] Wyman, *ibid.*, **53**, 3292 (1931).

The values given in the present investigation were obtained by an absolute method, were reproducible to better than 0.1%, and, it is believed, are entirely free from systematic errors. The principle underlying this method consists in determining the electrical resonance point of a small metal circuit completely immersed in the dielectric to be measured. The dielectric constant in question is equal to the square of the ratio of this resonant wave length divided by the resonant wave length of the same circuit in a vacuum, or, in practice, in air.[4] The size of the resonant circuit required for use at a given wave length increases rapidly with decrease in the dielectric constant. In the case of the alcohol–ether mixtures the circuit required for use at convenient wave lengths is considerable and would ordinarily involve more than a liter of liquid for adequate immersion to include the entire field. For this reason a special type of resonator built up of concentric cylinders and having a very small stray field was employed. This circuit necessitated the use of less than 100 cc. of solution for satisfactory immersion and at 25° resonated at 8.612 meters in pure ether and at 20.69 meters in pure alcohol. A description of this form of resonator has been given elsewhere.[5]

In order to make sure that no systematic errors were introduced by the use of such small amounts of liquid, owing to the stray field of the resonator not included in the liquid, a careful comparison was made of the dielectric constant of a sample of alcohol at 25° determined in one case with the resonator immersed in a large volume of liquid and in the other case with the resonator in a small tight-fitting glass vessel containing about 75 cc. and jacketed with circulating water drawn from the thermostat. The two values obtained for the dielectric constant were 24.32 and 24.33, respectively, the difference being no greater than the experimental error of the determinations.

In the case of the urea–water solutions, owing to the much greater values of the dielectric constant, it was convenient to use a small spiral resonator having a resonant wave length of 0.4111 meter in air. Although this resonator had a relatively far larger stray field than the other it was so small that it could be used with about 120 cc. of solution in a double-walled Pyrex vessel jacketed with circulating water of the desired temperature.

In the case of all the solutions investigated the variation of dielectric constant with temperature can be expressed with an accuracy as great as that of the measurements by means of the second degree equation: $\epsilon = a - b(t - 25) + c(t - 25)^2$. In this equation ϵ denotes the dielectric constant at temperature t, a is the dielectric constant at 25°, and b and c are constants. The experimental results which follow are therefore presented in terms of these constants.

II. Alcohol–Ether Mixtures.—These solutions were made up gravimetrically from the best commercial materials. The density of the alcohol, determined with a pycnometer, was found to be 0.7853 as compared with the figure 0.7851 given by "International Critical Tables." The discrepancy would correspond to less than 0.07% H_2O, which would make a difference of about 0.03 in the dielectric constant, an amount not greater than the errors of the measurement. In the case of the ether, owing to the high vapor pressure, it was not practicable to determine the density so accurately. The figure obtained, 0.708, is to be compared with the value 0.7077 from "International Critical Tables." It seemed unwise to attempt further purification of the sodium distilled ether from a sealed metal container on which the measurements are based. The results are contained in Table I.

100.00	.7853	24.28	1570	20

[a] Composition based on dielectric constant at 20°.

Urea Solutions.—The urea solutions were made up gravimetrically from Merck C. P. product and the density of each determined at 25° with a pycnometer. It was found that solutions allowed to stand for several hours at a temperature above 30 or 35° underwent a change associated with an increase of conductivity. For this reason measurements at lower temperatures were made first and the work above 25° was carried out as quickly as possible before the conductivity had shown any considerable increase, and before the dielectric constant showed any change independent of temperature. A similar change in the dielectric properties of urea solutions after standing for several days has been reported by Walden and Werner,[6] and Kockel[7] states that above 35° urea undergoes an irreversible change. The results are given in Table II and shown graphically in Fig. 1, where the full lines correspond to the values of *a*, *b* and *c* given in Table II and the circles are the experimental points. The accuracy of these data is not so great as in the case of the alcohol–ether mixtures owing to the far greater

(14) Matsouike, *Proc. Imp. Acad. Tokyo*, **5**, 29 (1929).

data on pure ether, there is considerable disagreement, as shown by Table III. The author's value of 4.336 at 20° is in best agreement with the figures of Richards and Shipley and of King and Patrick. The latter observers also report the dielectric constant of mixtures of ethanol and ether of 10, 20, 30, 100% by weight at 20°. Their values, which are given only to either two or three significant figures, are 1 or 2% higher than those reported above.

As regards the urea solutions there is a considerable discrepancy between the measurements at a single temperature by Harrington,[15] Furth[16] Walden and Werner,[6] Kniekamp[17] and Devoto,[18] none of which were extended to a concentration greater than about 3 moles per liter. The present results, on the basis of the limiting value of the dielectric constant--concentration curve at zero concentration, agree best with the values of Walden and Werner.[6]

Kockel[7] has carried out an investigation of the effect of temperature on the dielectric constant of urea solutions of 5, 10 and 15% by weight. These results have been applied by Lange and Robinson[19] to their data on the integral heats of dilution of potassium chloride in 5% urea solutions on the basis of the theory of Debye. Lange and Robinson point out that in accordance with an extension of the original theory the limiting slope of the curve relating the heat to the square root of the molar concentration should be given approximately by the expression

$$\frac{-1.66116 \times 10^7}{\epsilon} \times \frac{1}{\sqrt{\epsilon T}}\left(1 + \frac{T}{\epsilon}\frac{d\epsilon}{dT}\right) = A$$

where ϵ is the dielectric constant of the solvent and T is the absolute temperature. In terms of Kockel's data this expression actually demands a negative heat of dilution ($A = -228$) for potassium chloride in 5% urea. This is quite at variance with the facts, which show that the heats in this solvent are positive (A observed = 332) and only slightly lower than those in water and in a 15% sugar solution, for which the theoretical values of A are given as 661 and 532 and the observed values as 376 and 386, respectively. On the basis of the data presented in this paper the value of A calculated from the above expression for the 5% urea solution is 440, which is in as good agreement with the facts as in either of the other cases. It may be noted that the theoretical values of A for water as well as the 15% sugar solution given by Lange and Robinson are also based on the data of Kockel. If Wyman's[4] data for water, used elsewhere by Lange, are substituted, the value obtained for A is 513.

Summary

A report is given of a study of the variation with temperature, between 0 and 50°, of the dielectric constant of ethanol–diethyl ether and urea–water solutions as determined by a resonance method at wave lengths between 3.6 and 20 meters. The results are compared with data of previous investigators, and, in the case of the urea–water solutions, are applied to studies of Lange and Robinson on heats of dilution.

The Binary System Lead Iodide–Potassium Iodide[1]

BY HENRY S. VAN KLOOSTER AND EDWIN I. STEARNS

The melting point of lead iodide has been reported at such variant temperatures as 358[2] and 412°.[3] The melting point of potassium iodide has been given as low as 634° (1878)[4] and as high as 723°.[5] Many workers have confirmed the fact that only the double salt $KPbI_3 \cdot 2H_2O$ exists in the ternary system PbI_2–KI–H_2O,[6,7] but the anhydrous binary system has not heretofore been examined.

C. H. Herty[8] has driven off the water from this hydrate, $KPbI_3 \cdot 2H_2O$, and states that at 310° the salt decomposes with the liberation of iodine. It was therefore the purpose of this work to find the melting points of these two iodides and to decide what anhydrous double salts they form by determining the phase diagram by means of cooling curves.

The difficulty in melting lead iodide is that it decomposes in the presence of air. Several oxyiodides have been reported[9] but they have not been examined in the light of the phase rule and are thus to be considered on probation.

Apparatus and Materials.—The tube used to melt the various mixtures consisted, as illustrated in Fig. 1, of an outer test-tube and an inner air-excluding and thermocouple-protecting tube. This inner tube excluded the air by three factors. Its volume expelled nearly all the air to begin with, and further access of air was hindered both by the snugness with which the two tubes fit together and by the bulge of the inner tube resting upon the rim of the outer. The amount of decomposition could be seen by the iodine that condensed on the upper part of the tube which protruded from the furnace. A cooling curve taken when nitrogen filled the space between the inner and outer tubes, in which case no decomposition occurred, could not be distinguished from a cooling curve taken with the inner tube as the sole protection, in which case a small ring of iodine was formed.

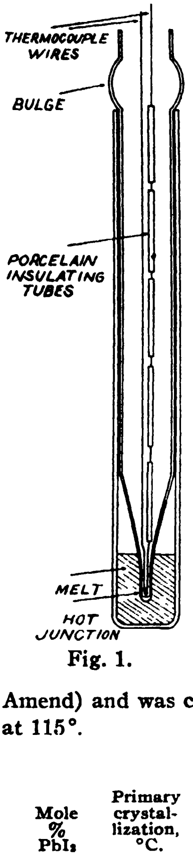

Fig. 1.

The thermocouple was of nichrome and alumel and the cold junction was kept at 20°. It was carefully calibrated with pure cadmium, lead, zinc and antimony. The calibration curve was very nearly a straight line and was extended as a straight line to beyond the melting point of potassium iodide.

An electric furnace was the source of heat and the e. m. f. was read with a millivolt meter made by Chas. Engelhard.

The lead iodide used in determining the equilibrium diagram was commercial lead iodide. Its purity is indicated by its cooling curve which has a long and strong horizontal and by the fact that its melting point, 412°, coincides with the melting point of C. P. lead iodide. The C. P. lead iodide was made by the admixture of solutions of C. P. lead nitrate (J. T. Baker Co.) and C. P. potassium iodide (J. T. Baker Co.) in the correct molar proportions. The precipitated lead iodide was washed by decantation ten times until a saturated ferrous sulfate solution placed above a 1 to 1 mixture of wash water and sulfuric acid no longer showed a brown color. It was then decanted five times more, placed on a filter, and washed ten times, allowing the previous water to drain off completely before adding more. It was then dried in an oven at 115° for two hours, pulverized, and further dried at 115° for three hours.

The potassium iodide was of U. S. P. quality (Eimer and Amend) and was crystallized twice from pure water. It was then dried for six hours at 115°.

EXPERIMENTAL RESULTS

Mole % PbI_2	Primary crystallization, °C.	Eutectic, °C.	Mole % PbI_2	Primary crystallization, °C.	Eutectic, °C.	Mole % PbI_2	Primary crystallization, °C.	Eutectic, °C
100	412	...	65	330	321	30	504	346
95	404	321	60	337	321	25	548	346
90	395	321	55	345	321	20	585	346
85	383	321	50	349	...	15	609	347
80	367	321	47.5	...	346	10	641	...
75	349	321	45	378	346	5	660	...
70	324	321	40	422	346	0	686	...
69	...	321	35	475	346			

Discussion of Results.—The phase diagram (Fig. 2) is a common type in which the two components form a congruently melting compound. It shows definitely that the compound $KPbI_3$ is the only anhydrous double salt formed. The melting point found for lead iodide, 412 ± 1°, is in exact agreement with the work of German and Metz previously referred to. It is thus recommended that this value be accepted as the true melting point. The melting point of potassium iodide, 686 ± 1°, is reasonably close to the value 684° given by Rassow[10] but does not check exactly with any given in the literature. The 346° eutectic composition is exceptionally close to the compound composition, but this is to be expected from the great difference in the melting points of $KPbI_3$ and KI.

The method of locating eutectic composition by plotting the eutectic halts against the composition of the melts and choosing the maximum was only approximate here, because unequal weights of samples were used and unequal rates of cooling prevailed. However, the eutectic compositions could be quite satisfactorily found by the intersection of the lines drawn through the points of primary crystallization.

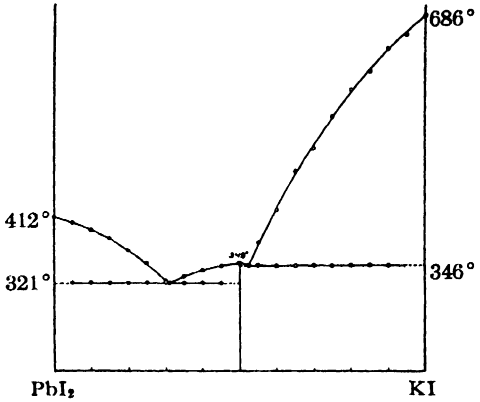

Fig. 2.—Phase diagram of PbI_2–KI.

Summary

The phase diagram of the binary system PbI_2–KI has been determined. Significant points are the three melting points, PbI_2 at 412°, $KPbI_3$ at 349°, KI at 686° and two eutectics, 69 mole % PbI_2 at 321°, and $47^1/_2$ mole % PbI_2 at 346°.

The Viscosity of Aqueous Solutions as a Function of the Concentration. II. Potassium Bromide and Potassium Chloride

BY GRINNELL JONES AND SAMUEL K. TALLEY

Recent papers from this Laboratory[1] have pointed out the significance of viscosities in the development of the modern theory of electrolytic solutions and have recorded data obtained by an improved technique. The present paper contains new data on aqueous solutions of potassium bromide over a wide range of concentration (0.001 to 3.75 *N*) and an extension of the data already published for potassium chloride up to 3 *N*.

Our new method of timing by means of a photoelectric cell which has been described in detail in the third paper referred to was used. The salts were carefully purified and are believed to have contained no impurities in significant amounts. The data are recorded in Table I in which the headings have the same significance as in our earlier paper, except that instead of giving the absolute densities of the solutions, the relative apparent densities in air (*i. e.*, the weight of the solution divided by the weight of an equal volume of water at the same temperature with no vacuum corrections applied) are given because this is the figure needed for the present

(1) Grinnell Jones and Malcolm Dole, THIS JOURNAL, 51, 2950 (1929); Grinnell Jones and S. K. Talley, *ibid.*, 55, 624 (1933); Grinnell Jones and S. K. Talley, *Physics*, 4, 218 (1933).

purpose. For the dilute solutions reported in the earlier paper the difference is insignificant. All measurements were made at 25.00°.

It will be noted that although all solutions of potassium bromide within the range of 0.01 to 3.75 normal have a viscosity less than that of water, nevertheless the 0.001, 0.002 and 0.005 normal solutions have a viscosity greater than that of water. This furnishes another case supporting the prediction of Jones and Dole that "At very low concentrations the viscosities of solutions of all strong electrolytes will be greater than that of water, including salts which at moderate concentrations show diminished viscosity."

The data recorded in this paper show that an equation of the form $\eta = 1 + A\sqrt{c} - Bc$, is only valid up to about 0.1 N for solutions of potassium bromide and up to about 0.2 N for solutions of potassium chloride. Both of these salts have a minimum viscosity (at about 0.8 normal for potassium chloride and at about 1.9 normal for potassium bromide). Other data in the literature indicate that salts which give solutions having a viscosity less than that of water will commonly have a minimum in their viscosity–concentration curves and again have a viscosity greater than that of water at high concentrations if they are sufficiently soluble. A more detailed discussion of the laws for the viscosity of concentrated solutions will be postponed until more extensive data are available. The results so far obtained, however, indicate that another term proportional to the square of the concentration must be added.

The viscosity of solutions of potassium bromide up to 2 N can be expressed approximately by the equation

$$\eta = 1 + 0.00474\sqrt{c} - 0.04904\,c + 0.01221\,c^2$$

The values computed by this equation are given in the table in the next to the last column. The greatest deviation up to 2 N is only 0.01%. The value of the coefficient of the square root term computed from the formula of Falkenhagen and Vernon[2] is 0.0049 which agrees satisfactorily with the value 0.00474 obtained from our experiments. For potassium chloride the equation

$$\eta = 1 + 0.0052\sqrt{c} - 0.01612\,c + 0.00808\,c^2$$

holds approximately up to 3 N. The greatest deviation between our experimental data and the values computed by this equation is only 0.016%.

Electron Diffraction and Molecular Structure: Carbonyl Compounds[1]

BY RALPH W. DORNTE[2]

This investigation was undertaken to determine the effect of the oxygen double bond on the valence angles of the carbon atom. Previous work[3] has shown that the angle between the halogen atoms of disubstituted methanes is 125° and becomes 115° in the case of the trisubstituted methanes. It seems desirable, therefore, to study this effect in carbonyl compounds and to determine their molecular structures.

The angular intensity of electrons diffracted by gas molecules with random orientation may be calculated by the equation[4]

$$I = k\,\Sigma_i\Sigma_j\psi_i\psi_j\,\frac{\sin x_{ij}}{x_{ij}} \tag{1}$$

in which

$$x_{ij} = 4\pi l_{ij}\sin\Theta/2/\lambda \tag{1a}$$

I is the relative intensity of electrons scattered at the angle Θ, k is a constant under the experimental conditions, the ψ's are the electron scattering coefficients of the atoms, l_{ij} is the distance between the ith and jth atoms of the molecule and λ is the wave length of the electrons. The double summation extends over all atoms of the molecule considered. The self-consistency of Wierl's results[5] and their agreement with x-ray diffraction data have shown that Z, the atomic number of the atom, may be substituted for ψ in Eq. 1 rather than the expression derived by Mott.[6] This simplified calculation of the theoretical intensity curves has been employed in the present work.

Experimental Procedure.—The procedure for electron diffraction is to allow a narrow beam of electrons to intersect a gas stream and to register the diffracted electrons on a photographic plate. The apparatus followed essentially the design by Wierl.[7] A hydrogen discharge served as a source of electrons which were accelerated by constant potential D. C.[8] The accelerating potential was measured by a calibrated electrostatic voltmeter. The electrons entered the diffraction chamber through a circular slit (0.1 mm.) in the electron nozzle which was at right angles to the gas nozzle. A trap immediately above the gas nozzle condensed the gas entering the diffraction chamber, which was evacuated by a high speed

diffusion pump.[9] A mechanical shutter interrupting the electron beam controlled the time of exposure. The diffraction photographs were photometered with a Zeiss recording microphotometer; the diameters of the diffraction rings were measured on the enlarged photometer curves. This procedure avoided the physiological error inherent in measurements on the diffraction picture.

Preparation of Materials.—Carbonyl sulfide was obtained by dropping 50% sulfuric acid on potassium thiocyanate. The gas was purified by passage through a concentrated solution of potassium hydroxide, concentrated sulfuric acid, calcium chloride and charcoal. The product was condensed and fractionated.

The carbonyl chloride was a Kahlbaum product which was dried over phosphorus pentoxide and fractionated.

Carbonyl bromide was prepared by the action of concentrated sulfuric acid on carbon tetrabromide and purified by shaking with mercury and fractionation.

The acetyl chloride and bromide were obtained from the Eastman Kodak Company and were fractionated.

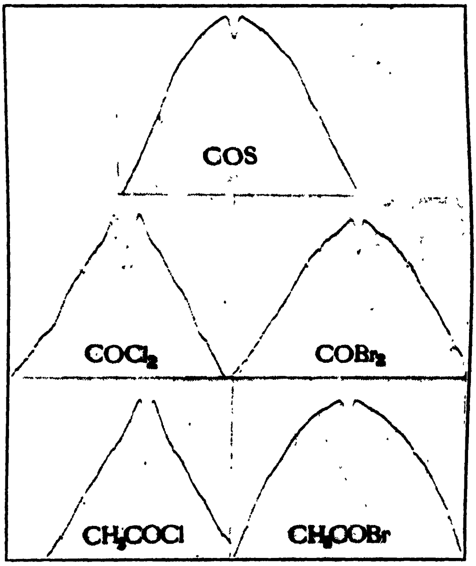

Fig. 1.—Microphotometer curves of electron diffraction photographs.

Results and Discussion

The photographs were obtained with electrons having a wave length corresponding to 45 kv. Figure 1 shows typical microphotometer curves of the diffraction pictures. The abscissas of these curves have been enlarged two-fold to emphasize the "bumps" indicating the diffraction maxima. In Table I are recorded, (1) the x values of the diffraction maxima, calculated for a definite molecular model, (2) the experimentally determined values of $\sin \Theta/2/\lambda$ for each maximum and (3) l, the corresponding carbon–oxygen interatomic distance in Å.

For carbonyl sulfide the relative intensity equation becomes

$$\frac{I}{k} = 2Z_CZ_O\frac{\sin x}{x} + 2Z_CZ_S\frac{\sin 1.40\,x}{1.40\,x} + 2Z_OZ_S\frac{\sin 2.40\,x}{2.40\,x} + Z_C^2 + Z_O^2 + Z_S^2 \qquad (2)$$

C–C = 1.54 ± 0.08
C–Br = 2.06 ± 0.10
<C–C–Br = 110° ± 10°

Equation 2 has been found to give the best correlation of the calculated and observed maxima, and is based on a linear model with C–O = 1.13 and C–S = 1.58 Å. A linear structure is consistent with the rather small electric moment of carbonyl sulfide.(10) The crystal structure of solid carbonyl sulfide has been determined by Vegard,(11) who found a linear structure with C–O = 1.10 and C–S = 1.96 Å. Dadieu and Kohlrausch(12) determined the interatomic distances, C–O = 1.04 and C–S = 2.38 Å., from the Raman effect and previous results on the infra-red absorption spectrum.(13) The nuclear separations obtained in this investigation are in good agreement with Wierl's results for carbon dioxide and carbon disulfide(7) and with the values $C\equiv O$ = 1.13 and $C=S$ = 1.63 Å. which are derived from the atomic radii formulated by Pauling.(14) It seems probable that the discrepancy among the several values for the interatomic distances of carbonyl sulfide may arise from resonance between two or more Lewis structures of the molecule as in the case of nitrous oxide.[15] For phosgene Eq. 1 becomes

(14) L. Pauling, *Proc. Nat. Acad. Sci.*, **18**, 293 (1932).

$$\frac{I}{k} = 2Z_CZ_O\frac{\sin x}{x} + 4Z_CZ_{Cl}\frac{\sin 1.61\,x}{1.61\,x} + 4Z_OZ_{Cl}\frac{\sin 2.34\,x}{2.34\,x} + 2Z_{Cl}^2\left(1 + \frac{\sin 2.64\,x}{2.64\,x}\right) + Z_C^2 + Z_O^2 \quad (3)$$

This intensity equation is based on a plane "Y" model with a 110° angle between the carbon–chlorine bonds. Intensity curves were calculated with this angle taking values from 100 to 135°, but the best correlation of calculated and observed maxima was obtained at 110°. The intensity distribution for carbonyl bromide is

$$\frac{I}{k} = 2Z_CZ_O\frac{\sin x}{x} + 4Z_CZ_{Br}\frac{\sin 1.81\,x}{1.81\,x} + 4Z_OZ_{Br}\frac{\sin 2.52\,x}{2.52\,x} + 2Z_{Br}^2\left(1 + \frac{\sin 1.97\,x}{1.97\,x}\right) + Z_C^2 + Z_O^2 \quad (4)$$

which is based on the same model as phosgene. The carbon–oxygen interatomic distance in carbonyl chloride and bromide (1.13 Å.) agrees well with the values obtained for formaldehyde (1.15 Å.) by electron diffraction,[16] and 1.2 Å. from the absorption spectra.[17] The absorption spectrum of phosgene[18] indicates a plane "Y" structure similar to formaldehyde. An angle greater than 110° might be expected in carbonyl chloride and bromide since an angle of 125° was found in the methylene halides. This difference seems reasonable when the interaction of the dipoles is considered. The repulsion between the carbonyl group and the halogen atoms is probably equal to the mutual repulsion of the halogen atoms.

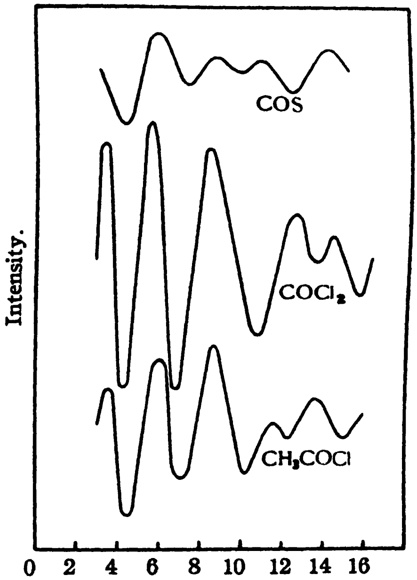

Fig. 2.—Theoretical intensity curves.

The effect of the hydrogen atoms was neglected in the intensity curves for acetyl chloride and bromide. The hydrogen–oxygen and hydrogen–halogen interatomic distances are variable if free rotation occurs around the carbon–carbon bond. Intensity curves were calculated for plane structures with 115, 125 and 135° angles between the carbon–oxygen and carbon–halogen bonds. A slightly better correlation of the maxima was

(15) L. Pauling, *Proc. Nat. Acad. Sci.*, **18**, 498 (1932).

(16) L. Bru, *Añales soc. españ. fís. quím.*, **30**, 483 (1932).

(17) V. Henri and S. A. Schou, *Z. Physik*, **49**, 774 (1928).

(18) V. Henri and O. R. Howell, *Proc. Roy. Soc.* (London), **A128**, 178 (1930).

possible for the usual tetrahedral model. The intensity equation for acetyl chloride is

$$\frac{I}{k} = 2Z_CZ_O\left(\frac{\sin x}{x} + \frac{\sin 2.11\,x}{2.11\,x}\right) + 2Z_C^2\left(1 + \frac{\sin 1.36\,x}{1.36\,x}\right) + 2Z_CZ_{Cl}\left(\frac{\sin 1.62\,x}{1.62\,x} + \frac{\sin 2.44\,x}{2.44\,x}\right) + 2Z_OZ_{Cl}\frac{\sin 2.34\,x}{2.34\,x} + Z_O^2 + Z_{Cl}^2 \qquad (5)$$

and the equation for acetyl bromide is

$$\frac{I}{k} = 2Z_CZ_O\left(\frac{\sin x}{x} + \frac{\sin 2.11\,x}{2.11\,x}\right) + 2Z_C^2\left(1 + \frac{\sin 1.36\,x}{1.36\,x}\right) + 2Z_CZ_{Br}\left(\frac{\sin 1.82\,x}{1.82\,x} + \frac{\sin 2.62\,x}{2.62\,x}\right) + 2Z_OZ_{Br}\frac{\sin 2.53\,x}{2.53\,x} + Z_O^2 + Z_{Br}^2 \qquad (6)$$

For these molecules the angle between the carbon–carbon bond and the carbon–halogen bond is 110 ± 10° while the other angles are each 125 ± 10°. The molecular structures of acetyl chloride and bromide are quite similar to the structure of acetone[19] which has been determined by the same method. Interatomic distances common to the three structures are in agreement.

Summary

The molecular structures of carbonyl sulfide, chloride and bromide, acetyl chloride and bromide have been investigated by electron diffraction. The results are in agreement with other structural determinations. Carbonyl sulfide has been found to have a linear structure. The other molecules have been represented by plane "Y" models. An angle of 110° has been found between the halogen atoms of carbonyl chloride and bromide. The tetrahedral model has been found for acetyl chloride and bromide. The carbon–oxygen interatomic distance has been found constant in the carbonyl compounds.

An Azeotropic Mixture of Secondary Butyl Alcohol and Secondary Butyl Bromide[1]

BY DAVID F. HOUSTON

An azeotropic (constant boiling) mixture of secondary-butyl alcohol and secondary-butyl bromide recently encountered in our work apparently is not recorded in the literature. The following study of this mixture has been made.

Experimental

Sec-butyl Alcohol.—Commercial *sec*-butyl alcohol[2] was fractionated in a six-plate bubbling-cap still,[3] without a Cottrell boiler, but with a thermometer immersed in the vapors. The fraction boiling at 99.4 to 100.5° was dried over anhydrous sodium sulfate, distilled over freshly ignited lime, and the constant boiling fraction collected. The refractive index and boiling point of the product are shown in Table I.

Sec-butyl Bromide.—A 50% excess of phosphorus tribromide was added dropwise to the commercial alcohol, cooled in ice water. The mixture was heated for one-half hour on the steam-bath, cooled and poured onto cracked ice. The oily layer was separated, distilled, thoroughly washed with water and 10% sodium carbonate solution, and dried over calcium chloride. The bromide was fractionated in the bubbling-cap still. The refractive index and boiling point of the constant boiling fraction are given in Table I.

Azeotropic Mixture.—A mixture of 150 ml. each of the alcohol and the bromide was distilled slowly from the bubbling-cap still. During a fore-run of about 20 ml., the temperature rose to 87.2°, where it remained while 155 ml. of the mixture was obtained. It then rose to the boiling point of the alcohol and again became constant. The refractive index and boiling point of the azeotropic mixture are given in Table I.

Composition of the Azeotropic Mixture.—From a curve drawn by plotting the refractive indices, at 20°, of a series of alcohol–bromide mixtures against the mole per-

Copper Selenate Tetrammine Dihydrate

By Willy Lange and Gerda v. Krueger

We recently described a method for preparing copper selenate tetrammine dihydrate in large crystals.[1] Slight variations in the procedure, however, often result in failure and occasionally no crystals at all are deposited from the ammoniacal solution. We have now perfected two new procedures which are entirely dependable.

(1) Fifteen grams of crystalline copper selenate (Kahlbaum) is dissolved by boiling in 25 cc. of 25% aqueous ammonia and, after filtering and cooling with ice, alcohol is added, the precipitate filtered off, washed with acetone and ether, and dried on a porous plate. Ten grams of this product is dissolved, for the greater part, by warming in 8 to 10 cc. of 25% aqueous ammonia and the hot solution is filtered as quickly as possible but without suction. The hot filtrate is then placed in a closed Erlenmeyer flask partially submerged in a large amount of hot water so that it will cool slowly. It is important that the solution be not shaken during this period.

(2) The same procedure is followed except that the hot solution in the Erlenmeyer flask is rapidly chilled to room temperature, whereupon needles of monohydrate precipitate. These are redissolved, for the greater

(1) This Journal, 53, 4013 (1931).

part, by adding carefully drops of the aqueous ammonia, the remainder of the crystals being dissolved by cautiously warming the closed flask. On cooling to room temperature no immediate precipitation occurs, but on being kept undisturbed in an ice refrigerator which maintained in general a temperature between 8 and 12°, but sometimes was even colder, crystals begin to deposit after two or three days.

Both of these methods always yield hexagonal crystals of the tetrammine dihydrate.

When a fresh quantity of crude dihydrate was dissolved, by warming, in the final filtrate obtained by the first method, on cooling, long needles of the monohydrate appeared. When the closed Erlenmeyer flask containing these crystals was allowed to stand at room temperature for three months, with a daily variation of 4 or 5°, the needles of the monohydrate were slowly absorbed and replaced by the large six-sided plates of dihydrate until finally only the dihydrate, analytically pure, in typical hexagonal tablets remained. The final solution contained 19.3% of ammonia which was, of course, partly in the copper complex.

Some Arsine Derivatives of Silver Salts

BY G. J. BURROWS AND R. H. PARKER

Various compounds of silver salts with basic substances are described in the literature. In most of these silver has a coördination valency of two. Thus silver halides (or nitrate) are known to combine with two molecules of ammonia, pyridine, aniline, quinoline, etc.[1] In addition, silver ammines have been described with compositions corresponding to the formulas, $AgCl \cdot NH_3$, $AgCl \cdot 3NH_3$ and $2AgCl \cdot 3NH_3$.

It was decided to investigate the action of phenyldimethylarsine and diphenylmethylarsine on silver salts. These two particular arsines were chosen on account of their ease of preparation and the fact that they are known to combine with the iodides of phosphorus, arsenic, antimony, bismuth and tin.[2] When silver chloride was digested with an aqueous alcoholic solution of phenyldimethylarsine a clear solution was readily obtained, from which white needles separated on cooling. These, on examination, were found to be bisphenyldimethylarsine silver chloride $[Ag(PhMe_2As)_2]Cl$. Compounds of other silver salts with phenyldimethylarsine and diphenylmethylarsine were prepared and examined. The

(2) Burrows and Turner, *J. Chem. Soc.* 119, 1449 (1921).

compounds isolated were all of the same type, the coördination valency of the silver being two. The relative proportions of silver salt and arsine were varied in attempts to obtain the analogs of the other ammine silver salts described, but in all cases the compound isolated was one in which two molecules of arsine were coördinated with one atom of silver.

The arsine derivatives are white crystalline compounds with characteristic melting points and are quite stable and unaffected by light. The following list, containing the salts so far prepared, illustrates the variations in melting point.

BIS-PHENYL DIMETHYL AND BIS-DIPHENYL METHYL ARSINE SILVER SALTS

		Yield, %	M. p., °C.	Arsenic, %			Silver halide, %	
				Calcd.	Found		Calcd.	Found
Diphenyl methyl	Chloride	60	121	23.8	23.5		22.7	22.4
	Bromide	50	110	22.2	21.9		27.8	27.6
	Iodide	..	132	..	..		32.5	32.5
	Nitrate	81	112	..	..	Ag,	16.2	16.3
Phenyl dimethyl	Chloride	..	97	29.6	29.2		28.3	28.1
	Bromide	..	79	..	..		34.1	33.9

It is interesting to note that the bromide has a lower melting point than the corresponding chloride in both series, while in the case of diphenylmethylarsine derivatives the iodide has the highest melting point. The iodide can only be prepared from the nitrate and as we have been unable to prepare the nitrate in the case of phenyldimethylarsine the corresponding iodide could not be isolated. Attempts to prepare arsine silver sulfate were also unsuccessful.

Although the chlorides and bromides are easily prepared by heating the silver halide and arsine in aqueous alcohol and allowing to cool, it was found that they could not be redissolved in aqueous alcohol or absolute alcohol or methyl alcohol except in the presence of excess of the arsine; the compounds appear to be decomposed on heating in these solvents. The halides are also insoluble in acetone, ether and benzene, undergoing decomposition on heating in the two latter liquids with loss of arsine. Bisdiphenylmethylarsine silver nitrate is remarkable in being soluble in aqueous alcohol, ethyl or methyl alcohol, acetone or benzene.

Unsuccessful attempts were made to isolate arsine derivatives of silver salts of optically active acids such as *d*-mandelic and *d*-bromocamphor sulfonic acids. Experiments were carried out with both diphenylmethylarsine and phenylmethylethylarsine. A derivative of the latter should contain arsenic as a center of asymmetry and it was therefore hoped that fractions differing in optical activity would be obtained. On warming the arsine and silver salt in alcohol, reaction undoubtedly took place and a clear solution was obtained but this could not be induced to crystallize. On concentrating the solution *in vacuo* a thick sirup (and ultimately a glassy residue) resulted which very slowly darkened on keeping. This portion of the investigation is being studied further.

Experimental

For the preparation of bis-diphenylmethylarsine silver chloride or the corresponding bromide, freshly precipitated silver chloride (1 mol) or silver bromide was well washed with hot water, then with 96% alcohol. It was then treated in hot alcohol on the water-bath with diphenylmethylarsine (2 mols) until the silver halide had dissolved. On cooling the complex salt separated in white needles. These were removed and washed once with ether. (N. B. Excessive treatment with ether appears to decompose the compound by removal of arsine.) A further crop of crystals was obtained by careful concentration of the mother liquor.

These compounds do not darken on exposure to light; they are insoluble in water, alcohol, acetone, ether or benzene. They are decomposed by concentrated nitric acid. In the analysis, a known weight was treated with excess of silver nitrate (crystals) and a few cc. of concentrated nitric acid and the silver halide precipitate well washed with water, and then alcohol (or acetone) and dried.

Bis-diphenylmethylarsine Silver Nitrate $[Ag(Ph_2MeAs)_2]NO_3$.—This compound was very readily obtained by adding an aqueous alcoholic solution of diphenylmethylarsine (2 mols) to a saturated solution (aqueous) of silver nitrate (1 mol). On agitating the solution the complex salt separated as a micro crystalline precipitate. This was washed with a little ether and dried over sulfuric acid.

Bis-diphenylmethylarsine Silver Iodide $[Ag(Ph_2MeAs)_2]I$.—Attempts to prepare this compound by the action of the arsine on silver iodide were unsuccessful. The relative solubilities of silver chloride, bromide and iodide in diphenylmethylarsine are similar to their relative solubilities in ammonia. The iodide was prepared from the nitrate. An aqueous alcoholic solution of bisdiphenylmethylarsine silver nitrate was treated with the calculated quantity of hydriodic acid, when a very pale yellow finely crystalline precipitate separated. This was filtered off, washed with a little ether and dried over sulfuric acid. It is quite insoluble in the ordinary solvents. During an analysis of this compound it was noticed that on warming with nitric acid and excess of silver nitrate the substance melted and crystallized on cooling. The crystalline mass was removed, washed with water, alcohol and finally ether. It melted at 113° and on analysis was found to be the nitrate.

When decomposed with nitric acid alone, silver iodide is formed, and this can be filtered and washed with acetone or alcohol and weighed.

Bis-phenyldimethylarsine silver chloride and the corresponding bromide were prepared in a similar manner to the bis-diphenylmethylarsine silver compounds using phenyldimethylarsine in place of diphenylmethylarsine. Their solubilities resemble those of the other series.

The Nitrogen Compounds in Petroleum Distillates.[1] IV. Cumulative Extraction[2] of Kero Bases.[3] The Isolation of 2,4,8-Trimethylquinoline among the Kero Bases

BY T. S. PERRIN AND J. R. BAILEY

Introduction.—The kero bases represent a very complex mixture of both aromatic and non-aromatic types in a percentage ratio of approximately 15:85, respectively. Especially as concerns the non-aromatic bases, the direct isolation of pure products from distillation fractions can be attained through fractional crystallization of their salts only in exceptional cases.

It is obvious that a practical method of separation of the bases into aromatics and non-aromatics, would simplify the isolation of individual products. Based on the observation of a wide difference in the distribution ratio of salts of the two families between water and certain solvents immiscible with water, a process, which accomplishes this end in a most satisfactory way, has been perfected and found of general application over the entire range of kero bases.

The present investigation has disclosed a ready solubility of the hydrochlorides of the non-aromatic bases in chloroform, as compared with a lesser solubility of the aromatic hydrochlorides, and among the latter are included the hydrochlorides of both pyridine and quinoline homologs. Furthermore, the non-aromatic hydrochlorides are very soluble in water, whereas corresponding salts of some of the methylated quinolines encountered crystallize nicely from water.

In resolution of petroleum bases into the two types, the following procedure will be found serviceable, where either crude bases or distillation fractions are employed. The bases are dissolved in an excess of 1:1 hydrochloric acid and the solution extracted with an equal volume of chloroform. Instead of chloroform, ethylene chloride may be used and, on account of the much lower cost, it should prove serviceable in industrial extraction. The initial chloroform extraction effects a high concentration of the aromatic hydrochlorides in the aqueous layer and of the non-aro-

---

(1) The investigation of organic nitrogen bases from the crude kerosene distillate of California petroleum was originally undertaken in connection with American Petroleum Institute Project 20, entitled: "Isolation and Investigation of Nitrogen Compounds Present in Petroleum."

For this research the Union Oil Company of California furnished the material, consisting of bases which were assembled when the refinery was operating largely on McKittrick crude from the San Joaquin Valley field and having a nitrogen content of 0.64%. Only recently the Texas Laboratory received three barrels of bases obtained from 3000 barrels of Edeleanu kerosene extract. This sulfur dioxide extract represents 25% of the kerosene fraction and the latter 5% of the crude oil refined; so it is evident that 80,000 barrels of California petroleum yield approximately 1 barrel of kero bases. However, all the crude distillates contain bases; so their aggregate amount would be considerably larger, were the gasoline, gas oil and lubricating oil fractions included.

(2) "Cumulative extraction" is explained in the text.

(3) "Kero bases" is an abbreviation for "kerosene bases."

matic hydrochlorides in the chloroform layer. In further segregation, the water layer is extracted several times with chloroform and the chloroform layer several times with water. Since there is always an appreciable difference in the refraction of the two types of bases within any boiling point range, refractive index determinations offer a convenient control at every stage of the process.

Its extensive application seems to warrant a specific name for this process and "Cumulative Extraction" is proposed, as embodying in a concise way the general result attained in progressive concentration of the aromatic hydrochlorides in water and the non-aromatic hydrochlorides in chloroform.

Cumulative extraction has been of especial service in simplifying isolations already accomplished by other methods, and in extending this work. Previous papers of this series have reported the isolation of 2,3,8-trimethylquinoline,[4] b. p. 280°, and of a naphthenic base of the formula $C_{16}H_{25}N$, b. p. 278.2°.[5] By the distribution of the salts of the fraction containing these two bases between water and chloroform, the separation and purification has been simplified greatly, and a third substance, 2,4,8-trimethylquinoline, has been isolated from the same distillation fraction (275° zone). The new procedure has been of further use in separation of 2,3- and 2,4-dimethylquinoline from the fractions in the 265° zone, and it is superior to an alternate method, described in Paper V of this series and which makes use of sulfur dioxide. Paper VI records the isolation, by cumulative extraction, of 2,8-dimethylquinoline from the 253° fraction of bases.

In final separation of the aromatics from small amounts of non-aromatics, either the free bases or their hydrochlorides can be converted in acetone solution to sulfates. The aromatic sulfates in great part separate from the solvent in crystalline form and the non-aromatic sulfates remain dissolved. It is evident also that both types of hydrochlorides can be converted directly to picrates, as well as mercuric chloride and zinc chloride double salts; however, corresponding salts of non-aromatic bases separate from mixtures almost invariably as non-crystallizing smears. It will be found advisable in picrating hydrochlorides to buffer the solution with sodium acetate; otherwise, where an excess of picric acid is used, it precipitates along with the picrates.

The employment of cumulative extraction has revealed the presence of aromatics and non-aromatics in all distillation fractions of kero bases. The boiling points and refractivities of several products, encountered below the quinoline range, indicate pyridine homologs. Where an aromatic base of known boiling point is suspected, it will be found, if present, in maximum concentration in a fraction boiling 3 to 5° lower than its own boiling point and, even when present in very small amount, it can be

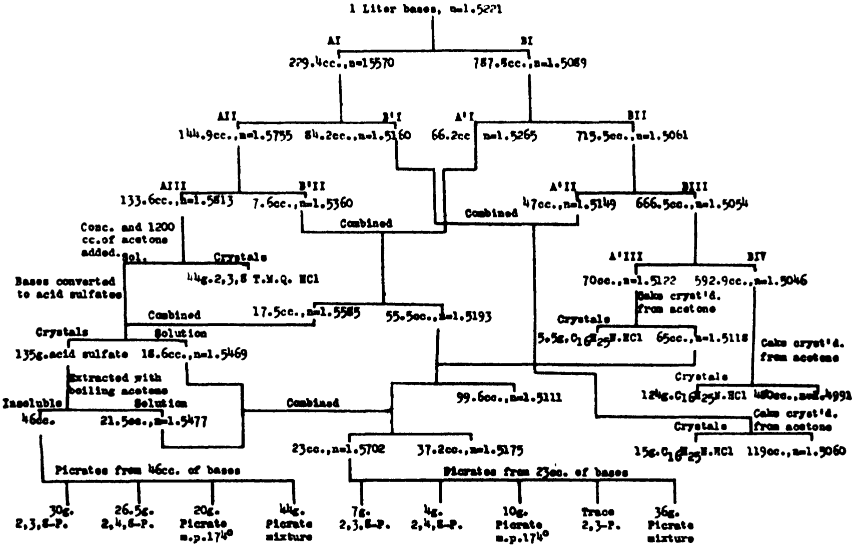
segregated from accompanying non-aromatics until its isolation in pure form is greatly simplified. A search for the common coal-tar bases, quinoline, isoquinoline, quinaldine and lepidine has given only negative results.

Experimental Part

Cumulative Extraction of a Distillation Fraction of Kero Bases Boiling at 273° and with n^{27}_D 1.5221.—One liter of bases[6] in one liter of 1:1 hydrochloric acid was extracted with 1200 cc. of chloroform and the aqueous layer AI separated from the chloroform layer BI. AI was washed with 400 cc. of chloroform, yielding fractions AII and B'I, followed by extraction of AII with 250 cc. of chloroform to yield fractions AIII and B'II. In a similar way BI was extracted with three successive portions of water, 400, 400 and 1000 cc., being split finally into fractions A'I, A'II, A'III and BIV. The accompanying flow-sheet is self-explanatory.



Flow-sheet in cumulative extraction.

"A" refers to hydrochlorides in water. "B" refers to hydrochlorides in $CHCl_3$. "n" = "n^{27}_D." "Cake" refers to residue after removal of solvent. "2,3,8-P" and "2,4,8-P" = "Picrates of 2,3,8- and 2,4,8-trimethylquinoline," respectively. "2,3-P" = "2,3-Dimethylquinoline picrate." Volumes, where given, refer to free bases.

The volumes of bases were arrived at by measuring the oil liberated with caustic soda from a fractional part of the hydrochloride solutions. The samples, after being dried, were used for refractivity determinations and finally converted to hydrochlorides before recombination with the fractions from which they were taken. A list of the end-products from processing the one liter of bases follows: 44 g. of 2,3,8-trimethylquinoline hydrochloride; 37 g. of 2,3,8-trimethylquinoline picrate; 30.5 g. of 2,4,8-trimethylquinoline picrate; 30 g. of unknown picrate, m. p. 174°; 80 g. of mixture of low melting picrates; 144.5 g. of hydrochloride of the $C_{16}H_{25}N$ base; 735.8 g. of non-aromatic bases (4 fractions, n^{27}_D 1.4991 to 1.5175).

---

[6] This material was purposely not exhaustively fractionated.

Isolation of 2,4,8-Trimethylquinoline.—This product was encountered by King and Bailey[7] at the time 2,3,8-trimethylquinoline was discovered, but was not identified.

After concentration of the aromatic bases by cumulative extraction of the 273° fraction, the ready solubility of 2,4,8-trimethylquinoline hydrochloride in water and of its

Ten cc. samples from each of the above fractions, dissolved in 10 cc. of 1:1 hydrochloric acid, were carried through a single extraction with 20 cc. of chloroform and then the bases in the aqueous and chloroform layers were precipitated from the dissolved hydrochlorides with an excess of caustic soda. In some cases a small amount of hydrocarbon oil was encountered.

(7) Ref. 4, p. 1243.

sulfate in acetone facilitated the separation from accompanying 2,3,8-trimethylquinoline. Final purification was effected through the picrate, which crystallizes from alcohol in slender rectangular plates melting at 193°.

The boiling point of 269–270° (pressure not given) for 2,4,8-trimethylquinoline, as recorded in the literature,[8] does not agree with our determination of 280° (corr.) at 746 mm. on both the synthetic product and the kero base. For this quinoline n_D^{50} is 1.5855.

Anal. Calcd. for $C_{12}H_{13}N$: C, 84.21; H, 7.60; N, 8.19. Found: C, 84.43; H, 7.42; N, 8.35.

Phthalone of 2,4,8-Trimethylquinoline.—The base and the calculated amount of phthalic anhydride are heated for three hours at 200°, the melt is dissolved in concentrated sulfuric acid and the solution is poured onto crushed ice. The phthalone crystallizes from alcohol in yellow microscopic needles melting at 282°.

Anal. Calcd. for $C_{20}H_{15}O_2N$: C, 79.73; H, 4.98; N, 4.65. Found: C, 79.65; H, 5.16; N, 4.71.

Comparative Efficiency of the Cumulative Extraction and Sulfur Dioxide Processes in Segregation of Aromatic Bases.—600 cc. of residual bases of the 263–267° fraction from which 2,3- and 2,4-dimethylquinoline had been isolated by the use of sulfur dioxide, as described in Paper V of this series, was carried through cumulative extraction. It developed that, whereas sulfur dioxide had removed 2,4-dimethylquinoline completely, an additional 5 g. of the 2,3-isomer could be recovered. The difficult solubility of the picrate of this base in alcohol simplified its purification. There was also encountered here in small amount a new $C_{12}H_{13}N$ base for which proof of structure and synthesis is under way.

Cumulative Extraction in Evaluation of the Nature and Amount of Aromatic Bases in Distillation Fraction.—The subjoined table gives the results from cumulative extraction of kero bases, within the b. p. range of 182–350°. The samples above 300° were imperfectly fractionated. It is probable that both aromatic and non-aromatic hydrochlorides of these bases exhibit within the two types a considerable variance in relative solubilities in water and chloroform, so frequently the initial chloroform extraction does not furnish a true picture of the proportionate amounts of the two types. However, from cumulative extraction when applied exhaustively—and this is possible with 10-cc. samples—estimates reliable within narrow limits of error can be reached.

The aromatic bases in the 182–220° fractions consist mainly of pyridine homologs, where an average n_D^{25} value[9] around 1.5000 may be expected. In fractions above 220° pyridines will probably not be encountered. Since quinoline homologs have an n_D^{20} value around 1.6000, the deduction follows from the data in Table I that fractions above 330° contain an appreciable quantity of aromatic bases of a higher order than quinolines.

Summary

Based on a wide difference in the distribution ratio of the hydrochlorides of aromatic and non-aromatic petroleum bases between water and chloroform, a method of segregation of the two types, for which the name "Cumulative Extraction" is proposed, has been developed. This process is now a standardized and reliable procedure of general application. The isolation by this method of 2,4,8-trimethylquinoline and a second $C_{12}H_{13}N$ base of unknown structure is described.

The Nitrogen Compounds in Petroleum Distillates. V. The Use of Sulfur Dioxide in the Separation of Petroleum Bases

BY BURNARD S. BIGGS AND JAMES R. BAILEY

Introduction.—Although the behavior of organic bases toward sulfur dioxide has been studied quite extensively,[1] apparently this reaction has not been employed as an agency in separation of mixtures of amines.

Sulfur dioxide forms addition compounds with both aromatic and non-aromatic bases, but it remains to be determined whether all kero bases enter into such combinations. Some of these products are stable at temperatures as high as 100°, while others have been found to dissociate quite rapidly at room temperature. Advantage has been taken of the differences in the relative stability and solubilities of these sulfur dioxide addition compounds to effect a partial separation of the kero bases.

The sulfur dioxide process is unsatisfactory, in that it does not effect quantitative separations. Also addition products of some of the non-aromatic bases layer out, and subsequent separation of individual aromatic bases in the form of picrates is retarded through the formation of smears.

Experimental Part

A 2000-cc. fraction of bases of b. p. 263–267° was dissolved in an equal volume of anhydrous ether, and sulfur dioxide was led in at room temperature to saturation. At first a small amount of oil separated which later redissolved. The excess of sulfur dioxide, along with part of the solvent, was allowed to evaporate to the point where a heavy viscous oil layered out, and then sufficient ether was added to restore the original volume. The supernatant layer was decanted and the viscous residue was washed with ether, dissolved in a little alcohol and treated with a slight excess of an alcoholic solution of picric acid. After complete precipitation, the picrates were washed with sufficient alcohol to remove smeary admixtures.

The alcoholic filtrate contained a considerable amount of non-aromatic picrates of a greater solubility in organic solvents than the aromatic salts. It may be that here the relative concentration of the various non-aromatics was decidedly different from that in the original fraction of bases, and in that event there is suggested an application of the sulfur dioxide reaction in partial resolution of non-aromatic mixtures.

Isolation of 2,4-Dimethylquinoline.—When the crystalline picrates were treated with an amount of hot glacial acetic acid sufficient to leach out the more soluble portion, 2,4-dimethylquinoline picrate separated from the filtered solution in long orange colored needles and was recrystallized several times from 95% alcohol, with filtration carried out around 40° to avoid the separation of admixtures. Finally a product melting at 194° was obtained.

2,4-Dimethylquinoline, synthesized according to Otto Fischer,[2] proved identical with the base obtained from the picrate of m. p. 194°. Furthermore, the kero base

(2) Otto Fischer, *Ber.*, **19**, 1037 (1886).

and the synthetic product were shown to be identical through comparison of several salts. Both the synthetic and the kero base boiled at 274° at 756 mm.[3]

Isolation of 2,3-Dimethylquinoline.—The picrates, referred to above as difficultly soluble in glacial acetic acid, were recrystallized from this solvent in the form of microscopic hexagonal prisms melting at 231°. The base, liberated from the purified picrate, proved identical with 2,3-dimethylquinoline, synthesized by the method of Eliasberg and Friedländer.[4] Several salts made from both the kero and the synthetic base were compared. The base itself is a white crystalline solid melting at 67° and boiling at 273° (750 mm.).[5]

All the filtrates obtained in the separation of the 2,3- and 2,4-dimethylquinoline picrates were combined and concentrated to a small volume, when a third picrate melting at 160° separated in radiating clusters of needles. This product is referred to in Paper IV by Perrin and Bailey, who find that, when pure, it melts at 174°.

The Nitrogen Compounds in Petroleum Distillates. VI. The Occurrence of 2,8-Dimethylquinoline in the Crude Kerosene Distillate of California Petroleum

BY G. R. LAKE AND J. R. BAILEY

Introduction.—All the quinolines so far encountered among the kero bases are 2, 3, 4 or 8 polymethyl homologs *with one methyl at position 2;* no quinoline substituted at positions 5, 6 or 7 has been identified. Whereas quinaldine is the only coal-tar quinoline yielding a phthalone (Quinoline Yellow), petroleum offers in synthesis of this class of dyes[1] a wealth of intermediates none of which has been obtained from any other natural source.

When the present investigation was begun, two of the three possible dimethylquinolines, with one methyl in position 2 and the other at position 3, 4 or 8, were known to exist among the kero bases,[2] but the 2,8-isomer[3] had not been encountered. Employing cumulative extraction on the 253–256° fractions, we have found 2,8-dimethylquinoline and established its identity with the synthetic base.

Experimental Part

Cumulative Extraction of the 253–256° Fraction of Kero Bases.—A quantity of this fraction was distributed between equal volumes of 1:1 hydrochloric acid and chloroform, and the two solutions were extracted further according to the method described in Paper IV.[4] The results are summarized in the subjoined flow sheet (see paper IV for an explanation of the symbols).

Final data from processing 6240 cc. of bases into six fractions are

	1	2	3	4	5	6
n_D^{25}	1.5832	1.5327	1.5193	1.5120	1.5082	1.5020
Vol., cc.	285	85	270	1010	1335	2920
Vol., %	4.6	1.4	4.3	17.6	21.4	46.8

Isolation of 2,8-Dimethylquinoline.—The aqueous solution of hydrochlorides marked AIV, representing 285 cc. of bases, *i. e.*, 4.6% of the starting material, was evaporated to a small volume from which on chilling the greater part of the 2,8-dimethylquinoline hydrochloride separated. Smeary admixtures were removed with a small amount of cold acetone, followed by recrystallization of the residue from alcohol. The yield of practically pure hydrochloride was 32 g. (0.4%). In a second extraction of 2250 cc. of bases, carried out more carefully, the yield was increased to 1.8%.

In final purification the hydrochloride was treated with the calculated amount of sodium bisulfate in concentrated aqueous solution and the separated acid sulfate recrystallized from 95% alcohol. Next the picrate, prepared from the acid sulfate in alcoholic solution, was recrystallized from 50% acetic acid and then from water. Finally the base, liberated from the picrate with ammonium hydroxide, was converted to the zinc chloride salt and the latter recrystallized from dilute hydrochloric acid. The base, regained from the zinc chloride salt by dry distillation,[30] gave the following constants: m. p. 24°;[5] b. p. 252.4° (754 mm.); n_D^{25} 1.5997; mol. wt. (by Rast micro camphor method) calcd. 157, found 159.

For characterization of the base the phthalone, as well as the following new salts, was prepared.

Acid Sulfate.—The calculated amount of sodium acid sulfate is added to a concentrated solution of the hydrochloride in water and the filtered sulfate crystallized from absolute alcohol in radiating clusters of needles melting at 187°.

Perchlorate, $C_{11}H_{11}N \cdot HClO_4$.—This salt, prepared by adding an aqueous solution of sodium perchlorate to the hydrochloride in water, crystallizes from water in slender rods and from alcohol in fine needle clusters melting at 189°. It is insoluble in the other common solvents with the exception of glacial acetic acid. Owing to its explosive nature concordant results were not obtained in the analysis.

Mercuric Chloride Salt.—Prepared in the usual way in dilute hydrochloric acid, this salt crystallizes from glacial acetic or hydrochloric acid in hair-like needles melting at 211°. Its solubilities are similar to those of the perchlorate.

Phthalone.—The base is heated with the calculated amount of phthalic anhydride for two hours at 200° and the melt crystallized from chloroform, glacial acetic acid or nitrobenzene in long slender rods melting with decomposition at 283°. It is only sparingly soluble in the other common solvents.

The Nitrogen Compounds in Petroleum Distillates. VII. New Reactions of the Naphthenic Base, $C_{16}H_{25}N$.[1] A New Naphthenic Base, $C_{13}H_{21}N$

BY B. F. ARMENDT AND J. R. BAILEY

Introduction.—Unrefined California petroleum distillates yield, along with aromatic bases, in preponderant amount a host of non-aromatic bases.[2] Since these non-aromatics represent, not only new substances, but also new structural types, their investigation may be considered of unusual scientific interest. In this connection, it may be mentioned, work is in progress to obtain experimental evidence of a possible structural relationship between the non-aromatic bases and petroleum hydrocarbons.

Because both the isolation and proof of structure of the low-boiling non-aromatic bases might be expected to present the least experimental difficulty, an investigation of fractions within the boiling point range of 215–216° was undertaken. Three barrels of kero bases originally available gave only 708 cc. of this material and from this 20 g. (0.004% of the three barrels) of a base of the formula $C_{13}H_{21}N$ was obtained. Research on this product has been limited to a comparison of its general behavior with that of the $C_{16}H_{25}N$ base.

All attempts to hydrogenate both the $C_{13}H_{21}N$ and the $C_{16}H_{25}N$ base ended in failure. They also resist dehydrogenation, a stability hardly to be expected of true *hydroaromatic* bases, and prolonged heating with alkaline permanganate has no oxidizing effect. The $C_{16}H_{25}N$ compound reacts readily with methyl iodide, but the methiodide of the $C_{13}H_{21}N$ compound is not formed under similar conditions. Attempts to employ the Hofmann reaction in degradation of the $C_{16}H_{25}N$ base were unsuccessful, probably due to rearrangement of the quaternary base to a pseudo form.

From the many theoretical possibilities, there has been selected provisionally formula I, for the $C_{13}H_{21}N$ base and the original structural interpretation of the $C_{16}H_{25}N$ base has been changed to II.

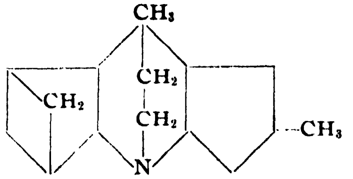
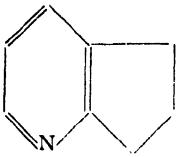
I



II



III

The n_{D}^{20} value, 1.4850, of I, as compared with the n_{D}^{20} value, 1.5129, of II, is accounted for by one more ring nucleus in a pyridindacine than in a pyrindine. Furthermore, the refractive difference here of 0.0279 is of the same order as that of 0.0342 between pyridine, where n_{D}^{20} is 1.5068, and 5,7-dihydropyrindine,[3] III, where n_{D}^{20} is 1.5410.

An unexpected observation was that the $C_{16}H_{25}N$ base, just like a quinoline methylated at 2, condenses readily with phthalic anhydride to produce a phthalone.[4] On the other hand, attempts to prepare a phthalone of the $C_{13}H_{21}N$ base gave a negative result. The phthalone of the pyrindacine is of a light orange color and sublimes undecomposed. The presence of a $CH(CO)_2$ complex was established through the preparation of a deep orange colored sodium salt which necessarily involved in its formation enolization of CHCO to C=COH.

Mabery and Wesson[5] in an investigation of "Nitrogen Bases of California Petroleum" found "phthalic anhydride condenses with the basic fractions in what is evidently a phthalone formation," and used this reaction in support of their claim that petroleum bases "consist mainly of alkylated quinolines (or isoquinolines)." It is now evident that phthalone formation cannot be accepted as an infallible test for quinoline bases.

Experimental Part. I

Isolation of the $C_{13}H_{21}N$ Base.—This product was first obtained in a preliminary experiment in an amount sufficient to determine its b. p. 225.6° and the n_{D}^{25} value, 1.4833. Also of importance was the m. p. of the picrate, 158.7°, along with its crystalline form and solubilities. The subjoined data pertain to the material assembled in quest of the $C_{13}H_{21}N$ base and represent combinations of distillation fractions in the order of boiling points:

No.	Cc.	B. p., °C.	n_{D}^{20}
I	163	215.3–218	1.4935–1.4972
II	190	220 –221.5	1.4875–1.4905
III	203	223 –224.5	1.4862–1.4880
IV	152	225 –226	1.4858–1.4865

Each of the four batches of bases was extracted with three successive portions of N

All the picrates obtained from acid extracts 2, 3 and 4 of each batch were subjected to fractional crystallization from 95% alcohol, until crystalline products were obtained. Next a number of melting points and mixed melting points were made as controls on the seven fractions of picrate mixtures most insoluble in alcohol. Three serial numbers are employed in listing below these picrates; the first number indicates the distillation fraction, the second the acid extraction, and the third the picrate precipitation; *e. g.*, "231" applies to the product that came from the first picrate precipitation of the third acid extract of distillation fraction II. "A" refers to initial melting point of picrates and "B" to the melting point after one recrystallization from alcohol.

Melting Points (uncorr.), °C.

Picrate fractions	M. p. A	M. p. B
231	163–164	163–164
241	142–143	159–160
331	162–165	165–166
341	145–147	160–161
342	145–158	160–161
431	144–145	159–161
441	145–146	160–161

Mixed Melting Points (uncorr.), °C.

Mixed picrate fraction	M. p. A	M. p. B
231 + 331	163.5–164.5	163.5–165
231 + 241	119–123	119–122
331 + 341	123–124	132–133
341 + 441	146–146.5	159.5–160.5
241 + 341	145.5–146	160–160.5
431 + 441	145.5–146	160.5–161
341 + 342	144–146	160–161
342 + 441	144–146	160–161
331 + 431	120–132	120–126

Preliminary experiments had disclosed that, where samples of two mixed picrates had an initial m. p. of 144–146.5° and, after recrystallization from alcohol, a m. p. of 159.5–161°, the $C_{13}H_{21}N$ base was present in high concentration. Accordingly picrates 241, 341, 342, 431 and 441 were combined and recrystallized from alcohol, and then from benzene. From 50 g. of pure picrate with m. p. 158.7°, 21.5 g. of the $C_{13}H_{21}N$ base was separated with ammonium hydroxide. From the reworked residues two other picrates, one of m. p. 115–118° and the other of m. p. 160°, were obtained but were not further investigated. No doubt the Perrin–Bailey method of cumulative extraction, which was perfected toward the close of the present investigation, will prove of service in developing the most practical procedure in isolation of the several bases in this temperature range.

Properties of the $C_{13}H_{21}N$ Base.—It is a colorless oil, with a faint basic but not unpleasant odor, insoluble in water and miscible in all proportions with the common organic solvents. The following physical constants were determined: m. p. 24.5°; b. p. 225.6° at 750 mm.; d_4^{20} 0.8700; n_D^{25} 1.4833 and n_D^{30} 1.4811.

Anal. Calcd. for $C_{13}H_{21}N$: C, 81.61; H, 10.98; N, 7.34. Found: C, 81.40; H, 11.03; N, 7.49. *Mol. wt.* Subs., 10.454 mg.; camphor, 206.452 mg.; Δt, 10.5°. Calcd. for $C_{13}H_{21}N$: mol. wt., 191; found: mol. wt., 185.

An attempt to prepare the methiodide by heating 0.5 cc. of base with 2 cc. of methyl iodide in a sealed tube for thirty hours at water-bath temperature gave a negative result. The base and phthalic anhydride, heated for four hours at 200°, did not react. Reduction experiments with the use of Adams catalyst were unsuccessful. In chloroform solution the base does not react with bromine even on warming, and it can be distilled over heated zinc dust unchanged. The base shows an unusual stability toward alkaline permanganate. In contrast to its stability in alkaline solution, the $C_{13}H_{21}N$ base in 1:5 sulfuric acid reduces permanganate readily. An attempt to effect nitration, in accordance with the procedure of Markownikoff for nitration of methylcyclopentane,[6] ended in failure.

Picrate.—This salt separates on addition of picric acid in water or alcohol to a solution of the acid sulfate and can be crystallized from benzene in yellow needles melting at 158.7°. It is readily soluble in alcohol, 50% acetic acid, acetone and ethyl acetate and only slightly soluble in water, ether and petroleum ether.

Anal. Calcd. for $C_{19}H_{24}O_7N$: C, 54.29; H, 5.71; N, 13.33. Found: C, 54.53; H, 5.61; N, 13.55.

Mercuric Chloride Salt.—This salt, prepared by addition of a solution of mercuric chloride to the base in dilute hydrochloric acid, is difficultly soluble in water and can be crystallized from alcohol in prisms melting at 131.6°.

Anal. Calcd. for $C_{13}H_{21}N{\cdot}HCl{\cdot}HgCl_2$, H_2O: N, 2.71; Cl, 20.60. Found: N, 2.85, 2.71; Cl, 20.64.

Chloroplatinate.—The chloroplatinate, prepared in dilute hydrochloric acid solution, crystallizes from dilute alcohol in well-defined rectangular plates, of an orange color and melting with decomposition at 205°. It is only moderately soluble in water and alcohol.

Anal. Calcd. for $C_{13}H_{21}N{\cdot}H_2PtCl_6$: Pt, 24.65; N, 3.45. Found: Pt, 24.32; N, 3.48.

Acid Sulfate.—This salt crystallizes out on dissolving the base in the calculated amount of sulfuric acid. It is very soluble in water and alcohol, difficultly soluble in ethyl acetate and can be crystallized from acetone in cubes melting at 155°.

Anal. Calcd. for $C_{13}H_{21}N{\cdot}H_2SO_4$: N, 4.84. Found: N, 4.82.

Experimental Part. II

The $C_{16}H_{25}N$ Base.—The $C_{16}H_{25}N$ base used in the following experiments was isolated from distillation fractions of kero bases, boiling in the temperature zone around 275°, by employment of the Perrin–Bailey cumulative extraction process.[7]

Phthalone.—The base and phthalic anhydride in molecular proportions are heated at 200° for four hours, the melt is dissolved in 15 cc. of concentrated sulfuric acid for each 10 cc. of base used, and the solution is poured onto crushed ice. In final purification the product is crystallized from 95% alcohol in thin rectangular plates, of a deep yellow color and melting at 208°. It dissolves readily in boiling glacial acetic acid, is more difficultly soluble in 95% alcohol, 50% acetic acid and ethyl acetate and is practically insoluble in water and dilute mineral acids. Like quinoline yellow, it sublimes undecomposed at 220° and 45 mm. Treated with sodium ethylate, it separates from alcohol in the form of a crystalline deep orange colored salt which hydrolyzes in water.

---

(6) Markownikoff, *Ann.*, **307**, 352 (1899).

(7) See Paper IV of this series by Perrin and Bailey.

In all attempts to hydrolyze the phthalone with dilute sulfuric acid and alcoholic potassium hydroxide, it was recovered unchanged. In oxidation experiments only gums were obtained, from which no crystalline product containing nitrogen was isolated. Unlike quinoline yellow, the new phthalone cannot serve as a spirit-soluble dye and, furthermore, sulfonation experiments ended in failure.

Anal. Calcd. for $C_{24}H_{27}O_2N$: C, 79.77; H, 7.48; N, 3.88. Found: C, 79.75; H, 7.31; N, 3.75. *Mol. wt.* Subs., 0.1008 g.; camphor, 1.060 g.; Δt, 11°. Calcd. for $C_{24}H_{27}O_2N$: mol. wt., 361. Found: mol. wt., 316.

Attempt to Condense Methylcyclopentane with Phthalic Anhydride.—It was of some interest to determine whether a hydrocarbon of naphthenic structure would condense, like the naphthenic base, with phthalic anhydride. However, all attempts to condense methylcyclopentane with phthalic anhydride,[8] with and without the use of zinc chloride, were unavailing.

Hydrochloride of the Dibenzal Compound.—Five grams of base, 6.5 g. of benzaldehyde and 0.5 g. of zinc chloride are heated for eighteen hours in a sealed tube at 190–210°. The viscous reaction product dissolved in ether is precipitated as the hydrochloride (9 g.) by shaking the solution with dilute hydrochloric acid. After being washed with ether and acetone, it crystallizes from a mixture of alcohol and chloroform in long flat prisms, with pyramidal end faces and melting at 241–242°.

Anal. Calcd. for $C_{30}H_{34}NCl$: N, 3.16. Found: N, 2.98.

Dibenzal Compound.—This substance, freed from the hydrochloride with ammonium hydroxide, is insoluble in water and separates from alcohol in ill-defined crystals melting at 120–121°. In chloroform it absorbs an amount of bromine corresponding to two double bonds. It is very resistant to alkaline permanganate.

Anal. Calcd. for $C_{30}H_{33}N$: C, 88.45; H, 8.11; N, 3.44. Found: C, 88.37; H, 7.83; N, 3.71. *Mol. wt.* Subs., 9.187 mg.; camphor, 77.2 mg.; Δt, 11.9°. Calcd. for $C_{30}H_{33}N$: mol. wt., 407. Found: mol. wt., 400.

Picrate of the Dibenzal Compound.—On addition of an alcoholic solution of picric acid to the hydrochloride in chloroform, a granular product, highly insoluble in water and the common organic solvents, separates. It crystallizes from a mixture of alcohol and chloroform in microscopic long flat prisms, with pyramidal end faces and melting at 249–250° with decomposition.

Anal. Calcd. for $C_{36}H_{36}O_7N_4$: C, 67.92; H, 5.66; N, 8.81. Found: C, 67.52; H, 5.41; N, 8.60.

Summary

This paper describes a non-aromatic base of the constitution $C_{13}H_{21}N$ occurring in the crude kerosene distillation of California petroleum.

In further study of the previously isolated $C_{16}H_{25}N$ base, the unexpected discovery has been made that it condenses with phthalic anhydride to form a phthalone.

The Preparation of Pure Triethanolamine (β, β', β''-Trihydroxytriethylamine)

BY FRANK E. E. GERMANN AND ODON S. KNIGHT

Very pure hydrochloride of triethanolamine can be prepared from technical triethanolamine as follows. The triethanolamine, with or without preliminary fractional distillation, is carefully neutralized with concentrated hydrochloric acid at 10 to 15° and a very slight excess of acid, as shown by litmus paper, added. In an hour the pure white crystals that have settled are filtered off with suction, thoroughly washed with 95% ethyl alcohol and dried for an hour at 110°; yield, 70%, based on the amount of triethanolamine present in the original mixture; m. p. 177–178°; Knorr gives 177°. Calculated percentage of chlorine, 19.10; found, 19.05.

The conversion of the hydrochloride into the free base with silver oxide or alcoholic solutions of sodium or barium hydroxide is difficult because of the solubility of the chlorides in triethanolamine or its ethyl alcoholic solution. For instance, using sodium hydroxide, on distilling off the ethyl alcohol, a small amount of the sodium chloride crystals was observed on the bottom of the flask and on attempting to distil the triethanolamine *in vacuo* much decomposition occurred. This observation led us to believe with Knorr[1] that the presence of any appreciable amount of chlorides causes decomposition on distillation.

Since sodium chloride is less soluble in the higher than in the lower alcohols, it was thought possible that isopropyl alcohol might be substituted with advantage for the ethyl alcohol in the saponification of the hydrochloride, provided the hydrochloride itself was sufficiently soluble in it. Measurements showed its solubility to be 1.1 g. per liter in isopropyl alcohol as contrasted with 3.0 g. per liter in ethyl alcohol, both at 65°.

One hundred grams of triethanolamine hydrochloride was then added to 400 cc. of isopropyl alcohol, to which an equivalent quantity of sodium hydroxide, quickly pulverized in a mortar, had been added. This mixture was refluxed for three hours on a water-bath and after standing overnight the precipitated sodium chloride was removed on a suction filter. The isopropyl alcohol was then distilled off at atmospheric pressure, after which the triethanolamine itself distilled over at 194–195° at 10 mm. pressure. A 90% yield of odorless, clear, pale straw-colored oil, specific gravity, 1.1239 at 20/20°, was obtained, which on titration with sulfuric acid showed a purity of 99%. Its nitrogen content determined on nine different samples by the Kjeldahl–Gunning–Arnold method was on the average 9.35% as against 9.39% calculated, with a maximum variation of 0.09%.

The Addition of Phenols to the Ethylenic Linkage. The Action of Phenols on Alkylene Halides[1]

BY RICHARD A. SMITH AND JOSEPH B. NIEDERL

It has been demonstrated in previous communications that phenolic bodies will add to unsaturated linkages, principally of the ethenoid type, in the presence of sulfuric acid or other cationoid condensing agents. The products generally are substituted phenols or phenyl ethers.[2]

In this report it will be shown that this type of condensation can be extended to unsaturated halides. The three cresols and phenol were condensed with allyl chloride in the presence of sulfuric acid. The products were identified as isopropenylphenols. These products have been resynthesized in several ways: (a) by the condensation of phenols with allyl alcohol,[3] (b) allyl esters,[4] (c) allyl ethers, and[5] (d) by direct rearrangement of the isomeric isopropenyl phenyl ethers.[2]

Two types of condensation are described. The first consists simply in allowing the phenol, the unsaturated halide and sulfuric acid to stand for an appropriate time at room temperature. The reaction rate is very slow. The second type is more rapid; heat is employed and glacial acetic acid is used in the capacity of a diluent to minimize sulfonation.

The experimental results are consistent with the reaction mechanism which has been advanced previously.

Experimental Part

Slow Condensation.—Phenol and the three cresols were condensed by this method. The procedure involved in all four condensations was similar. A mixture of one mole of the phenol, one mole of allyl chloride, and one mole of sulfuric acid was allowed to stand in a flask, protected from moisture by a calcium chloride drying tube, for a period of six months. The condensation products of phenol, *o*- and *p*-cresol were subjected to the same treatment for the isolation of the reaction product. A volume of water twice that of the reactants was added and the whole then neutralized with sodium carbonate. The organic layer which separated was then removed, water washed and dried with anhydrous sodium sulfate. Distillation at atmospheric pressure was used to obtain the final product. The refractive index and density were taken immediately after distillation to avoid possible errors due to polymerization. In the case of *m*-cresol, the condensation product separated as a crystalline solid, and this was merely filtered off and recrystallized. All of the products have been obtained by resynthesis, as has been stated, and the agreement in properties is satisfactory.

At periods during the condensations, the gases evolved were collected in silver nitrate solutions; it was found in each case that a precipitate of silver chloride was formed.

A blank run containing allyl chloride and sulfuric acid under the same experimental conditions did not yield a precipitate of silver chloride.

More Rapid Condensation.—It is possible to carry out the condensation at more elevated temperatures and so greatly decrease the reaction time. The method allows the isolation of the intermediate phenoxy compound in good yields where this is desired. If the reaction mixture be heated for a short time, the primary reaction product will be the ether; further heating increases the amount of the substituted phenol and decreases the relative amount of ether. The substituted phenol alone may be obtained as the final product. The condensation agent is again sulfuric acid; however, where heat is employed it is necessary to use a diluent to prevent sulfonation. Glacial acetic acid is used in this capacity. Equimolar quantities of allyl chloride, *m*-cresol and sulfuric acid (present as 33% of a glacial acetic acid solution) when refluxed for eight hours yielded approximately equal parts of the ether and the substituted phenol with about 30% of the *m*-cresol having reacted. It is advisable to use an excess of allyl chloride as there is some loss due to volatilization. After refluxing, the reactants were thrown upon water; the organic layer which separated was water washed and extracted with ten per cent. caustic potash. The alkali-insoluble portion was dried with anhydrous sodium sulfate and distilled. Analysis indicated the loss of water on distillation.

The alkaline extract was neutralized with 15% hydrochloric acid, the resulting organic liquid layer water washed and dried with anhydrous sodium sulfate. Distillation yielded isopropenyl-*m*-cresol. The hexa- and pentabromo derivatives were made from samples of this compound prepared by both the slow and rapid condensation. The procedure has been given in a former publication.[3]

Summary

The condensation of phenolic type compounds with the ethylenic linkage has been extended to unsaturated halides and the resulting condensation products were identified.

The Common Basis of Intramolecular Rearrangements. II.[1] The Dehydration of Di-*tert*-butylcarbinol and the Conversion of the Resulting Nonenes to Trimethylethylene and Isobutylene

BY FRANK C. WHITMORE AND E. E. STAHLY[2]

The older conception of molecular rearrangements as involving primarily the migration of groups (positive, negative or neutral free radicals) has been superseded in this Laboratory by the hypothesis that the metathetical and elimination reactions[1] of organic chemistry which give rise to most rearrangements, involve the following steps: (1) removal of a group with a complete octet of electrons, leaving an atom with six electrons. The ensuing changes may include the following: (2a) union with a negative ion to form the "normal" metathetical product; (b) The loss of a proton with the formation of a double bond. (c) The atom with only a sextet of electrons may take an electron pair from an adjacent atom, leaving that atom with only six electrons. The group originally held by the electron pair migrates with it. This hypothesis does not assume that a group leaves one part of the molecule and later attaches itself to a different part.[3] The important process is the transfer of an electron pair from an adjacent atom. (3) The *rearranged* fragment from 2c may undergo the processes in 2a, b, c.

---

[1] Whitmore, THIS JOURNAL, **54**, 3274 (1932).

[2] Presented in partial fulfilment of the requirements for the Ph.D. degree.

Since the important process is the satisfying of the electronically deficient atom, change (2c) might consist of the shift of an electron pair without carrying along its organic group. The latter would thus leave as a positive fragment in much the way that a positive proton leaves the molecule in (2b). The type of organic group most likely to part with an electron pair and become positive would be a tertiary group as evidenced by the striking difference in the action of acids on tertiary alcohols as contrasted with primary and secondary alcohols.

The compounds most likely to give such a splitting of the C–C linkage would thus be those capable of forming a fragment, $R_3C—C—C^{\oplus}$. Substances of this type are practically unknown and their synthesis is difficult. For some time, however, experiments along this line have been in progress in this Laboratory. The results have been complex in the extreme.[4] We have now found one case which gives definite results. It is the dehydration of di-*tert*-butylcarbinol at 180° to give a 77% yield of trimethylethylene. The other products are a small amount of isobutylene and a complex mixture containing some nonenes, a large amount of diisobutylenes and smaller amounts of diamylenes, triisobutylenes and tetraisobutylenes. Dehydration of the carbinol at 155° gives nonenes in 71% yield. Treatment of the nonenes with the dehydrating agent at 200° produces isobutylene, trimethylethylene, and polymers in yields of 50, 68 and 39%, respectively, thus accounting for 98% of the nonenes used.

The possible changes,[1] starting with di-*tert*-butylcarbinol, are as follows: (1) removal of the hydroxyl to give a positive di-*tert*-butylcarbinyl group. This is doubly a positive neopentyl system and consequently most susceptible to rearrangement.[5] No other change is probable.

(2) The transfer of an electron pair with any one of the six methyl groups to give the fragment, $(CH_3)_3C—CH(CH_3)—C^{\oplus}(CH_3)_2$. (A.)

(3*a*) Fragment A would be expected to lose a proton from the tertiary hydrogen or from one of the two methyl groups. The expected nonenes are formed in only small amounts, however, unless dehydration is carried out under the mildest possible conditions.

[4] Unpublished work of A. H. Homeyer, S. N. Wrenn, E. E. Stahly, A. L. Houk and J. W. Heyd.

[5] *Cf.* Whitmore and Rothrock, THIS JOURNAL, **54**, 3431 (1932); **55**, 1106 (1933).

(*b*) Another possible change would result in the transfer of the tertiary butyl group to give the fragment, $^{\oplus}CH(CH_3)—C(CH_3)_2—C(CH_3)_3$. No product corresponding to this fragment has been found.

(*c*) The change in fragment A, formed either from the carbinol or *by the addition of a proton to one of the nonenes*, which agrees with the experimental facts is *the transfer of the electron pair from the tertiary butyl group but without the transfer of that group*

$$(CH_3)_3C—CH(CH_3)—C^{\oplus}(CH_3)_2 \longrightarrow (CH_3)_3C^{\oplus} + CH_3CH{=}C(CH_3)_2$$

The positive tertiary butyl fragment gives isobutylene and its polymers. Part of the trimethylethylene is polymerized.

The significance of the apparent instability of the grouping, $R_3C—C—C^{\oplus}$, is being further studied especially in relation to the depolymerization of polymerized olefins.

Experimental

Distillation Equipment.—All of the columns were of the total condensation, adjustable take-off, adiabatic type.[6] The packed sections were as follows: column A, 73 × 2.3 cm.; column B, 65 × 2.5 cm.; column C, 40 × 1.3 cm.; column D, 40 × 1.3 cm.; column E, 25 × 1.0 cm. A, B and C were packed with glass tubes, 5 × 5 mm., and D and E were packed with glass helices.[7]

General.—Di-*tert*-butylcarbinol was prepared by reducing hexamethylacetone which was made by the sodamide synthesis[8] from diisopropyl ketone.

Preparation of Diisopropyl Ketone.—Oxidation of diisopropylcarbinol with sulfuric acid–sodium dichromate mixture below 35° gave a 74% yield of diisopropyl ketone,[9] b. p. 120–125° (742 mm.), n^{20}_{D} 1.4001.

Hexamethylacetone.—A typical preparation will be described.[9] Toluene was distilled through Column A and the fraction distilling at 110–110.5° (740 mm.) was dried over sodium. Three liters of this toluene was placed in a 5-liter 3-necked flask equipped with a mechanical stirrer, reflux condenser, and dropping funnel. Commercial sodamide (about 50%) was pulverized under toluene and 160 g. (2 moles) was suspended in the toluene. To this suspension was added 228 g. (2 moles) of diisopropyl ketone. The mixture was stirred vigorously while heating to brisk reflux in an oil-bath. When the evolution of ammonia ceased the solution was cooled and 270 g. of methyl sulfate (2.14 moles) was added during one hour. When the refluxing again ceased the mixture was heated to boiling for fifteen minutes and then allowed to cool. To the cold solution 400 cc. of water and 200 cc. of ammonium hydroxide were added during two hours and stirring continued for twelve hours. Vigorous stirring was necessary throughout the whole process. The upper layer was then separated and washed with 5% hydrochloric acid and 5% sodium carbonate solution successively. The main portion of toluene was distilled off and the remainder used in the next step. Some of the pentamethylacetone was purified by distillation through Column A: b. p. 132–134.5° (730 mm.); n^{20}_{D} 1.4073.

The combined crude products from methylation of 5 moles of diisopropyl ketone were methylated in 3 liters of toluene as above. Distillation of the final toluene solution through Column B gave 374 g. of hexamethylacetone, b. p. 144–50° (740 mm.) n^{20}_{D} 1.4191–1.4197; yield, based on diisopropyl ketone, 52%. It was identified by con-

version to methyl-di-*tert*-butylcarbinol by reaction with methylmagnesium chloride;[10] m. p. of carbinol, 42°.

Reduction of Hexamethylacetone.—The reduction was by the method of Krueger.[11] From 4 half-mole runs, 220 g. (76% yield) of solid carbinol, b. p. 108–113° (150 mm.), was obtained. Redistillation through Column D gave 198 g., b. p. 117–118° (166 mm.), m. p. 50–51°.

Dehydration of Di-*tert*-butylcarbinol.—In a typical dehydration 57.7 g. (1 mol) of carbinol and 2 g. (0.02 mol) of 1-chloro-4-naphthalenesulfonic acid[12] were placed in a 200-cc. flask attached to Column D. The take-off tube was attached to a copper coil condenser cooled with water at 10°. The receiver was cooled in an ice-bath and its outlet was connected to a gas collector containing saturated salt solution. The flask was heated in an oil-bath at 180°. Dehydration proceeded without *evolution of gas* until almost the theoretical amount of water had been drawn off (three hours). At this point the distillation temperature dropped from 88 to 34° (733 mm.), trimethylethylene distilled, and gas was evolved. After one and one-half hours the distillation temperature rose and the evolution of gas ceased. The receiver was changed and distillation was continued under reduced pressure to give 16.1 g. of material, b. p. 43° (737 mm.) to 132° (113 mm.) and a residue consisting of 6 g. of liquid and 2 g. of solid material. A total of 90% of the starting material was accounted for as follows: water, 6.2 g. (theory, 7.2); gas, 1.2 liters, trimethylethylene 21.4 g. (calcd. 28 g., yield 77%) 22.1 g. of high boiling material (polymers).

Identification of Trimethylethylene.—The above volatile olefin, b. p. 34° (733 mm.), n^{20}_{D} 1.3815, was identified by conversion to the dibromide and hydrolysis to methyl isopropyl ketone by refluxing with water.[13] After the small bromide layer had disappeared and an upper one formed, the ketone was distilled through Column E and the 2,4-dinitrophenylhydrazone prepared, m. p. 116–118°. Two crystallizations raised the m. p. to 117–118°. Starting with pure trimethylethylene obtained by fractionation of the olefins from pure *tert*-amyl alcohol, a similar series of transformations yielded a 2,4-dinitrophenylhydrazone, m. p. and mixed m. p. 117–118°, thus proving the olefin from di-*tert*-butylcarbinol to be trimethylethylene.

Higher-Boiling Olefins.—The olefins obtained from three similar dehydrations were combined and distilled through Column D; 21 cuts (0.5–2.0 g. each) were taken from 82° (742 mm.) to 161° (730 mm.) and sixteen similar cuts between 116° (182 mm.) and 141° (75 mm.). All fractions decolorized dilute carbon tetrachloride solutions of bromine. A curve obtained by plotting n^{20}_{D} against total distillate gave six small breaks in an otherwise steadily rising curve. A molecular weight determination was made for the fraction corresponding to each of these breaks. For the four higher boiling fractions Solty's modification of Rast's camphor method was used.[14] It was not satisfactory for the two more volatile samples because vaporization caused a serious error. The lowering of the freezing point of benzene was used in the usual manner for the latter two.

The cuts corresponding to the breaks and the b. p., n^{20}_{D}, and molecular weight of each follow: 5–8, 4.6 g., 101–119° (740), 1.415, 118; 11–13, 5.1 g., 125–132° (742), 1.423, 124; 18–20, 2.3 g., 142–151° (738), 1.430, 1.40; 23–26, 5.0 g., 159° (736)–122° (130), 1.436, 147; 30–31, 1.8 g., 127–131° (102), 1.440, 172; 32–33, 2.6 g., 131–132° (102), 1.441, 172. The fractions thus correspond in properties and molecular weights to nonenes, diamylenes, and triisobutylenes. Although there was no break in the curve for 35–36, the refractive index corresponded to that for the ordinary mixture of the tetraisobutylenes, n^{20}_{D} 1.452.[15]

[13] Whitmore and co-workers, THIS JOURNAL, 55, 1136 (1933).

[14] "Quant. Org. Micro. Analysis," P. Blakiston's Son and Co., New York, 1930, p. 219.

Analysis of the Gases.—An Orsat apparatus was used with 100-cc. samples of the gas (25°). Carbon dioxide was absorbed by 40% potassium hydroxide, oxygen by potassium pyrogallate solution, and isobutylene by 68% sulfuric acid,[16] other olefins by bromine water, and carbon monoxide by cuprous chloride in hydrochloric acid solution. Remaining gas was considered to be nitrogen as it was nearly four times the amount of oxygen. The average of three analyses gave the composition of the gas as 1% carbon dioxide, 29.7% isobutylene, 0.2% other olefins, 0.2% carbon monoxide and 69% air. Thus the total volume of gas, 1200 cc., corresponded to 0.9 g. of isobutylene, a yield of 4%.

Summary of Products.—The dehydration of 57.7 g. of di-*tert*-butylcarbinol at 180° gave the following: water, 6.2 g. (86%), trimethylethylene, 21.4 g. (77%), isobutylene, 0.9 g. (4%) and polymers, 22.1 g. (42%).

Dehydration of the Carbinol at Lower Temperature without Splitting.—The dehydration of 43 g. of di-*tert*-butylcarbinol by 1.5 g. of 1-chloro-4-naphthalenesulfonic acid was conducted below 155°. The water formed was not drawn off but allowed to reflux in the column. After two and one-half hours the bath was removed and the pot cooled. The olefins were shaken with 30 cc. of 10% sodium hydroxide solution and extracted with ether. The ether solution after drying over sodium was distilled through Column D. The main fractions of the olefins, 18.6 g., 71% yield, distilled 123–140° (733 mm.) and had n^{20}_{D} 1.4230–1.4262. A residue of unchanged carbinol of 13 g. remained, m. p. and mixed m. p. 42–45°.

Splitting of the Nonenes Obtained from Di-*tert*-butylcarbinol.—To 18.5 g. of the nonenes was added 0.4 g. of 1-chloro-4-naphthalenesulfonic acid and the flask attached to Column D and heated as in the dehydration. Upon heating the bath to 145–205°, gas was evolved and trimethylethylene distilled. The total products obtained were: 2300 cc. of gas (27°), 7.0 g. of trimethylethylene, b. p. 34–36°, n^{20}_{D} 1.3800, 7.2 g. of yellow liquid residue, n^{20}_{D} 1.4350; total products recovered, 18.3 g. (98%). Analysis of the gas with an Orsat apparatus showed it to contain 73.1% isobutylene and 3% trimethylethylene or 3.9 g. and 0.2 g., respectively. The nonenes were thus split to yield 68% trimethylethylene, 50% isobutylene and 39% polymers.

Summary

1. Di-*tert*-butylcarbinol has been dehydrated to give a 77% yield of trimethylethylene together with isobutylene and its polymers.

2. The dehydration has been shown to proceed by way of nonenes which are unstable at 180–200° in the presence of the dehydrating agent.

3. These unusual reactions are interpreted in terms of the current theory of molecular rearrangements.

4. This type of reaction is being further studied.

The Effect of Traces of Carbon Disulfide on the Yields of Grignard Reagents[1]

BY FRANK C. WHITMORE AND DARWIN E. BADERTSCHER[2]

The preparations of many of the compounds needed for researches in progress in this Laboratory involve the use of Grignard reagents. Inasmuch as maximum yields are desirable it seemed worth while to investigate means of increasing the yields of Grignard reagents.

The effect of added substances and also of other factors, such as speed of addition and concentration of halide, has been studied by several workers.[3] A decreased yield of alkyl Grignard reagent usually is accompanied by an increase in the amount of olefin which is formed, apparently by the removal of hydrogen halide from the halide molecule by the magnesium. In acid pickling baths for removal of the surface oxide from iron and steel it is customary to add small amounts of so-called inhibitors which, while they do not interfere with oxide removal, do check the action of the acid on the metal itself. Rhodes and Kuhn[4] have made a careful study of these inhibitors and find certain cyclic nitrogen compounds to be the most effective. Consequently the effect of traces of pyridine, acridine, and α-picoline on the yield of *tert*-butyl- and *tert*-amylmagnesium chlorides was studied. In no case was the yield of Grignard reagent raised appreciably by traces of the inhibitors. Larger amounts of inhibitor delayed the reactions and decreased the yields. Thus the inhibiting action extended to the formation of the Grignard reagent as well as to the formation of hydrogen by the action of magnesium.

Freundler and Damond[5] noticed in the preparation of *sec*-butylmagnesium bromide that when a certain lot of ether was used the yield of Grignard reagent was increased and the amount of olefin formed was decreased. On careful investigation they found that this particular lot of ether had a small amount of carbon disulfide present as an impurity.

This lead looked promising and has been investigated in a quantitative manner. Traces of carbon disulfide present during its preparation raise the yield of Grignard reagent from primary and secondary bromides and iodides. The increase in yield is greatest in the more concentrated halide–ether solutions (compare Tables I and II). The increase in yield is accompanied by a marked decrease in the total volume of gas evolved (Table

II). The exact composition of these gases, with and without carbon disulfide present, is being studied at the present time. *tert*-Butyl bromide gave erratic results. Primary, secondary and tertiary chlorides are being investigated. The chlorides appear to be rather sensitive to traces of carbon disulfide, small amounts being sufficient to completely stop the reaction. The violence of the reaction between the halide and magnesium is in all cases moderated when carbon disulfide is present.

In each case in which the Grignard reagent was prepared in the presence of a trace of carbon disulfide the yield of product prepared from the reagent and the carbonyl compound was higher, based not only on halide, *but also on Grignard reagent,* than when the reagent was prepared in the absence of carbon disulfide (see Table II). This phenomenon is being studied further with the purpose of investigating the effect of traces of carbon disulfide on the reducing, coupling and enolizing action of the Grignard reagent.

In all cases in which carbon disulfide was present the solution became jet black, due to the presence of a small amount of very finely divided black solid, the nature of which has not been investigated.

Other workers in this Laboratory have fully confirmed our results.

Experimental

The results are listed in Tables I and II. Only a few details need be noted. In the larger runs, it was found advisable to start the reaction with a small amount of a concentrated solution (about 1:1) of halide in *pure* ether because the carbon disulfide, while it raises the yield, retards the start of the reaction. The carbon disulfide is then added to the remainder of the halide–ether solution, once reaction is started.

TABLE I

Halide	Ratio CS_2 to ether by vol.	Yield of RMgX, % CS_2 present	Yield of RMgX, % No CS_2 present
Isopropyl bromide	1:500	No reaction	82.5
	1:1000	87.9	
	1:2500	81.5	65.1
	1:2500	84.3	74.0
	1:4000	88.3	
Isobutyl bromide	1:4000	86.8	81.7
	1:4000	88.5	83.2
sec-Butyl bromide	1:4000	84.8	78.2
Capryl bromide	1:600	No reaction	67.0
	1:4000	71.2	66.0
sec-Butyl chloride	1:600	No reaction	87.2
	1:4000	79.6[a]	87.3
tert-Butyl bromide[b]	1:4000	40.6	38.9
	1:4000	44.5	43.3

[a] Reaction hard to start and did not proceed smoothly.

[b] Further experiments with *tert*-butyl bromide gave erratic results with poor checks.

TABLE II (LARGER RUNS)

ISOPROPYL BROMIDE; PREPARATION OF METHYL ISOPROPYL CARBINOL

Size of runs, 0.75 mole. Vol. of ether used, 250 cc. 0.1 cc. of CS_2 used in each run in which CS_2 was present.

	CS_2 present			No CS_2	
Yield of RMgX, %	89.6	97.0	89.3	64.4	56.5
Gas evolved, liters	2.9	1.1	0.7	4.7	6.9
Yield of carbinol, %					
Based on halide	48.0	61.7		29.3	20.0
Based on Grignard		63.4			34.0

n-PROPYL BROMIDE: PREPARATION OF METHYLETHYL-*n*-PROPYLCARBINOL FROM *n*-PROPYLMAGNESIUM BROMIDE AND METHYL ETHYL KETONE

Size of runs, 2.0 moles. Volume of ether used, 500 cc.

	0.25 cc. CS_2	0.4 cc. CS_2	No CS_2
Yield of RMgX, %	88.3	88.2	65.5
Gas evolved, liters	3.7	4.6	11.8
Yield of carbinol, %			
Based on halide	70.5	69.0	51.5
Based on RMgX	80.0	78.2	65.5

ISOPROPYL IODIDE

Size of runs, 0.25 mole. Volume of ether used, 90 cc.

	0.1 cc. CS_2	No CS_2
Yield of RMgX, %	79.0	56.0

It appears from the results with *n*-propyl bromide (Table II) that only a trace of carbon disulfide is necessary. There was very little difference in the yield of *n*-propylmagnesium bromide when 0.25 cc. and 0.4 cc. of carbon disulfide was present.

The reactions in Table I were carried out using 0.05 mole of halide and 30 cc. of ether in each.

The reactions were carried out in all-glass apparatus, two reactions being carried out at once, one with and one without carbon disulfide. The reactions given in Table II were carried out with larger amounts as indicated.

Summary

1. "Pickling" inhibitors do not increase the yield of Grignard reagents.

2. Traces of carbon disulfide raise the yield in the preparation of the Grignard reagents from several aliphatic primary and secondary bromides and isopropyl iodide. Chlorides are being studied at the present time.

3. The increase in yield is accompanied by a decrease in the volume of gas evolved during the preparation of the Grignard reagent.

4. Preliminary experiments indicate that the yield of product prepared from the Grignard reagent and a carbonyl compound is higher, based on Grignard reagent, when the reagent was prepared in the presence of a trace of carbon disulfide. This work is being continued.

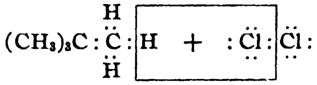
Preparation and Properties of Neopentyl Chloride in Relation to Molecular Rearrangements[1]

BY FRANK C. WHITMORE AND GEO. H. FLEMING[2]

Tissier[3] and Richard[4] prepared what appeared to be neopentyl chloride. The former stated that the monochloride obtained by the chlorination of neopentane was identical with that obtained from neopentyl alcohol and dry hydrogen chloride and that it decomposed on distillation. It has recently been found in this Laboratory that neopentyl chloride cannot be prepared from the alcohol.[5] In the present study it has been found that neopentyl chloride, formed by the chlorination of neopentane, is stable at 200° for long periods of time and is extraordinarily inactive, giving none of the ordinary reactions of alkyl halides except the formation of a Grignard reagent. Through that reaction and the action of phenyl isocyanate, it has been converted to *tert*-butylacetanilide, thus showing that it forms a Grignard reagent without rearrangement.[6]

The failure to obtain neopentyl chloride from neopentyl alcohol and its successful preparation from neopentane by chlorination illustrate again the instability of the "positive" neopentyl group and the stability of the same group when "negative."[7] The latter also confirms the common conception that chlorination involves the entrance of "positive" chlorine into the molecule. Thus the formation of neopentyl chloride may be represented electronically as involving the change:



$$(CH_3)_3C:\overset{H}{\underset{H}{\overset{..}{\underset{..}{C}}}}:\boxed{H \;+\; :\overset{..}{\underset{..}{Cl}}:}\overset{..}{\underset{..}{Cl}}:$$

in which the neopentyl group is not deprived of any of its electrons. The stability and inactivity of neopentyl chloride are strong indications of the tenacity with which the neopentyl group holds its electrons. The "electronegativity" of this group is being studied in a variety of ways in this Laboratory.

Experimental

Chlorination of Neopentane.—The reaction of neopentane and chlorine in direct sunlight at room temperature is extremely vigorous, much heat is evolved and there is some charring. With the light of a 1000-watt tungsten lamp, the chlorination takes place more slowly.

---

(4) Richard, *ibid.*, [8] **21**, 323 (1910).

(5) Whitmore and Rothrock, THIS JOURNAL, **54**, 3431 (1932).

(6) *Cf.* Whitmore and Lux, *ibid.*, **54**, 3448 (1932).

(7) *Cf.* Whitmore and Homeyer, *ibid.*, **54**, 3436 (1932).

Neopentane was chlorinated by passing chlorine over the surface of the hydrocarbon at 0° in diffused daylight. After distillation of a small sample of the crude chloride had shown it to be stable, the main fraction was distilled at atmospheric pressure through a precision column.[6] *No tertiary amyl chloride was formed during the chlorination or the distillation.*

Pure neopentyl chloride has the following physical constants: d_4^{20} 0.866; n_D^{20} 1.4042; f. p. −20 ± 1°; mol. ref. 30.01, calcd. 30.06; b. p. (Cottrell) 84.4° (760 mm.), 83.9° (750 mm.), 83.5° (740 mm.).

Reactivity of Neopentyl Chloride

Formation of Grignard Reagent.—Neopentyl chloride in dilute ether solution reacts slowly with magnesium. The product with phenyl isocyanate gives an anilide, m. p. 125–126°. A known sample of *tert*-butylacetanilide had m. p. 131° and mixed m. p. 126–128°, showing that the conversion of the chloride to the Grignard reagent involved no rearrangement. The Grignard solution with mercuric chloride gives neopentylmercuric chloride, m. p. 116.5–117°.[8]

Magnesium without Solvent.—*n*-Amyl chloride reacts completely with magnesium in eighteen hours at 200°, whereas neopentyl chloride was recovered unchanged after seventy hours under the same conditions.

Silver Acetate in Ether.—Contrary to the results of Tissier,[3] neopentyl chloride failed to react when heated for six hours at 40° and twelve hours at 60°.

Other Reagents.—While *n*-amyl chloride reacts completely with alcoholic potash in one hour at 100°, neopentyl chloride remained unchanged at the end of twenty hours under the same conditions. The chloride failed to react with cuprous cyanide in a sealed tube at 90° during two hundred hours. While *n*-amyl chloride reacts with potassium iodide in acetone to the extent of about 33%, neopentyl chloride gives no reaction under the same conditions.[9] The chloride failed to react with potassium acetate in absolute ethyl alcohol at 125° during thirty hours. Neither *n*-amyl nor neopentyl chloride reacted appreciably with diphenylmercury at 125° during seventeen hours. The former reacted slightly more than the latter when heated at 200°.

The other neopentyl halides are being prepared and studied in this Laboratory.

Summary

1. Neopentyl chloride has been obtained by direct chlorination of the corresponding hydrocarbon.

2. The physical constants of this chloride have been determined.

3. Neopentyl chloride has been found to be very stable and inactive chemically. The Grignard reagent has been formed.

The Isolation of a Sodium Sulfuric Acid Ester of Galactan from Irideae Laminarioides (Rhodophyceae)

BY W. Z. HASSID

Several investigators,[1] working on marine algae reported ethereal sulfates in these plants. However, in no case was the complete structure of these compounds determined with any degree of certainty.

In the present work the writer has isolated from *Irideae laminarioides* a comparatively simple ethereal sulfate, the complete chemical nature of which has been determined.

Extraction.—The plants *Irideae laminarioides* were collected at Moss Beach, California, washed immediately with distilled water, dropped into boiling 95% alcohol and boiled for ten minutes. The plants were brought to the laboratory, the alcohol poured off, the contents ground and extracted in a Soxhlet extractor, first with methyl and then with ethyl alcohol, until free of chlorophyll. The extracted residue was then dried at 50° in a vacuum oven.

Thirty grams of this material was heated with four liters of water on a steam-bath for several hours, until a colloidal solution was formed The solution was filtered on a large Buchner funnel through a silk filter. The residue on the silk filter was taken up with about three liters of water, heated for several hours on the steam-bath and filtered again. The combined filtrates were placed in a large evaporating dish and evaporated to about 800 cc. The solution was then poured into two liters of 90% alcohol. A milky colloidal solution was formed and was allowed to stand for several hours. The clear supernatant solution was decanted from the residue, which settled at the bottom, and concentrated under reduced pressure to about 500 cc. It was then slowly poured with continual stirring into 10 volumes of 95% alcohol, whereupon a precipitate of white flocculent threads formed. After an hour this was filtered and washed, using a silk filter, first with 95% and then with absolute alcohol and finally dried in a vacuum oven at 50°. About 10 g. of a snow white substance was obtained, which did not reduce Fehling's solution. It formed a colloidal solution when dissolved in water. Its specific rotation $[\alpha]_D$ was 69.2 after two reprecipitations from alcohol. When dissolved in water its *P*H was 6.8.

Hydrolysis.—A solution of 10 g. of the dry material in 500 cc. of 2% sulfuric acid was heated under a reflux condenser at a temperature of 105–110° for seven hours, cooled and nearly neutralized with a hot saturated solution of barium hydroxide and completely neutralized with barium carbonate. The mixture was then heated to 80° and allowed to stand overnight, filtered, the precipitate washed with hot water and the filtrate diluted to one liter. Aliquot portions of this were concentrated under reduced pressure. The reducing value of four 10-cc. aliquots was determined in terms of glucose with Fehling's solution, using the Munsen Walker tables. The mean value, when arbitrarily calculated to galactose applying Browne's factor 0.898[2] to the value for glucose, indicated hydrolysis of 54.0%.

Identification of Galactose.—(1) An aliquot representing 2 g. of the prepared ester was evaporated under reduced pressure to a thin sirup. The concentrated solution was treated with a large volume of methyl alcohol and then 1 cc. of glacial acetic acid was added, inoculated with a minute crystal of galactose and allowed to stand for several days. The crystals which deposited in the bottom of the beaker were collected, dissolved in water, and an orange-yellow phenylosazone was prepared. Its melting point was 194–196°. This corresponds to the melting point of the phenylosazone of galactan, given by Mulliken[3] as 196°.

Bird and P. Haas, *Biochem. J.*, **25**, 403 (1931); W. L. Nelson and L. H. Cretcher, *J. Biol. Chem.*, **94**, 147 (1931).

(2) C. A. Browne, "Handbook of Sugar Analysis," John Wiley and Sons, New York, 1912, p. 421.

(2) A confirmatory test showed that the phenylosazone could be prepared from the sirupy hydrolyzate without first obtaining the actual galactose crystals.

Quantitative Determination of Galactose.—Van der Haar's modification of the Kent–Tollens–Creydt method[4] with the additional precautions suggested by Wise and Peterson[5] was used for the quantitative determination of galactose. A determination, in triplicate, on the substance under consideration showed 53.2% anhydrogalactose.

Test for Pentose Sugars.—(1) Tollens' phloroglucinol method was applied to the hydrolyzed and unhydrolyzed substance. Both samples gave a yield equivalent to 0.5% of furfural. However, this result was probably due to the hydroxymethylfurfural obtained from the galactose, as it is in fair agreement with the results of Wise and Peterson,[5] who report 0.47% hydroxymethylfurfural due to galactose, and Schorger and Smith,[6] who report 0.55%.

(2) Samples of the hydrolyzed and unhydrolyzed substance were also examined for pentose sugars by the thiobarbituric acid method of Dox and Plaisance.[7] No precipitate of furfural malonyl-thiourea was obtained by the addition of the thiobarbituric acid to the hydrochloric acid distillate.

(3) Attempts were also made to determine whether any pentose or methylpentose sugar was present in the hydrolysis products of the substance, using various phenylhydrazine derivatives. No evidence was obtained for the presence of either pentoses or methylpentoses.

Test for Uronic Acids.—Dore's[8] modification of the Le Fèvre method for determination of uronic acid was applied to this substance. The results were negative.

Determination of the Sodium Ethereal Sulfate Group.—Ignition of the substance in an electric muffle at red heat showed the ash content to be 25.4%. The ash was analyzed for sulfur from the weight of barium sulfate obtained when the ash was dissolved and the sulfate precipitated with barium chloride. The sulfur content was 5.84%.

The original substance was analyzed for its sulfur content in a Parr bomb by oxidation with sodium peroxide and potassium chlorate; 11.5% sulfur was found by this method.

The substance was also hydrolyzed for two hours with 1:4 hydrochloric acid and the products of hydrolysis were examined for sulfur: 12.4% sulfur was found.

Sulfur in the substance by the Parr bomb method	11.5%
Sulfur in the substance by the hydrolysis with hydrochloric acid	12.4%
Sulfur in the ash	5.8%

From the above results it is evident that the sulfur content in the substance is approximately double the quantity of that in the ash.

Tests for sulfate ions were also made by dissolving the substance in warm water and adding barium chloride. There were no sulfate ions present in the solution.

(7) A. W. Dox and G. P. Plaisance, THIS JOURNAL, **38**, 2156 (1916).

(8) W. H. Dore, unpublished data.

Fifty-mg. portions of the ash were analyzed for sulfate, calcium, magnesium and sodium: 34.8 mg. of sulfate was found, 13.5 mg. of sodium and 1 mg. each of calcium and magnesium.

These results are in close agreement with the assumption that the ash is chiefly sodium sulfate.

Preparation of the Sulfuric Acid Ester of Galactan.—(1) Two grams of the substance was dissolved in 200 cc. of water and placed in an electrodialysis apparatus described by Greenberg and Greenberg.[9] The electrodialysis proceeded for seventy-two hours. The solution was then concentrated to a small volume and poured into 95% alcohol. The physical appearance of the precipitated substance thus obtained was quite different from that of the original. The fibrous structure had disappeared and the appearance was that of an amorphous granular powder. It gave an acid reaction; its *P*H was 3.6.

(2) Another 2-g. portion of the substance was dissolved in 200 cc. of water, placed in an 800-cc. capacity collodion bag. The bag with the solution was placed in a vessel in which water at 55° was continuously circulating. The dialysis proceeded for seventy-two hours. At the end of that time the solution in the bag was concentrated to a small volume and poured into alcohol as before. The acid ester was obtained as in (1).

Since no pentose sugar and no uronic acid could be found in the isolated substance, galactose appears to be the only sugar present. This conclusion is also supported by the fact that the reducing value corresponding to 54% of the substance, when arbitrarily calculated to galactose, was in satisfactory agreement with the value 53.2% calculated as anhydrogalactose by the modified Van der Haar method.

That the substance is a sodium ethereal sulfate was apparent from the fact that it contained approximately double the quantity of sulfur found in its ash, and from the fact that most of the ash consisted of sodium sulfate.

Comparison of actual results with calculated values, as shown in the table, indicates that there is one unit of galactose in the substance for each sodium ethereal sulfate group.

	Calculated, %	Found, %
Sulfur	12.1	12.0
Carbohydrate portion	54.8	54.0
Sodium ethereal sulfate	45.0	44.7

The table shows a close agreement between the percentages found and percentages calculated for the sulfur content, carbohydrate fraction and the sodium ethereal sulfate group.

Corresponding to the results which have been obtained for various polysaccharides, it might be expected that the structure of this substance is represented by a number of anhydrogalactose units united by glucosidal linkages or oxygen bridges to form chains or rings. The fact that this substance is fibrous strongly suggests that its structure may be a chain rather than a ring structure. Presumably the ethereal sulfate groups exist as side chains formed by replacement of hydroxyl groups. It is impossible of course to determine with certainty the position of the linking oxygen bridges, but assuming that the galactose units possess the usual

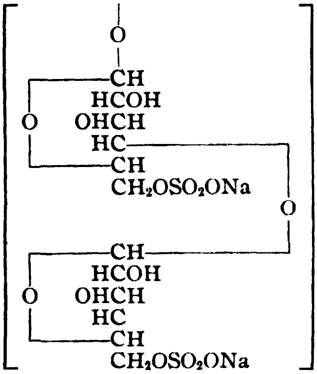
---

[9] D. M. Greenberg and L. D. Greenberg, *J. Biol. Chem.*, **99**, 1 (1932).

1:5 ring, it is perhaps not unreasonable to propose a chain structure similar to that put forward by Sponsler and Dore[10] for cellulose.

The position of the ethereal sulfate group is in doubt, but one may anticipate that it would be found attached to the sixth C atom. The following consideration upholds the validity of this suggestion: the galactose unit has a 1:5 ring structure, and therefore the group attached to the sixth C atom must protrude from the ring. Owing to the steric position of the groups attached to this atom, they will tend to be more reactive than other groups. Hence the ethereal sulfate group is assigned to the sixth C atom as the most probable position.

In accordance with these ideas the arrangement shown is tentatively proposed showing the linkage between two units.



The polysaccharide itself is made up of an unknown number of these building units, perhaps similarly arranged.

The sulfur in this substance is apparently united with the carbohydrate portion, since it is not precipitated as sulfate when barium chloride is added to an aqueous solution of this substance.

The sodium, however, appears to exist in ionic form, since it moves freely and passes through a collodion membrane when the substance is subjected to electrodialysis or plain dialysis.

The rest of the substance may be considered as a large negatively charged colloidal micelle and does not pass through the membrane.

The writer wishes to acknowledge his indebtedness to Mr. W. H. Dore for the valuable advice received during the course of the experimental work.

Summary

1. A sodium sulfuric acid ester of galactan has been isolated, apparently for the first time, from *Irideae laminarioides*.

2. When subjected to dialysis the sodium was practically all removed from the substance and an acid sulfuric ester of galactan resulted.

---

(10) O. L. Sponsler, and W. H. Dore, "Colloid Symposium Monograph," Chemical Catalog Company, Inc., New York, 1926, Vol. IV, p. 174.

3. No sulfur was removed by dialysis.

4. The physical properties of this acid were different from those of the original substance. It had the appearance of an amorphous granular powder in contrast with the fibrous structure of the original substance.

5. A 1% solution of the acid had a *P*H of 3.6.

6. The tentative structural formula shown is proposed for the substance in which *n* is unknown.

The Synthesis and Reactions of Certain Nitrogen Ring Compounds over Nickel

BY CHARLES F. WINANS AND HOMER ADKINS

In this group of three papers we are surveying the application of nickel as a catalyst for reactions which result in the formation of amines.[1] These reactions are of four general types. In the first type are those in which an amine reacts with an alcohol or amine with the elimination of water or ammonia

$$\mathrm{ROH + RNH_2 \longrightarrow R_2NH + H_2O} \qquad \text{(I)}$$

$$\mathrm{RNH_2 + RNH_2 \longrightarrow R_2NH + NH_3} \qquad \text{(II)}$$

In the second group a cyano, oximino, nitro or nitroso group is hydrogenated successively to an imine and an amine

$$\mathrm{RC{\equiv}N \xrightarrow{H_2} RCH{=}NH} \qquad \text{(III)}$$

$$\mathrm{R_2C{=}NOH \xrightarrow{H_2} R_2C{=}NH + H_2O} \qquad \text{(IV)}$$

$$\mathrm{RCH{=}NH \xrightarrow{H_2} RCH_2NH_2} \qquad \text{(V)}$$

In the third group a nitrogen to nitrogen or nitrogen to carbon bond undergoes hydrogenolysis with the formation of amines

$$\mathrm{RCH(N{=}CHR)_2 \xrightarrow{H_2} RCH_2NH_2 + (RCH_2)_2NH} \qquad \text{(VI)}$$

$$\mathrm{RNHNHR \xrightarrow{H_2} 2RNH_2} \qquad \text{(VII)}$$

In the fourth group an imine, aldehyde or ketone adds an amine, followed in most cases by hydrogenolysis with the elimination of ammonia or water

$$\mathrm{RCH{=}NH + R'NH_2 \longrightarrow RCH(NH_2)NHR \xrightarrow{H_2} RCH(R)NH + NH_3} \qquad \text{(VIII)}$$

$$\mathrm{RCH{=}O + R'NH_2 \longrightarrow RCH(OH)NHR \xrightarrow{H_2} RCH(R)NH + H_2O} \qquad \text{(IX)}$$

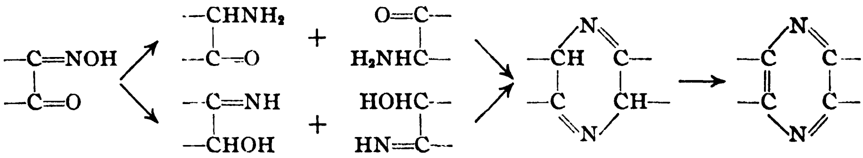
(1) Winans and Adkins, THIS JOURNAL, (a) 54, 306 (1932); (b) 55, 2051 (1933).

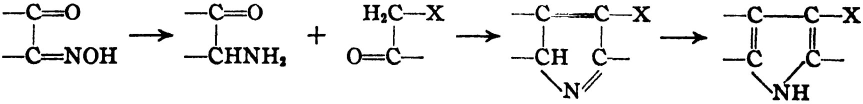
The present paper is concerned primarily with the application of these reactions in the synthesis and transformation of nitrogen ring compounds. A summary of the experimental results obtained in the synthesis of certain pyrrolidones, pyrazines and pyrroles is given in Table I, while in Table II is found a summary of the results in the hydrogenation and hydrogenolysis of certain α-amino nitriles, glyoxalones and pyrazolones.

Pyrazines.—The tendency toward the formation of pyrazines at the expense of open chain amines when α-oximino ketones or alcohols are subjected to hydrogenation over nickel has been noted previously in connection with the hydrogenation of benzil dioxime and benzoin oxime over nickel.[1b] Braun and Meyer[2] first observed this reaction in the reduction of oximes with sodium amalgam. The monoxime of benzil over nickel gave more tetraphenylpyrazine than of the open chain amino alcohol, while the oximino-acetoacetic ester, -acetophenone, and -hydrindone, gave only the corresponding pyrazines. The reaction (*cf.* IX) may be formulated as involving either the reaction of an amino with a carbonyl group or an imino with a hydroxyl group. In either case, the resulting dihydro pyrazine would be oxidized by air, according to Braun and Meyer, to the pyrazine



The second hypothesis must be assumed to explain the formation of a pyrazine from benzoin oxime, but since the yield of the pyrazine was much lower from benzoin oxime than from benzil oxime, reaction probably also proceeds according to the first hypothesis.

Pyrroles.—Knorr's[3] well-known and generally applicable synthesis of pyrroles involves the reduction with zinc and acetic acid of an α-oximino (isonitroso) ketone in the presence of a ketone having an active methylene group adjacent to the carbonyl. The type synthesis according to Knorr is as follows where X is acyl or carbalkoxy



The synthesis, in addition to the reduction, involves two types of reaction, one a Knoevenagel condensation of a ketone with an active methylene in the presence of an amine, and the other the reaction of an amine with a carbonyl.

The application of catalytic hydrogenation at 100-200 atmospheres over nickel to the Knorr synthesis has been quite successful. The reactions proceeded to completion at temperatures of 50 to 90° within less than one hour. Success in the use of catalytic hydrogenation in this synthesis depends upon attaining conditions under which the oximino group is hydrogenated without the carbonyl group being affected. Eight variously substituted pyrroles as indicated in Table I have been prepared and isolated in yields of from 23 to 74%, the average being over 50%. The yields are, in the case of the five pyrroles previously reported, higher than those obtained by Knorr's original method. Knorr and Lange[4] obtained better yields (based upon the amino ketone) through the isolation and reaction of the latter with the β-diketone or β-keto ester.

TABLE I

SYNTHESIS OF PYRROLIDONES, PYRAZINES AND PYRROLES

Name and moles of hydrogen acceptors	Yield of products
Ethyl β-phenyl-β-cyanopyruvate (0.09)	26% 4-Phenyl-3-keto-pyrrolidone (m. p. 288–289°)
Ethyl β-phenyl-β-cyanopropionate (0.15)	89% 4-Phenylpyrrolidone (m. p. 76–77°)
Ethyl β-cyanopropionate (0.15)	38% Pyrrolidone (m. p. 23–26°)
Ethyl γ-oximinovalerate (0.10)	63% 5-Methylpyrrolidone (m. p. 33–35°)
Dimethylglyoxime (0.26)	18% 2,3-Diaminobutane (b. p. 145–155°)
	76% Tetramethylpyrazine hydrate (m. p. 76–77°)
Benzil monoxime (0.09)	42% Tetraphenylpyrazine (m. p. 242–243°)
	36% α,β-Diphenylethanolamine (m. p. 160–161°)
Oximinoacetoacetic ester (0.16)	43% 2,5-Dimethyl-3,6-dicarbethoxy-pyrazine (m. p. 87–88°)
Oximinoacetophenone (0.10)	54% 2,5-Diphenylpyrazine (m. p. 193–194°)
Oximinohydrindone (0.03)	78% 2,3,5,6-Di-indenopyrazine (m. p. 270–271°)
Oximinoacetoacetic ester (0.11); diacetylmethane (0.11)	63% 2,4-Dimethyl-3-acetyl-5-carbethoxy-pyrrole (m. p. 143–144°)
Oximinoacetoacetic ester (0.10); acetoacetic ester (0.10)	67% 2,4-Dimethyl-3,5-dicarbethoxypyrrole (m. p. 135–136°)
Oximinoacetophenone (0.10); acetoacetic ester (0.10)	35% 2-Methyl-3-carbethoxy-4-phenyl-pyrrole (m. p. 107°)
Oximinodiacetylmethane (0.10); acetoacetic ester (0.10)	74% 2,4-Dimethyl-5-acetyl-3-carbethoxy-pyrrole (m. p. 140–141°)
Oximinodibenzoylmethane (0.025); acetoacetic ester (0.025)	51% 2-Benzoyl-3-phenyl-4-carbethoxy-5-methylpyrrole (m. p. 156–157°)
Oximinohydrindone (0.03); acetoacetic ester (0.03)	44% 2-Methyl-3-carbethoxy-4,5-indeno-pyrrole (m. p. 199–200°)
	39% Ethyl β-amino-(1-hydroxy-N-2-hydrineno)-butyrate (m. p. 95–96°)
Oximinobenzoylacetylmethane (0.03); acetoacetic ester (0.03)	56% 2,4-Dimethyl-3-carbethoxy-5-benzoylpyrrole (m. p. 110–111°)
Oximinoacetoacetic ester (0.05); benzoyl acetonitrile (0.05)	23% 2-Phenyl-3-cyano-4-methyl-5-carbethoxypyrrole (m. p. 85–86°)

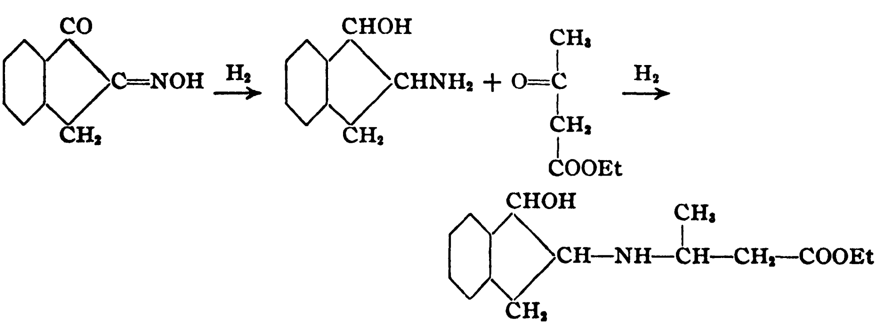
TABLE II

HYDROGENATION OF α-AMINO NITRILES, GLYOXALONES AND PYRAZOLONES

Name and moles of hydrogen acceptor	Yield of products
Methyleneaminoacetonitrile (0.59)	66% N-Methylethylenediamine 109–111°
	18% Di(β-N-methylaminoethyl)-amine 95–100° (25 mm.)
Diethylaminoacetonitrile (0.36)	37% N,N-Diethylethylenediamine 140–150°
	23% Di(β-diethylamino-ethyl)-amine130–135° (26 mm.)
Piperidinoacetonitrile (0.36)	50% β-Piperidino-ethylamine 80–85° (22 mm.)
	24% Di-(β-piperidinoethyl)-amine 160–170° (22mm.)
Piperidinoisobutyronitrile (0.24)	78% Piperidine 100–110° (740 mm.)
Piperidinocaprylonitrile (0.17)	79% Piperidine 100–110°
	22% *n*-Octylamine 85–87° (14 mm.)
Piperidinophenylacetonitrile (0.20)	82% Piperidine 100–110°
	50% β-Phenethylamine 75–80° (8 mm.)
	24% Di-β-phenethylamine 170–175° (8 mm.)
4,5-Diphenylglyoxalone (0.08)	82% 4,5 - Dicyclohexyl - dihydroglyoxalone, m. p. 237–239°
4,5-Dicyclohexylglyoxalone (0.04)	77% 4,5 - Dicyclohexyl - dihydroglyoxalone, m. p. 237–239°
4,5-Diethylglyoxalone (0.03)	76% 4,5-Diethyldihydroglyoxalone, m. p. 192–193°
1 - Phenyl - 3 - methylpyrazolone - 5 (0.11)	68% Butyranilide, m. p. 90–91°
1,3-Diphenylpyrazolone-5 (0.04)	95% β-Phenylpropionanilide, m. p. 89–90°
1 - Phenyl - 3 - methyl - 4 - benzalpyrazolone-5 (0.02)	80% α-Benzyl-β-aminobutyranilide (as hydrochloride)

The reaction of oximinohydrindone with acetoacetic ester gave a considerable yield of a product in addition to the pyrrole. Apparently to some extent the hydrogenation of the carbonyl group of oximinohydrindone preceded or accompanied the hydrogenation of the oximino group thus limiting the Knorr synthesis, for a yield of 39% of ethyl β-amino-(1 hydroxy N-2 hydrindeno)-butyrate was obtained, *i. e.*



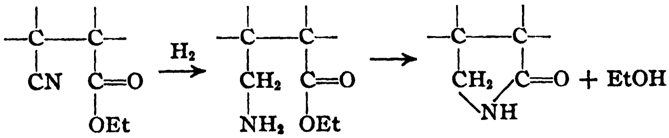
Knorr and Lange observed a similar reaction in attempting to prepare a pyrrole from oximinoacetone and methyl ethyl ketone.

It should be pointed out that isomeric pyrroles were formed from oximinoacetoacetic ester and diacetylmethane, and from oximinodiacetylmethane and acetoacetic ester. From this result it would seem reasonable to expect that such pairs of isomers could be prepared by switching the oximino group from one to the other of a pair of suitable compounds. However, such is not the case for from oximinoacetoacetic ester and dibenzoylmethane none of the expected pyrrole was obtained, but only a trace of 2,5-dimethyl-3,6-dicarbethoxypyrazine and large amounts of dibenzoylmethane. While oximinobenzoylacetylmethane plus acetoacetic ester was readily converted into a pyrrole, changing the oximino group from the diketone to the ester (oximinoacetoacetic ester and acetylbenzoylmethane) gave anomalous results. A compound of m. p. 128° was obtained in 89% yield (calculated as the pyrrole), but four rather than two molecular equivalents of hydrogen was absorbed in the process. The analysis for carbon showed 65.7 instead of 70.8 as calculated for the pyrrole, and the hydrogen was 7.13 instead of 6.27. The carbon content agreed with that for an amino alcohol in which one carbonyl group had been hydrogenated (thus making impossible the Knoevenagel condensation necessary for a Knorr pyrrole synthesis) but the hydrogen analysis was too low for this compound (7.85). The analysis for nitrogen gave values (5.03) between those for the pyrrole (5.16) and the amino alcohol (4.78). Similarly a product, m. p. 95–96°, analyzing low in carbon and high in hydrogen for a pyrrole, was obtained from the hydrogenation of a mixture of oximinopropiophenone and acetoacetic ester. Obviously, these data do not establish the nature of these two products but they do indicate that the course of the reaction is modified by the position of the oximino group.

The formation of a cyanopyrrole from oximinoacetoacetic ester and benzoyl acetonitrile is a new development of the pyrrole synthesis, and depends on the fact that over nickel a cyano group is less readily reduced than an oximino group. Under carefully controlled conditions the pyrrole synthesis was carried out without hydrogenation of the cyanide, giving rise to 2-phenyl-3-cyano-4-methyl-5-carbethoxypyrrole.

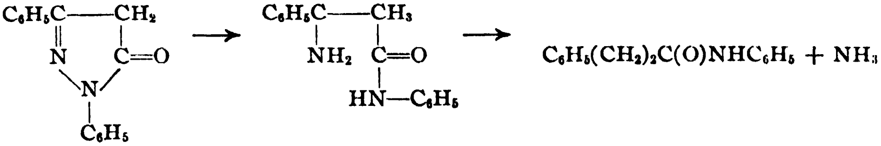
A crystalline product could not be isolated from the reaction mixture of oximinoacetoacetic ester and diethyl keto succinate.

Pyrrolidones.—Pyrrolidone itself and two derivatives, *i. e.*, 4-phenyl, and 4-phenyl-3-keto, were obtained by the hydrogenation at 50–90° of three β-cyano esters, the type reaction being as indicated



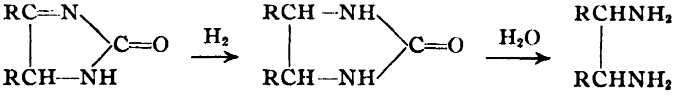
The amine produced by the hydrogenation of an oximino ester, γ-oximinovalerate, lost alcohol and 5-methylpyrrolidone was formed. The yields in all cases were greater than those previously reported for the preparation of these compounds.

Pyrazolones.—The nitrogen to nitrogen bond in pyrazolones is apparently readily cleaved by hydrogen over nickel at 120–150° (*cf.* VII). Two pyrazolones which had no substituent in position 4 (*i. e.*, derived from β-keto esters having no α-substituent) underwent cleavage of the cycle with the subsequent elimination of ammonia to give a substituted amide. This reaction took place almost quantitatively with 1,3-diphenylpyrazolone-5 and to the extent of 68% with the 1-phenyl-3-methylpyrazolone.



Pyrazolones having an ethyl, benzyl, benzal or β-phenylethyl radical in the 4 position apparently underwent a similar cleavage without the occurrence of the second step involving the elimination of ammonia. The hydrogen absorption was correct for this reaction and no ammonia was eliminated. The resulting β-amino anilides could not be purified satisfactorily. However, in the case of the 4-benzyl (or benzal) substituted pyrazolone an excellent yield (80%) of the hydrochloride of the α-benzyl-β-aminobutyranilide was isolated. The failure to obtain a similar product from the ethyl and β-phenylethyl substituted pyrazolones was apparently due to lack of material.

Glyoxalones.—Either 4,5-diphenyl- or dicyclohexyl-glyoxalone was hydrogenated at 200° in good yield (77–82%) to 4,5-dicyclohexyl dihydroglyoxalone. Similarly 4,5-diethylglyoxalone was converted into the corresponding dihydro compound. The relative ease of hydrogenation of the double bond in these two glyoxalones is to be contrasted with the complete resistance to hydrogenation of the similar double bond in the imidazole or glyoxaline series.[1b] The hydrogenation of the double bond in the glyoxalones renders available a method for the preparation of 1-2 diamines from the corresponding acyloins.



α-Aminonitriles.—The hydrogenation of six α-aminonitriles did not result in the development of a generally satisfactory method for the preparation of 1,2-diamines. Methyleneaminoacetonitrile was readily hydrogenated at 80–100° and a fair yield (66%) of N-methylethylenediamine was obtained. Diethyl aminoacetonitrile gave only a 37% yield of the desired amine, while four different α-piperidinonitriles underwent a rapid hydrogenolysis at the piperidino linkage and none of the desired β-piperidino-amine was obtained. This is a further example of the type of reaction listed as VIII above.

$$C_5H_{10}NCH(R)CN \longrightarrow C_5H_{10}NH + RCH_2CH_2NH_2$$

Experimental Part

The synthesis of the heterocyclic compounds listed in Table I was effected with approximately 4 g. of a Raney nickel catalyst.[5,6] The pyrrolidones were prepared in ether solution at 70–90°, absorption of hydrogen being complete in 0.75–1.0 hour. The pyrroles and pyrazines were formed in alcoholic solution at 70–90° in 0.75–1.0 hour. At this temperature hydrogenation of the oximino group was effected readily, and the resulting amino ketone condensed to give a pyrazine or pyrrole before the carbonyl group was reduced. The hydrogenations were, in general, carried out at the lowest temperature consistent with reasonable speed in an attempt to avoid side reactions. This hydrogenation temperature was found experimentally by observing the so-called "inflection point," the temperature above which the drop in pressure of hydrogen due to absorption was greater than the rise in pressure due to the heating of the bomb and contents. The "inflection temperature" is determined in part by the void in the bomb, which in this case was such that the drop in pressure per mole of hydrogen absorbed was about 2300 pounds per sq. inch.

In the synthesis of 4-phenyl-2,3-diketopyrrolidine, tetraphenylpyrazine, 2-methyl-3-carbethoxy-4,5-indenopyrrole, 2,4-dimethyl-3-acetyl-5-carbethoxypyrrole, 2,4-dimethyl-5-acetyl-3-carbethoxypyrrole and 2,4-dimethyl-3,5-dicarbethoxypyrrole crystals of the reaction product had separated from the mixture in the bomb. These were redissolved in the reaction solvent, filtered from the used catalyst and recrystallized. In the other cases where no crystals had separated the reaction mixtures were filtered from the catalyst, allowed to evaporate in air for two to three days and then if necessary in a vacuum desiccator over sulfuric acid in order to effect crystallization. By this process a thick sirup was obtained in the preparation of 2-phenyl-3-cyano-4-methyl-5-carbethoxypyrrole. The sirup was extracted with hot methylcyclohexane from which were deposited long needles of the cyanopyrrole on evaporation of the solvent. This product was then easily recrystallized from methylcyclohexane.

Oximinohydrindone and acetoacetic ester gave a crystalline product from the reaction mixture which was difficultly soluble in 95% alcohol. This was the 2-methyl-3-carbethoxy-4,5-indenopyrrole referred to above. After removal of these crystals the addition of water to the mother liquor gave a precipitate of fine white crystals which after recrystallization from methylcyclohexane gave the correct analysis for ethyl β-amino-(1-hydroxy-N-2-hydrindeno)-butyrate.

Most of the heterocyclic compounds were recrystallized from 70% alcohol. Glacial acetic acid was used for tetraphenylpyrazine, and methylcyclohexane for 4-phenylpyrrolidone and 2-phenyl-3-cyano-4-methyl-5-carbethoxypyrrole. Pyrrolidone, 5-methylpyrrolidone and tetramethylpyrazine were isolated by distillation.

The hydrogenations of the α-aminonitriles listed in Table II were effected in ether or ethanol solution with approximately 8 g. of Raney nickel in half an hour at 80–100°. The products of the reaction were separated by distillation under reduced pressure through a small Widmer column.

The glyoxalones were hydrogenated at 200° with a kieselguhr supported nickel catalyst[7] in ethanol solution in three to five hours. The crystalline hydrogenation product had separated from the reaction mixture when the bomb was opened.

The pyrazolones were hydrogenated in ethanol at 150° with approximately 5 g. of

Raney nickel in three hours. Evaporation of the reaction mixture in air deposited crystals of the anilides. The hydrochloride of the anilide of α-benzyl-β-aminobutyrate was formed in ether and had a m. p. of 155–156° after recrystallization from ethanol.

Anal. Calcd. $C_{17}H_{21}ON_2Cl$: Cl, 11.62. Found: Cl, 11.55.

The 4,5-dicyclohexylglyoxalone was prepared by refluxing 40 g. of duodecahydrobenzoin and 22 g. of urea in 150 ml. of glacial acetic acid for six hours. On cooling to room temperature crystals of the product separated. The reaction mixture was poured into 500 ml. of water, and the filtered product was washed with water to remove excess urea and acetic acid, and with ether to remove unchanged acyloin. After drying in air the product weighed 37 g. (82%), m. p. 287–289°.

The 4,5-diethylglyoxalone was prepared by refluxing 40 g. of propionin $C_2H_5C(O)CH(OH)C_2H_5$ and 35 g. of urea in 100 ml. of glacial acetic acid for six hours. The cooled solution from which some crystals had separated was poured into 400 ml. of water. The precipitated product was filtered, washed with water and recrystallized from 95% ethyl alcohol. After drying in air the product weighed 23 g. (44%) m. p. 293–294°.

The following compounds were prepared as previously described: ethyl β-phenyl-β-cyanopyruvate,[8] ethyl β-phenyl-β-cyanopropionate,[9] ethyl β-cyanopropionate,[10] oximinoacetoacetic ester,[11] oximino acetophenone,[12] oximinohydrindone,[13] oximinodiacetylmethane,[14] oximinodibenzoylmethane,[15] oximinobenzoyl acetone,[16] methyleneaminoacetonitrile,[17] diethylaminoacetonitrile,[18] piperidinoacetonitrile,[19] piperidinophenylacetonitrile,[19] 1-phenyl-3-methyl-pyrazolone-5,[20] 1,3-diphenylpyrazolone-5,[21] and 4,5-diphenylglyoxalone.[22]

The properties of the following list of compounds prepared in this investigation have been compared with those previously described by others: pyrrolidone,[23] 5-methylpyrrolidine,[24] 2,3-diaminobutane,[25] tetramethylpyrazine,[26] α,β-diphenylethanolamine,[27] tetraphenylpyrazine,[28] 2,5-dimethyl-3,6-dicarbethoxypyrazine,[29] 2,5-diphenylpyrazine,[30] 2,4-dimethyl-3-acetyl-5-carbethoxypyrrole,[31] 2,4-dimethyl-3-ethyl-5-carbethoxypyrrole,[32] 2,4-dimethyl-3,5-dicarbethoxypyrrole,[33] 2-methyl-3-carbethoxy-4-phenylpyrrole,[34] 2,4-dimethyl-5-acetyl-3-carbethoxypyrrole,[35] 2,4-dimethyl-3-carbeth-

Summary

Catalytic hydrogenation over nickel has been applied successfully to the Knorr synthesis of a number of pyrroles. Pyrrolidones have been prepared from cyano or oximino esters which upon hydrogenation yielded γ-amino esters. A number of pyrazines have been prepared from α-dioximes and α-oximino ketones, or alcohols. The double bond in glyoxalone in contrast to that in glyoxaline rings may be hydrogenated over nickel, thus making it possible to prepare 1,2-diamines from acyloins. The nitrogen to nitrogen bond in pyrazolones has been shown to be subject to hydrogenolysis. Deamination resulted in the case of certain pyrazolones but β-amino acid

anilides from the pyrazolones substituted in the 4 position were stable, thus permitting the preparation of certain β-amino acids. The hydrogenation of α-aminonitriles to substituted 1,2-diamines has not been generally successful due in part to the ease of hydrogenolysis of compounds of this type.

The Reaction between Aliphatic Orthoformates and Acetone

BY HOWARD W. POST

Ethyl orthoformate reacts with acetone in absolute ethyl alcohol solution to yield a compound known as a ketone acetal or ketal

$$CH_3COCH_3 + HC(OC_2H_5)_3 \longrightarrow HCOOC_2H_5 + (CH_3)_2C(OC_2H_5)_2 \qquad (1)$$

a drop or two of concentrated sulfuric acid or equally effective ammonium chloride, hydrochloric acid or pyridine hydrochloride acting as catalyst.[1]

It would seem at first glance that Equation 1 is not needed inasmuch as the ketone could be conceived as reacting with the alcohol, splitting off water which then would react with the ortho ester. Moreover, if it is the orthoformate which reacts, why is the alcohol necessary? To answer these questions and if possible to obtain information as to optimum conditions for the reaction, several runs were made using various solvents and catalysts, in most cases ethyl compounds.

The reagents, acetone, alcohol and orthoformate, were mixed in equimolecular amounts and allowed to stand at the temperature of the room (which was quite constant around 25°) for five to seven days. Where sulfuric acid was used as a catalyst the color of the solution darkened and the temperature rose as much as 10° during the first twenty-four hours. The products were isolated according to Claisen's method.[1]

Using the following amounts of reagents with various catalysts the following yields of ketals were obtained: 0.143 mole + 1 drop H_2SO_4, 13%; 0.286 mole + 1.3 g. NH_4Cl, 26%; 0.19 mole + 0.75 g. NH_4Cl, 30%; 0.68 mole + 1 drop HCl, 27%. Omission of the solvent or of the orthoformate gave zero yields. Using equimolecular amounts of isoamyl alcohol as a solvent also gave zero yields. Replacement of the ethyl alcohol by ethyl ether using 1 drop of sulfuric acid as catalyst gave an unchanged yield (13%).

A series of runs was then carried out to determine the applicability of this reaction to the preparation of higher homologs of diethyl ketal.

Equimolecular amounts of acetone, the alcohol and the corresponding orthoformate were used. In each case 0.15 g. of ammonium chloride was used as a catalyst for every hundredth mole of acetone. The amounts of acetone varied between one-tenth of a mole and four-tenths of a mole.

---

[1] Claisen, *Ber.*, **29**, 1007 (1896); *ibid.*, **47**, 3171 (1914); Arbusow, *ibid.*, **40**, 3303 (1907); Tschitschibabin and Jelgasin, *ibid.*, **47**, 48 and 1851 (1914).

The orthoformates were prepared according to the methods in the literature.[2]

With propyl alcohol yields of 25–30% of dipropyl ketal were obtained. With butyl, isobutyl, amyl and isoamyl alcohols no ketals were obtained but considerable quantities of orthoformate were recovered (30–50%), the amount varying directly as the molecular weight in a qualitative sense.

Diethyl ketal and butyl alcohol were mixed in molecular proportions of 1:2 and allowed to stand for one week at room temperature and illumination. The products from this reaction were identified as dibutyl ketal and ethylbutyl ketal

$$(CH_3)_2C(OC_2H_5)_2 + C_4H_9OH \rightleftharpoons C_2H_5OH + (CH_3)_2C(OC_2H_5)OC_4H_9 \qquad (2)$$

$$(CH_3)_2C(OC_2H_5)OC_4H_9 + C_4H_9OH \rightleftharpoons C_2H_5OH + (CH_3)_2C(OC_4H_9)_2 \qquad (3)$$

No catalyst of any sort was added. Attempts to repeat this reaction with ketal and alcohol involving radicals close to each other in radical weight were unsuccessful because of inability to isolate the pure products. The physical constants of the products were too close together to make identification certain. In this run 10.0 g. of $(CH_3)_2C(OC_2H_5)_2$ was mixed with 11.2 g. of C_4H_9OH. A 16% yield of ethylbutyl ketal resulted, and a 10% yield of dibutyl ketal.

The properties of these ketals are shown in the table. Values for the refractive indices are taken from the literature.[3]

KETALS

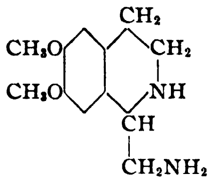
Isoquinoline Derivatives. II. Synthesis of 1-Aminomethyl-6,7-dimethoxy-1,2,3,4-tetrahydroisoquinoline

BY H. J. HARWOOD[1] AND T. B. JOHNSON

In continuing a study of the effect of various groups on the pharmacological action of isoquinoline derivatives the preparation of a 1-aminomethylisoquinoline appeared to be of particular interest because of the combined isoquinoline and β-phenylethylamine groupings.

Child and Pyman[2] attempted to prepare such an aminomethylisoquinoline by the action of ammonia and of potassium phthalimide on 1-chloromethyl-6,7-dimethoxy-3,4-dihydroisoquinoline but without success. These authors also dehydrated α-benzamido-N-(3,4-dimethoxyphenylethyl)-acetamide in the hope of obtaining 1-benzamidomethyl-6,7-dimethoxy-3,4-dihydroisoquinoline which could then be converted into the amino derivative. The desired compound was not obtained, however; a double ring-closure took place with the formation of 5,6-dihydro-8,9-dimethoxy-3-phenyl-imidaz-(4,3-α)-isoquinoline.

1-Aminomethyl-6,7-dimethoxy-1,2,3,4-tetrahydroisoquinoline (I) has been prepared in this Laboratory. N-(3,4-Dimethoxyphenylethyl)-α-phthalimidoacetamide was dehydrated to give 1-phthalimidomethyl-6,7-dimethoxy-3,4-dihydroisoquinoline. The latter was reduced catalytically to the 1,2,3,4-tetrahydro derivative, which was then hydrolyzed to yield the desired aminoisoquinoline I.



I

The attempted ring closure of N-(β-phenylethyl)-α-phthalimidoacetamide to form 1-aminomethyl-3,4-dihydroisoquinoline yielded only an extremely small amount of product which was not investigated further.

A second and much simpler method of preparing I seemed possible through the ring closure of N-(3,4-dimethoxyphenylethyl)-α-triazoacetamide followed by catalytic reduction. Attempts to carry out this reaction were without success. The ring closure of α-amino-N-(3,4-dimethoxyphenylethyl)-acetamide hydrochloride was also unsuccessful.

[a] From glycine and phthalic anhydride according to the method of Drechsel.[3]

[b] From phthalylglycine and thionyl chloride; b. p. 172–174° (5 mm.). Gabriel[4] gives 84–85° as the melting point.

[c] From phthalylglycyl chloride, β-phenylethylamine and 10% sodium hydroxide solution. Crystallized from alcohol. An attempt to bring about ring closure in this amide using phosphorus oxychloride in boiling toluene was unsuccessful. Using phosphorus pentoxide in boiling xylene a very small amount of basic product was obtained which was not investigated further.

[d] From phthalylglycyl chloride, homoveratrylamine[5] and 6% sodium carbonate solution. Crystallized from alcohol.

[e] By treatment of above amide with phosphorus oxychloride in boiling toluene for one and one-half hours. Toluene diluted with petroleum ether and precipitate dissolved in hot water and product precipitated with ammonium hydroxide. Crystallized from alcohol. If the above aqueous solution is allowed to cool without the addition of alkali, yellow crystals of a "phosphate" of undetermined constitution separate; sulfate obtained by diluting an alcoholic sulfuric acid solution with ether. Crystallized from absolute alcohol, m. p. 229–231°.

Anal. Calcd. for $C_{20}H_{18}N_2O_4\cdot H_2SO_4\cdot H_2O$: H_2O, 3.86. Found: loss at 60° and 3 mm., 3.93, 3.75. Calcd. for $C_{20}H_{18}N_2O_4\cdot H_2SO_4$: S, 7.14. Found: S, 6.87 and 6.75.

[f] Prepared by the catalytic reduction of the dihydroisoquinoline. The reduction was carried out either on a dilute hydrochloric acid solution of the free base or on an aqueous solution of the "phosphate" at 3 atmospheres pressure using Adams platinum oxide catalyst. The isoquinoline hydrochloride was obtained by evaporation of the solution and was recrystallized from alcohol. Thirteen grams of dihydroisoquinoline "phosphate" yielded 10 g. of tetrahydroisoquinoline "phosphate," m. p. 244–245° (effervescence).

[g] Ten grams of the above phthalimido-tetrahydroisoquinoline "phosphate" was suspended in 30 cc. of alcohol and treated with 3 cc. of hydrazine hydrate. The mixture was warmed until all had dissolved, cooled and the gelatinous mass treated with an excess of dilute hydrochloric acid and warmed. The phthalic acid which separated was filtered and the filtrate evaporated to dryness. An attempt was made to convert this crude isoquinoline salt into the sulfate by treating an aqueous solution with about 50% sul-

---

(3) Drechsel, *J. prakt. Chem.*, [2] **27**, 418 (1883).

(4) Gabriel, *Ber.*, **40**, 2647 (1907).

(5) Prepared as previously described, Harwood and Johnson, THIS JOURNAL, **55**, 2555 (1933).

furic acid. The sulfate failed to precipitate. The solution was neutralized with sodium hydroxide, filtered from sodium sulfate and evaporated to a volume of about 100 cc. Upon making strongly alkaline with sodium hydroxide the aminoisoquinoline separated as a viscous oil. The aqueous layer was removed by means of a separatory funnel, the oil dissolved in a small volume of water and made just acid by the addition of 50% sulfuric acid. Upon diluting with alcohol a mass of white crystals formed. After recrystallization from dilute alcohol the 1-aminomethyl-6,7-dimethoxy-1,2,3,4-tetrahydroisoquinoline sulfate melted with effervescence at about 274–275°. The melting point varied considerably with the rate of heating. A yield of 3.4 g. of pure product was obtained.

Anal. Calcd. for $C_{12}H_{18}N_2O_2 \cdot H_2SO_4 \cdot 2H_2O$: H_2O, 10.12. Found: loss at 60° and 3 mm., 10.27, 10.38.

[h] Prepared according to the method of Bertho and Maier.[6]

[i] Six grams of homoveratrylamine was dissolved in 10 cc. of water, cooled in an ice-bath and with shaking treated alternately with small portions of *N* sodium hydroxide solution and triazoacetyl chloride. A total of 4.4 g. of acid chloride and 33 cc. of sodium hydroxide solution was used. The product separated as an oil which finally solidified and was crystallized from benzene. Attempts to bring about ring closure in this compound using phosphorus oxychloride in boiling toluene or benzene, phosphorus pentoxide in boiling xylene and phosphorus pentachloride in chloroform at room temperature were without success.

[j] Four grams of the above amide was dissolved in 50 cc. of alcohol and hydrogenated at 3 atmospheres pressure using Adams platinum oxide catalyst. After two hours the solution was filtered, treated with 1.25 cc. of concentrated hydrochloric acid and evaporated to dryness under reduced pressure. The residue was extracted with 30 cc. of hot absolute alcohol in several portions and the hot solution diluted with an equal volume of dry ether. A white crystalline precipitate separated which weighed 3.6 g. and was recrystallized from alcohol–ether. An attempt was made to bring about ring closure in this amide using phosphorus pentachloride in chloroform at room temperature. No definite product could be isolated.

Summary

1. Starting with phthalylglycyl chloride and homoveratrylamine, N-(3,4-dimethoxyphenylethyl)-α-phthalimidoacetamide has been prepared in good yield.

2. By treatment with phosphorus oxychloride this amide undergoes a molecular condensation giving 1-phthalimidomethyl-6,7-dimethoxy-3,4-dihydroisoquinoline. The latter when reduced catalytically is converted smoothly into the corresponding 1,2,3,4-tetrahydroisoquinoline.

3. This 1,2,3,4-tetrahydroisoquinoline interacts smoothly with hydrazine hydrate to give 1-aminomethyl-6,7-dimethoxy-1,2,3,4-tetrahydroisoquinoline.

Researches on Pyrimidines. The Molecular Rearrangement of 2-Ethylmercapto-5-phenyl-6-thiocyanopyrimidine[1,2]

BY YUOH-FONG CHI AND YU-LIN TIEN

A further study of the behavior of potassium thiocyanate toward imino chlorides of the pyrimidine type has led to interesting results which are now reported in this paper. Following the technique of Wheeler, Johnson[3] and co-workers, the authors have investigated the action of 2-ethylmercapto-5-phenyl-6-chloropyrimidine[3] (II) on thiocyanates and find that they interact smoothly to form a normal thiocyanate (III). The structure of this rhodanide is established by the fact that it undergoes a normal change when allowed to interact with a thiol acid[3b,d,4] giving 2-ethylmercapto-5-phenyl-6-thiopyrimidine, V. This new thiocyanpyrimidine (III) exhibits a chemical behavior similar to that of 2-ethylmercapto-5-carbethoxy-6-thiocyanpyrimidine[3d] and 2-ethylmercapto-4-methyl-6-thiocyanpyrimidine.[3e] It can be distilled under a pressure of 2 mm. at 215° without decomposition and without molecular conversion into its isothiocyanate modification, IV. The stability of the rhodanide (III) is greatly influenced by the presence of certain reagents, and a molecular rearrangement to the corresponding isothiocyanate (IV) can be accomplished easily at a temperature very much below that of the boiling point of the pyrimidine thiocyanate. The conditions under which this change is brought about are described in the experimental part of this paper.

(4) Wheeler and Merriam, *ibid.*, **23**, 283 (1901).

ethylthiourea hydrogen bromide was dissolved. A cold solution of 10.6 g. of sodium hydroxide dissolved in 20 cc. of water, was then added very slowly. The mixture was left overnight in an ice box. On acidifying this alkaline solution with acetic acid, the oxypyrimidine separated. After purification by crystallization from 95% alcohol, it melted at 153–154° to a clear oil. The yield of the pure oxypyrimidine was 33 g. It is soluble in hot water and alcohol.

Anal. Calcd. for $C_{12}H_{12}ON_2S$: N, 12.07. Found: N, 11.91, 11.86.

2-Ethylmercapto-5-phenyl-6-chloropyrimidine, II.—Twenty grams of 2-ethylmercapto-5-phenyluracil was dissolved in 60 cc. of cold phosphorus oxychloride and the solution heated in an oil-bath at 130–140° for nine hours. After the removal of the excess of phosphorus oxychloride under diminished pressure, there was left a sirup, which would not solidify on cooling. It was treated with cracked ice in order to decompose double phosphorus compounds, the temperature never being allowed to rise above 0°. It was then extracted with ether and the ethereal solution dried with anhydrous calcium chloride. After the ether was distilled off, it left a yellow oil which solidified on cooling. It distilled as follows: 72 mm. at 175°, 10 mm. at 218°, and 20 mm. at 231–232°. The product solidified in the receiver, and melted at 38–39°. The yield was 15 g. or 70%. It is insoluble in water but very soluble in alcohol, benzene, and petroleum ether. On account of its great solubility in most organic solvents, it cannot be purified by crystallization.

Anal. Calcd. for $C_{12}H_{11}N_2SCl$: N, 11.18. Found: N, 11.16, 10.96.

2-Ethylmercapto-5-phenyl-6-thiocyanpyrimidine, III.[5]—This compound can be obtained by the action of potassium thiocyanate on the above chloride in boiling alcohol or benzene solutions. Fifteen grams of the chloropyrimidine, boiling at 175° at 2 mm. pressure, and 10 g. of potassium thiocyanate were dissolved in 40 cc. of absolute alcohol and the solution refluxed on a water-bath for one-half hour, when the reaction was complete. The solution was filtered while hot and chilled, when the thiocyanate separated immediately in the form of colorless needles. The yield was 16 g. or 97%. After purification by crystallization from benzene and ligroin (1:1), it separated as colorless flat needles and melted at 90° to a colorless oil. It distilled at 215° under a pressure of 2 mm. It can also be purified by crystallization from alcohol. The thiocyanate is insoluble in alkali but soluble in benzene, toluene and xylene, very soluble in hot alcohol and insoluble in petroleum ether.

Anal. Calcd. for $C_{13}H_{11}N_3S_2$: N, 15.38. Found: N, 15.30, 15.32.

Proof of Structure of the Thiocyanate.—That the compound described above (melting at 90°) is to be represented by a normal rhodanide or thiocyanate structure is established by the following experimental facts: (1) it does not undergo any change leading to the formation of a thiourea when exposed to the action of concentrated aqueous ammonia, (2) it can be crystallized from hot alcohol without conversion to a thiourethan and (3) the compound reacts with thioacetic acid to form the thiopyrimidine described below.

2-Ethylmercapto-5-phenyl-6-thiopyrimidine, V.—Two grams of 2-ethylmercapto-5-phenyl-6-thiocyanopyrimidine was dissolved in 10 cc. of thioacetic acid and the solution warmed on a water-bath for six to eight hours. After cooling, the thiopyrimidine separated in the form of yellow needles. It was purified by crystallization from absolute alcohol, and separated on cooling in the form of yellow plates melting at 171° to a clear oil.

Anal. Calcd. for $C_{12}H_{12}N_2S_2$: N, 11.29. Found: N, 11.30, 11.28.

---

[5] The pyrimidine chloride and thiocyanate experiments were first performed by Miss Tse Yuh Ho and were described in her thesis submitted to the Faculty of the College of Arts and Sciences of the University of Chekiang as a partial fulfilment of the requirements for the B.S. degree from that institution in June, 1932.

This compound was identified as 2-ethylmercapto-5-phenyl-6-thiopyrimidine as follows. When mixed with the thiopyrimidine prepared by the action of sodium hydrosulfide upon the corresponding chloropyrimidine, the melting point was not altered.

The procedure used for preparing the thiopyrimidine by interaction of the chloropyrimidine and sodium hydrosulfide was as follows. Four grams of the corresponding chloropyrimidine and 1 g. of freshly prepared sodium hydrosulfide were dissolved in 15 cc. of absolute alcohol, and the solution heated to boiling for two hours. It was slightly acidified with one drop of glacial acetic acid. The solution was filtered to separate the insoluble sodium chloride, while hot, and when cooled the thiopyrimidine separated in the form of yellow needles. It was purified by crystallization from absolute alcohol and melted at 171°. The yield was 52%.

Anal. Calcd. for $C_{12}H_{12}N_2S_2$: N, 11.29. Found: N, 11.32.

The Molecular Rearrangement of 2-Ethylmercapto-5-phenyl-6-thiocyanopyrimidine into its Isomeric Form, IV

2-Ethylmercapto-5-phenyl-6-isothiocyanopyrimidine, IV.—Four grams of the thiocyanate was refluxed in 10 cc. of xylene for thirty hours, giving a red colored solution. After distilling off xylene, the isothiocyanate residue was extracted with petroleum ether and the solution concentrated and finally chilled, when the isothiocyanate separated in the form of colorless needles. The yield was about 70%. The compound was purified by crystallization from petroleum ether, and melted at 84–85° to an oil. On standing, the isothiocyanate becomes colored.

Anal. Calcd. for $C_{13}H_{11}N_3S_2$: N, 15.38. Found: N, 15.01.

Proof of Structure of the Isothiocyanate, IV

2-Ethylmercapto-5-phenyl-6-thioureapyrimidine $C_{13}H_{14}N_4S_2$.—The thiocyanate was rearranged into the isothiocyanate form as described above and a petroleum ether solution of the latter combined with an excess of concentrated aqueous ammonia. The corresponding thiourea was formed immediately and 2.4 g. was obtained from 4 g. of the thiocyanate. It was purified by crystallization from ethyl acetate and it separated in colorless needles melting at 204° to a clear oil.

Anal. Calcd. for $C_{13}H_{14}N_4S_2$: N, 19.31. Found: N, 19.22, 19.02.

2-Ethylmercapto-5-phenyl-thioureapyrimidine, $C_{19}H_{18}N_4S_2$.—Four grams of the rearranged thiocyanate gave 3.2 g. of this compound by treatment with aniline at ordinary temperature. This was purified by crystallization from a benzene–ligroin mixture and separated in yellow needles melting at 149°.

Anal. Calcd. for $C_{19}H_{18}N_4S_2$: N, 15.30. Found: N, 15.14, 15.02.

2-Ethylmercapto-5-phenyl-6-thionethylurethan-pyrimidine $C_{15}H_{17}ON_3S_2$.—Four grams of the thiocyanate was rearranged to the isothiocyanate modification and then dissolved in 10 cc. of absolute alcohol. The solution was heated for a few minutes, and on cooling the urethan separated in the form of colorless needles. The yield was 2.5 g. or about 53% of the theoretical. After crystallization from alcohol it melted at 85–85.5°.

Anal. Calcd. for $C_{15}H_{17}ON_3S_2$: N, 13.16. Found: N, 13.17, 13.18.

2-Ethylmercapto-5-phenyl-6-thionmethylurethan Pyrimidine, $C_{14}H_{15}ON_3S_2$.—This was formed by warming the crude isothiocyanate with 10 cc. of methyl alcohol. It crystallized from methyl alcohol in the form of colorless needles melting at 79–80° to a clear oil.

Anal. Calcd. for $C_{14}H_{15}ON_3S_2$: N, 13.77. Found: N, 13.87, 13.62.

Experimental Conditions Influencing the Rearrangement of the Pyrimidine Thiocyanate.—A. While the thiocyanate can be distilled under diminished pressure without change into the isothiocyanate modification, it can be rearranged at a temperature much lower than its boiling point. Heating of the thiocyanate at 120° for three hours gave an oil, in which there was not any detectable amount of the isothiocyanate modification. Digestion of the pyrimidine thiocyanate in benzene did not produce a rearrangement. Heating in xylene solution for ten hours produced no change; but the change was brought about by refluxing in xylene solution for thirty hours.

B. At the boiling point of ethyl alcohol the pyrimidine thiocyanate undergoes no change and can be crystallized repeatedly from this solvent without structure alteration. On heating in alcohol at 100° for six hours the thiocyanate also undergoes no change. On the other hand, when heated in alcohol solution at 140° (75° below its boiling point) the thiocyanate is transformed into the isothiocyanate and the latter combines with alcohol, giving the corresponding thionurethan. Two grams of the thiocyanate dissolved in 10 cc. of absolute alcohol was heated at 140° for two hours. After the tube was opened, the solution was left in an ice box for two weeks. The thionethylurethan separated extremely slowly. The yield was one gram. This crystallized from alcohol and melted sharply at 85°. Mixed with the thionethylurethan described above, the melting point was not altered.

Summary

1. 2-Ethylmercapto-5-phenyluracil has been prepared by condensing the sodium salt of ethylformylphenylacetate with pseudoethylthiourea hydrogen bromide in the presence of alkali.

2. This uracil derivative interacts with phosphorus oxychloride to form 2-ethylmercapto-5-phenyl-6-chloropyrimidine.

3. 2-Ethylmercapto-5-phenyl-6-thiocyanpyrimidine is formed by interaction of potassium thiocyanate with 2-ethylmercapto-5-phenyl-6-chloropyrimidine in boiling ethyl alcohol or benzene solutions.

4. This pyrimidine thiocyanate distils at 215° at 2 mm. pressure and is rearranged to its isomeric form, the isothiocyanate, (1) by heating with alcohol at 140° and (2) by digestion in boiling xylene. Both the thiocyanate and the isothiocyanate can be obtained as crystalline compounds.

5. The structure of the thiocyanate is established by interaction of the compound with thioacetic acid. This gives 2-ethylmercapto-5-phenyl-6-thiopyrimidine, which can also be synthesized normally by the action of sodium hydrosulfide on the corresponding chloropyrimidine.

6. The thiocyanate does not interact with alcohols, ammonia or aniline. The isothiocyanate reacts with these same reagents to form the corresponding thionurethans and thioureas, respectively.

Researches on Pyrimidines. Synthesis of 5-Phenylcytosine

BY YUOH-FONG CHI AND YU-LIN TIEN

If we limit ourselves to carbon substituted pyrimidines there are only four phenyl derivatives of cytosine and isocytosine to be considered, namely, the phenyl constructions represented by formulas I, II, III and IV, respectively.

$\mathrm{NCONHC(C_6H_5){=}CHCNH_2}$

I

$\mathrm{HNC(NH_2){=}NC(C_6H_5){=}CHCO}$

II

$\mathrm{NCONHCH{=}C(C_6H_5)CNH_2}$

III

$\mathrm{HNC(NH_2){=}NCH{=}C(C_6H_5)CO}$

IV

Jaeger[1] and Warmington[2] independently prepared 4-phenylisocytosine II by the interaction of guanidine carbonate with ethyl benzoylacetate, and their observation was confirmed later by the work of Johnson and Hill.[3] The latter investigators also made the interesting observation that this pyrimidine II occurs in four isomeric crystalline modifications. Later Johnson and Hemingway[4] synthesized the 4-phenylcytosine I, but, so far as the authors are aware, 5-phenylcytosine III and 5-phenylisocytosine have not been prepared. The object of this short paper is to report our method of synthesizing the new phenylcytosine derivative represented by formula III.

Our method of procedure was to start with 2-ethylmercapto-5-phenyluracil and prepare first 2-ethylmercapto-5-phenyl-6-chloropyrimidine according to the technique of Chi and Tien.[5] This chloropyrimidine reacted smoothly with ammonia in alcohol solution at 150°, forming 2-ethylmercapto-5-phenyl-6-aminopyrimidine V, $\mathrm{NC(SC_2H_5){=}NCH{=}C(C_6H_5)CNH_2}$. When digested with hydrobromic acid this aminopyrimidine was destroyed with evolution of ethylmercaptan, yielding the hydrobromide of the desired 5-phenylcytosine III in good yield. The free pyrimidine base was easily obtained by treatment of its hydrobromide with ammonia.

Experimental Part

2-Ethylmercapto-5-phenyl-6-aminopyrimidine, V.—This pyrimidine is formed by heating 2-ethylmercapto-5-phenyl-6-chloropyrimidine[6] with strong alcoholic ammonia at 150°. Usually about four hours of heating are necessary to bring about a complete reaction. The cooled reaction mixture is filtered to separate undissolved ammonium chloride and the alcohol solution finally evaporated to dryness. The residue left behind

(4) Johnson and Hemingway, *ibid.*, **37**, 378 (1915).

(5) Chi and Tien, *ibid.*, **55**, 4181 (1933).

was then extracted with boiling benzene, and the filtered benzene solution diluted with petroleum ether. On cooling the desired aminopyrimidine separated in the form of colorless rhombic crystals. It was purified by recrystallization from a benzene–petroleum ether mixture and it melted at 87–88° to a clear oil. The yield from 16 g. of the chloropyrimidine was 8.5 g.

Anal. Calcd. for $C_{12}H_{13}N_3S$: N, 18.18. Found: N, 18.38, 18.39.

5-Phenylcytosine, III.—This pyrimidine was obtained in the form of its hydrobromic acid salt by hydrolysis of 2-ethylmercapto-5-phenyl-6-aminopyrimidine with hydrobromic acid. Five grams of the mercaptopyrimidine was dissolved in 20 cc. of hydrobromic acid (48%) and the mixture refluxed on a sand-bath for fifteen hours, when the evolution of ethylmercaptan had ceased. The hydrobromide separated on cooling. After evaporating the excess of acid the salt was then purified by crystallization from water. It separated in the form of colorless long needles which sintered at 270° and melted at 280–281° with decomposition. The yield of the hydrobromide was 3.5 g. It was dried in a vacuum desiccator and analyzed.

Anal. Calcd. for $C_{10}H_{10}ON_3Br$: N, 15.68. Found: N, 15.52, 15.32.

In order to obtain the free pyrimidine base (5-phenylcytosine), this hydrobromide was dissolved in water and the hydrobromic acid neutralized by adding aqueous ammonia solution. The pyrimidine separated at once in a crystalline condition. The base is insoluble in cold ammonia but soluble in sodium hydroxide solution. The pyrimidine is soluble in boiling water and 95% alcohol. It crystallizes from water in the form of colorless needles and from alcohol in the form of colorless rhombic prisms. The yield from 1 g. of the hydrobromide is 0.6 g. The pyrimidine does not melt or decompose below 310°. It was dried over concentrated sulfuric acid in a vacuum desiccator and analyzed.

Anal. Calcd. for $C_{10}H_9ON_3$: N, 22.46. Found: N, 22.52, 22.57.

Hydrochloride $C_{10}H_9ON_3{\cdot}HCl$.—This salt is easily obtained by dissolving the 5-phenylcytosine in dilute hydrochloric acid and then allowing the solution to crystallize. It separated in the form of colorless needles which sintered at 270° and melted at 277–278°. For analysis, the salt was recrystallized from water and dried at 120°.

Anal. Calcd. for $C_{10}H_{10}ON_3Cl$: N, 18.80. Found: N, 18.85.

Summary

1. The action of alcoholic ammonia upon 2-ethylmercapto-5-phenyl-6-chloropyrimidine gives the corresponding aminopyrimidine, 2-ethylmercapto-5-phenyl-6-aminopyrimidine.

2. This mercaptopyrimidine is hydrolyzed by digestion with hydrobromic acid, giving 5-phenylcytosine hydrobromide.

A Chemical Examination of the Volatile Oil of Sarothra Gentianoides L. and the Detection Therein of Normal Nonane[1]

BY MARSTON TAYLOR BOGERT AND SIMON J. MARION

The solid members of the paraffin series are quite widely distributed in the plant kingdom, where they often appear as waxy coatings or excretions on various parts of the plant. Naturally, because of their relatively high boiling points, they are not so often found in the volatile oils obtained from these plants by distillation, although occasionally they are present in sufficient amount to cause the oil to congeal at temperatures but little below the normal, as is the case with the atar of rose, for example.

Of the liquid paraffins, on the other hand, the only one definitely identified as a plant constituent is the *n*-heptane which has been reported in the *Pinus sabiniana* and *Pinus jeffreyi* of California and in the "petroleum nuts" of the *Pittosporum resiniferum*, from the Philippine Islands. Brooks, in his well-known volume on "The Non-Benzenoid Hydrocarbons," Chemical Catalog Co., Inc., New York, 1922, remarks (p. 89) that "Normal heptane enjoys the distinction of being the only saturated hydrocarbon, other than the solid paraffins, formed by phytochemical processes."

It has been reported[2] that the crude wood turpentine produced by the destructive distillation of the longleaf pine contains pentane, but this report lacks confirmation.

Some six years ago, the late Dr. Emerson R. Miller[3] described a preliminary investigation of the volatile oil of *Hypericum perforatum*, in the course of which he collected a low-boiling fraction, whose properties were such as to suggest the presence therein of an aliphatic hydrocarbon not hitherto discovered in any essential oil. Based upon our own results, as recorded beyond, with a closely related species, it seems to us quite probable that Dr. Miller was right in believing that this low-boiling fraction from *H. perforatum* consisted largely of a nonane,[4] although of course this still remains to be proved.

The family of the *Hypericaceae*, containing some ten genera and over 300 species, includes the well-known St. John's Wort, or *Hypericum*, genus, of which only *H. perforatum*, as noted above, seems to have been studied to any extent, either pharmacologically[5] or chemically. From the days of Dioscorides, who lived about the first century A. D., the St. John's Worts have been popular domestic remedies, having been used for a remarkably extensive list of ailments. Concerning the species *Sarothra gentianoides* L. (*H. sarothra* Michx.), one authority[6] records it as "a much used laxative, alterative, and vulnerary, under the names of Pineweed, False St. John's Wort, Orange Grass and Nitweed."

In the summer of 1923, the junior author, working with Dr. E. R. Miller at the Auburn (Ala.) Experiment Station, made a preliminary examination of a volatile oil obtained from *Sarothra gentianoides* L. but, due to the resignation of the junior author from the staff of the Experiment Station and the death of Dr. Miller, this investigation was suspended until a few years ago, when it was resumed as a coöperative undertaking by the chemical laboratories of Lenoir Rhyne College and Columbia University.

Collection and Distillation of the Plant.—The material used was collected in late August and early September, in the years 1925–1929, inclusive, and mostly in the neighborhood of Hickory, Catawba County, North Carolina.

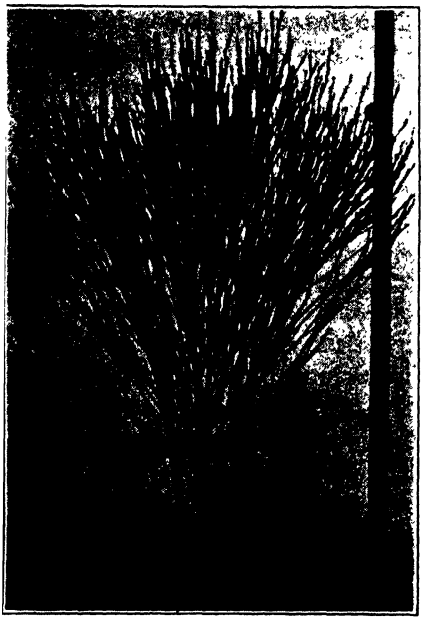

Plate I.—*Sarothra gentianoides* L., in full bloom.

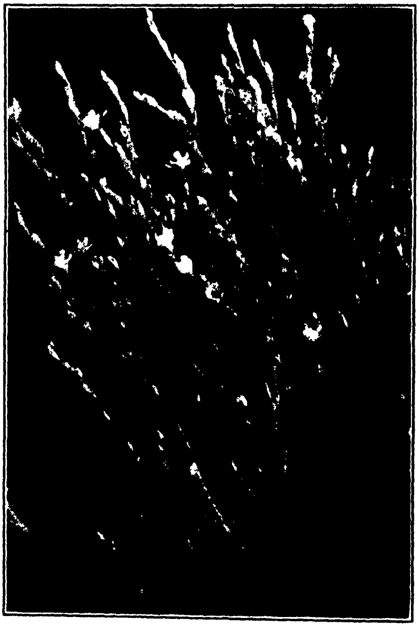

Plate II.—*Sarothra gentianoides* L., enlarged bushy top of plant, showing details of flowers.

The plants were pulled up by the roots, shaken to remove adhering dirt, examined carefully as to species, and all foreign matter removed. The entire fresh green herb, tops, stems and roots, was distilled with steam in

---

(6) Millspaugh, *Am. Medicinal Plants*, I, Sec. 30 (1887).

100-lb. lots for periods of about three hours. The yield of volatile oil which separated in the distillate varied from 0.072 to 0.222%, for different years, due probably to different climatic conditions during the growing season. The general average yield of filtered oil, unwashed and undried, was approximately 0.1 to 0.2%, based on the weight of the fresh whole green plant.

The distillations carried out in 1925 are shown in Table I and it will be observed that the yields from the whole green plants, while not uniform, are consistently higher than the 1926 average of 0.098%. It is believed that this is due principally to the plentiful rainfall during the growing period, for we have noted that higher yields of oil are always obtained from the herbs gathered from low moist meadow land. It is possible that the better yield of oil in 1925 (as compared with 1926) may have been influenced somewhat also by the fact that the 1925 distillations were carried out with smaller lots.

During the season of 1925, distillations were also made on different portions of the plants, both fresh and dry. On August 27, 49 lb. of the whole fresh green herbs was collected and the bushy tops cut off, and the two portions, tops and roots, distilled separately. The 49 lb. gave 41 lb., or 83.6% of tops, and 8 lb., or 16.4% of roots and coarse stems. The tops gave a yield of 50.4 g. of oil, and the roots and coarse stems only 1.7 g. Therefore, 96% of the oil is localized in the tops of the plants, representing 83% of the mature herb.

TABLE I

1925 DISTILLATIONS

Date	Material, lb.	Yield, g.	Yield, %
	(1) Whole Green Plants		
Aug. 26	156.0	103.0	0.145
Sept. 17	15.0	15.0	.220
Sept. 19	21.0	21.1	.222
		Av. % yield...	.196
	(2) Green Tops Alone		
Aug. 27	41.0	50.4	0.217
Sept. 2	67.0	103.2	.339
Sept. 18	15.0	21.7	.318
		Av. % yield...	.291
	(3) Dry Tops Alone		
Sept. 17	11.0	13.2	0.264
Sept. 17	10.0	8.3	.183
Oct. 8	9.0	12.3	.301
		Av. % yield...	.249

As mentioned above, the average yield of oil obtained from the harvest of 1926 was only 0.098%, probably because of the very hot dry summer.

During this same 1926 season, a quantity of material was allowed to dry from ten days to four weeks in a cool, dry shed, spread out in a thin layer so as not to heat. In this drying, the herbs lost about 70% in weight, as well as some of the volatile oil, so that when distilled the yield of oil averaged only 0.095%, calculated to the dry basis. The only marked difference between this oil and that distilled from the green plants was that it was darker and had a more pronounced pinene odor.

An acre of plants was raised from seed sown in the spring of 1926 and harvested in August, 1927, but the yield of oil was no better than from the wild herb growing under similar climatic conditions.

The largest amount of material collected in any one season was in 1929, when nearly two tons were distilled and approximately two liters of filtered oil obtained.

Examination of the Oil.—The oil used for the following examination was distilled from the entire green plants—tops, stems and roots. It was filtered, washed thoroughly with water and then dried over anhydrous sodium sulfate.

Its color lay in the Green-Yellow zone, between Normal Tones and Tint 1, of the Bradley Color Standard. Its odor was agreeable, recalling that of oranges, with a slightly balsamic suggestion. It was soluble in chloroform, carbon tetrachloride, ether or absolute alcohol. Cold concentrated sulfuric acid changed its color first to a yellow, then to a purple and finally to a dark red. Cold concentrated nitric acid changed it first to a yellow, then to a dark red, with dark particles floating at the junction of the two liquid layers. It was unaffected by concentrated hydrochloric acid either hot or cold. The only effect produced by glacial acetic acid was to dissolve the oil. Neither cold nor hot 3 *N* sodium hydroxide caused any change in the color of the oil. Neutral potassium permanganate solution, or an equal volume of a 5% solution of bromine in carbon tetrachloride, was instantly decolorized by the oil. At −17° the oil did not congeal, but assumed a slight milkiness which cleared up at +5°.

The following constants were determined: d_{20}^{20} 0.7665, n_D^{20} 1.4262, $[\alpha]_D$ +6.39, A. V. 0.58, S. V. 4.43, Ester No. 3.85, S. V. after acetylation 17.35.

Fuchsine and phenylhydrazine tests showed the presence of only traces of aldehydes or ketones. Further, the tests for phenols indicated that they also were present only in minute amount, if at all.

Following a qualitative examination for various elements, a combustion was run on the oil with this result: C, 84.03; H, 14.75; O, 1.22.

It was obvious from these results that the oil must consist mainly of hydrocarbons.

Fractionation of the Oil.—After removal of phenols, aldehydes, ketones, acids and esters, by the usual methods, from 360 cc. of the original whole green oil, the residual oil was washed, dried over anhydrous sodium sulfate and distilled four times with a 4-bulb Young fractionating column. Table II records the results obtained, compared with the constants of the original oil itself.

An examination of this table will disclose several unusual features. In the first place, 70% of this hydrocarbon oil distilled below 150°, and over 60% between 145 and 150°. This fact, taken in conjunction with the exceptionally low density of the oil and the other constants already recorded for the whole green oil, made it seem most likely that Fractions 1, 2 and 3, consisted mainly of acyclic hydrocarbons. Further, it was very significant that the only common volatile oils, of known composition, whose sp. gr. are lower than that of the *Sarothra* oil, are those from *Pinus sabiniana* (d_{15}, 0.6962–0.6971) and *Pinus jeffreyi* (d_{15}, 0.695–0.711), both of which consist principally of *n*-heptane. The density of the *Hypericum perforatum* oil, mentioned at the beginning of this paper, was reported by Miller[3] as 0.8065 to 0.8180 at 15°.

TABLE II

Whole green oil	B. p., °C.	d^{20}_{20} 0.7665	n^{20}_{D} 1.4262	$[\alpha]_D$ +6.39	No. cc. 360
Fraction 1	140–145° at 758 mm.	0.7265	1.4071	+ 4.05	25
Fraction 2	145–150° at 758 mm.	.7366	1.4129	+ 7.52	210
Fraction 3	40–60° at 8–10 mm.	.7687	1.4278	+18.96	33
Fraction 4	60–110° at 8–10 mm.	.8014	1.4453	+ 7.46	13
Fraction 5	110–125° at 8–10 mm.	.8927	1.4892	− 9.77	30
Fraction 6	125–140° at 8–10 mm.	.9073	1.4844	− 4.75	8
Residue	Above 125–140° at 8–10 mm.				15
				Total	334
				Loss in handling, etc.	26
					360

Inasmuch as Fraction 2 of the above table represented over 60% of the distillate, had the characteristic odor of the plant and obviously contained the major portion of the low-boiling constituent, preliminary qualitative experiments were conducted with it, as well as some elementary analyses. The results of these experiments and analyses, taken in conjunction with the physical constants noted in the table, indicated that the major constituent of this fraction was a paraffin, probably a nonane, mixed with some olefin, perhaps a nonene or decene.

Isolation and Identification of *n*-Nonane.—As our interest lay primarily in the isolation and identification of this paraffin, a larger quantity of the oil, freed as far as possible from oxygenated compounds by suitable treatment, was repeatedly distilled and a fraction b. p. 146–152° at 735 mm. was collected. This was washed with concentrated sulfuric acid as long as it colored the acid, then with concentrated nitric acid, followed by water, dilute sodium carbonate solution, and water again. After being dried over anhydrous sodium sulfate, it was refluxed for two hours over metallic sodium and then repeatedly fractionated over the same material, finally taking the cut which boiled at 148.5–149.5° (corr.) at 735 mm. A calculation based on Craft's formula, $dt = KT_{\text{Bo}}\ (760 - P)$, and assuming that the liquid is non-associated, gives a boiling range of 149.5–150.5° at 760 mm.

A number of fractionations, therefore, were carried out with the oil distilled in different seasons from the whole green plant, and yields of 14–20% were obtained of a fraction of this b. p. (149.5–150.5°).

TABLE III

	Sarothra nonane	*n*-Nonane
B. p. at 760 mm., °C.	149.5–150.5	149–151

---

(7) This was carried out in the laboratory of Dr. H. D. Crockford, Department of Physical Chemistry, University of North Carolina, Chapel Hill, N. C., to whom we are most grateful.

(8) We owe this determination to the courtesy of Professor E. E. Randolph, Department of Chemical Engineering, North Carolina State College, Raleigh, N. C.

Bearing in mind the fact that nearly 60% of the whole green oil distilled at temperatures not exceeding 150°, and that the narrow *n*-nonane cut (b. p. 149.5–150.5°), amounted to 14–20%, a conservative estimate would be that the original oil from the whole green plants contains at least 20% of *n*-nonane.

The carefully purified fraction referred to above, b. p. 148.5–149.5° at 735 mm., or 149.5–150.5° at 760 mm., was optically inactive, and in all its chemical reactions (potassium permanganate, bromine solutions, etc.) behaved like a paraffin hydrocarbon. The product was analyzed and various constants determined.

Table III gives the results side by side with those which appear in the literature (or are calculated).

Synthesis of *n*-Nonane.—As a further check upon the identity of the paraffin hydrocarbon isolated from the *Sarothra* oil, *n*-nonane was synthesized for purposes of comparison, by the method of Clarke and Adams,[9] condensing *n*-heptaldehyde first with ethylmagnesium bromide, hydrolyzing the product to the nonanol, converting this into the corresponding iodide, removing hydriodic acid from the latter by the action of strong alcoholic potassium hydroxide and catalytically reducing the nonene to nonane.

The synthetic *n*-nonane so obtained possessed the following constants: b. p. 149.5–150.5° at 760 mm., d_{20}^{20} 0.712, f. p. −51°, n_D^{25} 1.4055. In other respects it likewise appeared to be identical with the nonane isolated from the *Sarothra* oil. No change in boiling point could be detected when the two were mixed.

Other Hydrocarbons Present in the Oil.—Having isolated and identified the *n*-nonane in Fraction 2 of Table II, this same fraction was examined for olefins, inasmuch as its behavior with potassium permanganate and with bromine indicated clearly the presence of unsaturated hydrocarbons.

A portion of the oil was oxidized by potassium permanganate, the alkaline solution, filtered from precipitate and separated from unoxidized oil, acidified with dilute sulfuric acid and the acid solution distilled with steam. The silver salt prepared from the distillate contained 41.65% silver (average of four determinations), as compared with 41.67% silver in silver caprylate.

From the same distillate the sodium salt of the acid was prepared, and its aqueous solution exhibited a levo rotation of $[\alpha]_D$ −15.8°.

From another portion of Fraction 2, oxidized by chromic acid, an acid was obtained whose silver salt contained 52.19% silver. Silver valerate contains 51.64% silver.

The two acids isolated as oxidation products of Fraction 2, hence, seem to be valeric and active caprylic. These acids could have been formed either from a single tridecene, carrying its olefin bond between carbons 5 and 6, or from 2 different olefins, one a pentene and the other an octene. The latter is the more likely, in view of the physical properties of Fraction 2, the identification of caprylic acid in the whole green oil, and the fact that octene, C_8H_{16} (b. p. 123–124°; *d* 0.7275; n_D 1.4066), is the only olefin which has been detected in essential oils.

Preliminary tests indicate that the higher-boiling fractions shown in Table II are probably made up mainly of terpenes and sesquiterpenes, but this part of the investigation is still unfinished.

Oxygenated Constituents of the Oil.—Preliminary experiments were carried out also on the oxygenated constituents of the oil. Although the amount of material available was in most cases insufficient for conclusive results, these experiments are recorded for the benefit of other workers and because it is uncertain when this investigation can be resumed.

Reference to Table II showed that these constituents could not total more than 16.5% and, as noted above, the elementary analysis of the original oil disclosed only 1.22% (by difference) of total oxygen.

---

[9] Clarke and Adams, THIS JOURNAL, 37, 2536 (1915).

Free Acids.—After shaking 750 cc. of the whole green oil with excess of a 3% sodium bicarbonate solution, the aqueous solution was separated, concentrated, acidified with dilute sulfuric acid, extracted with ether and the ether extract evaporated. The residual dark brown oil, of hircin odor, was dissolved in dilute sodium hydroxide and the silver salt prepared therefrom. This salt darkened and apparently suffered some decomposition on drying, which would make the analytical figures for silver too high. Ignition of the dry salt showed the presence of 49.63% of silver. The silver content of silver valerate is 51.64%, and of silver caproate 48.39%. The presence of caproic acid, therefore, is indicated.

Esters.—The saponification value (4.43) determined on the original oil showed the presence of a small percentage of ester. Some of the oil, therefore, after removal of phenols, aldehydes, ketones and free acids, was saponified with $N/2$ alcoholic potassium hydroxide. The alkaline solution was separated, concentrated, acidified with dilute sulfuric acid, and the acid solution distilled with steam. The distillate had an acid reaction and yielded a silver salt containing 41.69% of silver. The silver salt of caprylic acid contains 41.67% of silver.

Alcohols.—From Fraction No. 5, Table II, there was prepared, by the method of Wallach,[10] a nitroso chloride, which melted at 106.5°. The melting point recorded in the literature for the nitroso chloride of *l*-α-terpineol is 107–108°, and the odor and other properties of this fraction resembled those of liquid α-terpineol.

The constants noted in Table II for Fraction No. 6 corresponded fairly well with those of geraniol. Some of this fraction, hence, was oxidized by a chromic acid mixture, as recommended by Beckmann,[11] and the odor of citral was immediately evident, and the oily product behaved toward the Schiff reagent like citral itself.

Phenols.—Free acids were removed from the oil by agitation with dilute aqueous sodium bicarbonate. The undissolved oil was separated, extracted with a 3% potassium hydroxide solution, the alkaline extract acidified with dilute sulfuric acid and shaken with ether. Evaporation of the ether extract left a small quantity of a brownish residue, of vaseline-like consistency, from which a 3,5-dinitrobenzoate, m. p. 207° (uncorr.), was prepared by the method of Phillips and Keenan.[12]

Aldehydes.—After removal of acids and phenols, the oil was shaken with a 40% sodium bisulfite solution, the bisulfite extract separated and hydrolyzed by boiling with sodium carbonate, and the liberated aldehyde collected with ether. Removal of ether left a very small quantity of an oil, which gave a deep red with the Schiff reagent, and yielded a crystalline semicarbazone, m. p. 105–106° (uncorr.), when dissolved in 30 parts of glacial acetic acid and treated with a solution of 4 parts of semicarbazide hydrochloride in a little water, a *P*H at which ketones do not form semicarbazones so readily.

It is worthy of note that the melting point of *n*-caproic aldehyde (*n*-hexanal) semicarbazone has been reported as either 106°,[13] or 114.5–115°.[14]

Ketones.—A qualitative test on the original oil indicated the presence of a trace of ketone. A small sample of the oil, from which acids, phenols, aldehydes, etc., had been removed, as described above, was treated with a solution prepared from 50 g. of semicarbazide hydrochloride, 50 g. of sodium acetate, a small amount of water and sufficient ethyl alcohol to make a homogeneous mixture. After standing for three days, some crystals separated which, after recrystallization from alcohol, melted at 231–232° (uncorr.). Camphor semicarbazone melts at 236–238°. The amount of material we had available was not enough for its positive identification.

Summary

1. The volatile oil of *Sarothra gentianoides* L. consists largely of liquid acyclic hydrocarbons, of which at least 20% is *n*-nonane, a compound which has not hitherto been found in nature.

2. In addition to *n*-nonane, there is evidence of the presence of the following: a low-boiling optically active olefin (probably an octene), unidentified terpenes and sesquiterpenes, α-terpineol, geraniol, traces of phenols, aldehydes and ketones, caproic acid and a caprylic ester.

Preparation and Dehydration of 4,4-Dimethylpentanol-2 (Methylneopentylcarbinol)

BY FRANK C. WHITMORE AND AUGUST H. HOMEYER[1]

The dehydration of dimethylneopentylcarbinol[2] and of methylethylneopentylcarbinol[3] gives olefins without rearrangement and with dehydration chiefly from the smaller groups. The neopentyl group shows little tendency to supply the proton in the dehydrations. The acid splitting of a C–C linkage in certain olefins having a neopentyl group attached to the ethylenic carbon has been observed.[4] Methyl neopentyl ketone reacts with sodium hypobromite as if it enolized exclusively from the methyl group.[5] Moreover, neopentylethylene adds hydrogen bromide entirely contrary to Markownikoff's rule.[6] In a further study of the neopentyl group, methylneopentylcarbinol has been prepared and dehydrated. Contrary to expectation the dehydration took place mainly from the neopentyl rather than the methyl group, the chief product being 4,4-dimethylpentene-2. No product of any rearrangement was detected.

4,4-Dimethylpentene-2 has been reported by Favorsky and Alexeeva[7,8] who gave its boiling point as 84–86°. Edgar, Calingaert and Marker[9] found that dehydration of 4,4-dimethylpentanol-3 gave a mixture of 4,4-dimethylpentene-2 and rearranged olefins. Boord and Schurman[10] prepared 4,4-dimethylpentene-2 by dehydration of 4,4-dimethylpentanol-3 by the methyl xanthate method.

Experimental

Preparation of 4,4-Dimethylpentanol-2.—A total of 746 g. of 4,4-dimethylpentanone-2 was reduced[11] in twelve runs in moist benzene solution with sodium. The product was distilled through an 85 × 2.1 cm. packed column.[12] The fore-run from each distillation was used in the next reduction. The yield was 548 g., 72%; b. p. 137–137.5° (736 mm.); n^{20}_D 1.4188; d^{20}_4 0.8115; MR. found 36.12, calcd. 36.17.

The residue was 176 g. corresponding to 23% of the original ketone. Distillation through a 70 × 1 cm. indented column showed it to be the pinacol, 2,2,4,5,7,7-hexamethyl-octanediol-4,5: b. p. 98–100° (2–3 mm.); m. p. 34–36°. It crystallized very slowly; the index of refraction taken soon after distillation was n^{20}_D 1.461. *Anal.* Calcd. for $C_{14}H_{30}O_2$: C, 73.0; H, 13.1. Found: C, 72.6; H, 13.4. The rearrangement of this pinacol is being studied.

Derivatives of 4,4-Dimethylpentanol-2.—α-Naphthyl urethan, from petroleum ether, m. p. 86.5–87°. 3,5-Dinitrobenzoate, from dilute alcohol, m. p. 95.2–95.7°. The carbamate was prepared by converting the carbinol to the chloroformic ester with phosgene and then treating it with aqueous ammonia; m. p. 71°. *Anal.* Calcd. for $C_8H_{17}O_2N$: N, 8.81. Found: N, 8.82. The acetate distilled at 92–92.5° (90 mm.); n^{20}_D 1.4071; d^{20}_4 0.8563; MR. found 45.44, calcd. 45.30. The *tert*-butyl acetate distilled at 92–94° (7–8 mm.), n^{20}_D 1.4195. Chloral mono-(methylneopentylcarbinyl)-acetal was prepared by adding 12 g. of pure methylneopentylcarbinol to 16 g. of Eastman anhydrous chloral. An exothermic reaction occurred. On the following day the product was washed with three 50-cc. portions of water and dried over calcium chloride. The product was a colorless oil, heavier than water, n^{20}_D 1.459. Distillation was not attempted.

Dehydration of 4,4-Dimethylpentanol-2.—Two hundred and fifteen grams of the carbinol was mixed with 5.5 cc. of 100% sulfuric acid. The mixture was added to the distilling flask in 40–50 g. portions and dehydrated by distilling through a 91 × 1.4 cm. packed column.[12] Distillation was regulated by controlling the rate of heating and take-off so that the head temperature did not exceed 80°. Twenty-three cc. of water was separated from the distillate. The product was washed with sodium bicarbonate solution, dried over 5 g. of potassium carbonate and fractionated through the 91 × 1.4 cm. column at 739 mm. using a reflux ratio of 10:1.

Fraction	B. p., °C.	n^{20}_D	d^{20}_4	Wt., g.	MR. found
1	74–75.3	1.3970	0.6885	41	34.31
2	75.3–75.6	1.3970	.6892	65	34.28
3	75.6–76.2	1.3981	.6903	42	34.31

The yield of olefins was 148 g. or 82%. The residue was 36 g., consisting chiefly of the unchanged carbinol. The calculated molecular refraction of the heptenes is 34.06 (Eisenlohr's values). Similar results were obtained in another experiment.

4,4-Dimethylpentene-1, b. p. 72.35° (760 mm.), n^{20}_D 1.3911, has been prepared in this Laboratory.[6] We are indebted to C. E. Boord for the properties of 4,4-dimethylpentene-2, b. p. 76.0–76.1° (760 mm.), n^{20}_D 1.3986. From the refractive indexes it is estimated that the olefin mixture contained 82% of 4,4-dimethylpentene-2 and 18% of 4,4-dimethylpentene-1.

---

[11] Whitmore and Krueger, THIS JOURNAL, 55, 1531 (1933).

[12] Whitmore and Lux, *ibid.*, 54, 3451 (1932).

Ozonolysis.—Analysis of the olefin mixture by ozonolysis[13] was difficult because the ozonide was dangerously explosive. Decomposition by a boiling suspension of zinc dust was accompanied with foaming.

Formaldehyde was identified by the resorcinol-sulfuric acid test, by the Rimini-Schryver[14] test, and by its condensation product with dimethyldihydroresorcinol,[15] m. p. 185–187°. The yield of formaldehyde as determined by iodimetric titration was 5.6%.

Acetaldehyde was isolated to the extent of 25.4% as acetaldehyde–ammonia, m. p. 90°. It was also identified by the Leys test.[16]

The oil isolated from ozonolysis of 58 g. of olefin amounted to 35 g. It contained both aldehydes and acids and separation even by repeated fractionation was not satisfactory. The aldehydes were oxidized to acids by excess alkaline potassium permanganate. The acids were separated as well as possible by several distillations and converted to the amides. Trimethylacetamide, m. p. 154–155°, was obtained after four crystallizations from ethyl acetate by adding petroleum ether. The mixed melting point with a known sample showed no depression. *Tert*-butylacetamide was not obtained pure. After repeated crystallizations it melted at 124–125° and a mixture with a known sample, m. p. 131°, melted at 126–127°. A mixture of *tert*-butyl acetamide (7.5 mg.) with trimethylacetamide (5.0 mg.) melted at 123–125°.

A search for acetone in the aqueous products of ozonolysis by attempting to obtain its dibenzylidene derivatives failed. The method was checked successfully with a known 3% solution of acetone.

Summary

Reduction of methyl neopentyl ketone in moist benzene solution with sodium gave 4,4-dimethylpentanol-2 (72% yield) and 2,2,4,5,7,7-hexamethyloctanediol-4,5. Dehydration of the carbinol gave 4,4-dimethylpentene-2 and 4,4-dimethylpentene-1 in the ratio 4.5:1.

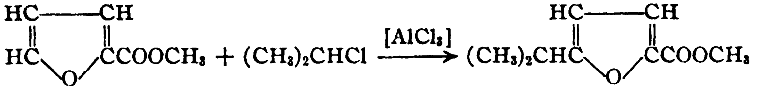
Super-Aromatic Properties of Furan. II. The Friedel-Crafts Reaction

BY HENRY GILMAN AND N. O. CALLOWAY

Introduction

The scission of furylphenyllead and furylthienyllead compounds by hydrogen chloride has been presented as evidence in support of the super-aromatic nature of furan.[1] In a by-and-large definition of aromatic compounds and aromatic properties,[1] the Friedel–Crafts reaction is important historically as one of a small number of transformations peculiarly characteristic of aromatic compounds.[2] We now know that this reaction is shown not only by unsaturated aliphatic compounds, but also apparently by some saturated aliphatic compounds.[3] However, the reaction is still considered, in the aggregate, as a transformation that is typical of aromatic compounds.

Not all aromatic compounds undergo the Friedel–Crafts reaction. This is particularly true of many benzenoid types having a meta-orienting substituent. One of the most striking illustrations is nitrobenzene, which finds application as a solvent or medium for some Friedel–Crafts reactions. Not only do furan and 2-methylfuran undergo acylation,[4] but we have found that some so-called negatively substituted furans also participate in Friedel–Crafts reactions. Methyl 2-furoate, for example, undergoes ready alkylation and acylation under customary conditions, and the related methyl benzoate does not show these reactions. Substitution takes place in the α-position.



(I)

The same type of condensation occurs with 2-furoic acid and with 2-furyl phenyl ketone. The reaction with 2-furyl phenyl ketone is particularly significant because it presents an opportunity to observe the relative aromaticities of a 2-furyl and a phenyl nucleus in a symmetrical compound. Condensation takes place only in the furyl nucleus.

Braun and Kuhn, *Ber.*, **45**, 1267 (1912), and **60**, 2557 (1927); Norris and Couch, THIS JOURNAL, **42**, 2329 (1920); Wieland and Bettay, *Ber.*, **55**, 2246 (1922); Nenitzescu and Ionescu, *Ann.*, **491**, 189 (1931); Hopff, *Ber.*, **64**, 2739 (1931), and **65**, 482 (1932); Unger, *ibid.*, **65**, 467 (1932).

[4] Reichstein, *Helv. Chim. Acta*, **13**, 356 (1930).

This preferential nuclear substitution, and the condensations with methyl furoate but not with methyl benzoate, together with the fact that benzene can be used as a medium for some Friedel–Crafts reactions of furan are advanced as supporting evidence for the concept that furan has super-aromatic properties.

As previously mentioned,[1] some benzenoid types are apparently more aromatic than others. This is especially true of benzene derivatives having amino and phenolic or substituted amino and substituted phenolic[4] groups. In accordance with this general principle it has been found that methyl anisate (p-$CH_3OC_6H_4COOCH_3$), unlike methyl benzoate, undergoes the Friedel–Crafts reaction. Also, the correlation of the α-positions in naphthalene with the α-positions in furan[5] finds support in the observation that the Friedel–Crafts reaction takes place with ethyl α-naphthoate.

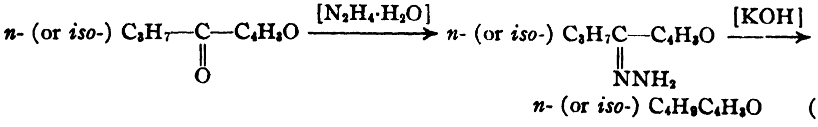
Constitution of Products.—The structure of 5-*tert*-butyl-2-furyl phenyl ketone was established by comparison with the product obtained by interaction of 5-*tert*-butyl-2-furoyl chloride with benzene and aluminum chloride.

The ketones obtained from furan and acid chlorides were identical with those prepared from 2-furylmercuric chloride and the acid halides, and from 2-furonitrile and the appropriate Grignard reagent.[6]

The alkylation products of methyl 2-furoate were somewhat unusual in the sense that the alkyl group appeared to undergo rearrangement so that, for example, each of the four butyl chlorides (as well as butylene) gave some of the same product: namely, methyl 5-*tert*-butyl-2-furoate. The structure of this compound was established by a process of exclusion. The *n*-butyl-, isobutyl-, and *sec*-butyl derivatives were synthesized and shown to be unlike the compound obtained by the Friedel–Crafts reaction which was characterized as follows

$$\text{5-}C_4H_9C_4H_2OCOOCH_3\text{-2} \xrightarrow{[HOH]} \text{5-}C_4H_9C_4H_2OCOOH\text{-2} \xrightarrow{[-CO_2]}$$
$$\text{5-}C_4H_9C_4H_3O \xrightarrow[\text{[NaAc]}]{[HgCl_2]} \text{5-}C_4H_9C_4H_2OHgCl\text{-2} \qquad \text{(III)}$$

This mercurial as well as the butylfuran from which it was prepared were shown to be unlike the other three possible 5-butyl-2-furylmercuric chlorides and the corresponding 2-butylfurans. The *n*-butyl- and isobutylfurans were synthesized as follows



$$n\text{- (or } iso\text{-) } C_3H_7\underset{\displaystyle O}{\underset{\|}{C}}C_4H_3O \xrightarrow{[N_2H_4\cdot H_2O]} n\text{- (or } iso\text{-) } C_3H_7\underset{\displaystyle NNH_2}{\underset{\|}{C}}C_4H_3O \xrightarrow{[KOH]}$$
$$n\text{- (or } iso\text{-) } C_4H_9C_4H_3O \qquad \text{(IV)}$$

The following reactions illustrate the synthesis of *sec*-butylfuran

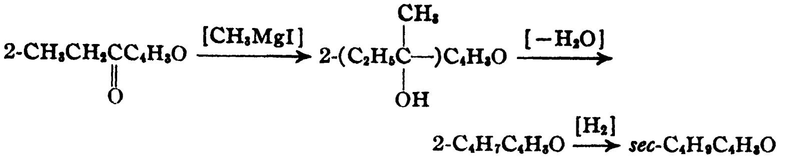
(6) Asahina and Murayama, *Arch. Pharm.*, **252**, 435 (1914).



$$2\text{-}CH_3CH_2\underset{\underset{O}{\|}}{C}C_4H_3O \xrightarrow{[CH_3MgI]} 2\text{-}(C_2H_5\overset{\overset{CH_3}{|}}{\underset{\underset{OH}{|}}{C}}\text{—})C_4H_3O \xrightarrow{[-H_2O]} 2\text{-}C_4H_7C_4H_3O \xrightarrow{[H_2]} sec\text{-}C_4H_9C_4H_3O$$

(V)

This sequence of reactions is related to that used recently[7] for the preparation of 2-isopropylfuran $C_4H_3OCOOC_2H_5 \xrightarrow{[CH_3MgI]} C_4H_3OC(CH_3)_2OH \xrightarrow{[-H_2O]} C_4H_3OC(CH_3){=}CH_2 \xrightarrow{[H_2]} C_4H_3OCH(CH_3)_2$. Our isopropylfuran is identical with this compound, and thus gives added support to the generalization[5] that nuclear substitution occurs in an α-position if one be available.

Methyl chloride gave a dithio ester, as a consequence of interaction with the carbon disulfide;[8] ethyl chloride and ethyl bromide apparently undergo a reaction like that observed with methyl chloride; both *n*-propyl and isopropyl chloride gave the same isopropyl derivative [methyl 5-isopropyl-2-furoate], so that smooth alkylation of methyl furoate really starts with the propyl halides; and the amyl and hexyl derivatives, prepared from *n*-amyl chloride and *n*-hexyl bromide, probably are branched chain types by analogy with the formation of *tert*-butylfuran from each of the four isomeric butyl halides.

The structures of the acylation products of methyl furoate were established as follows, using acetic anhydride as a type

$$C_4H_3OCOOCH_3 + (CH_3CO)_2O \xrightarrow[\text{[SnCl}_4]]{[FeCl_3 \text{ or}]} CH_3COC_4H_2OCOOCH_3 \xrightarrow{[HOH]} CH_3COC_4H_2OCOOH \xrightarrow{[-CO_2]} 2\text{-}CH_3COC_4H_3O \quad (VI)$$

The chief problem in determining the constitution of a monoacylated nuclear substituted product of a di-α-substituted furan having like substituents concerns the integrity of the furan nucleus. The nucleus is not cleaved significantly in a Friedel–Crafts reaction. This was established in the case of the acetylated 2,5-dimethylfuran by preparing the same compound from 2,5-dimethylfurylmercuric chloride and acetyl chloride. The resulting 2,5-dimethyl-3-furyl methyl ketone was prepared earlier by the condensation of succinic acid and acetic anhydride with zinc chloride.[9]

An anomalous reaction takes place between 2-furfural and isopropyl chloride. The product is not 5-isopropyl-2-furfural, but appears to be a related dihydrofuran or possibly a compound formed by nuclear cleavage.

Experimental Part

2-Furyl Phenyl Ketone and *tert*-Butyl Chloride.—Eight grams (0.05 mole) of 2-furyl phenyl ketone in carbon disulfide were brought into reaction with *tert*-butyl chloride and aluminum chloride under the conditions described later [see "Alkylation of Methyl 2-Furoate"], with the exception that no ice-bath was used. The resulting 5-*tert*-butyl-2-furyl phenyl ketone (30% yield) is unusually stable: b. p. 180–182° (20 mm.) and 187–189° (22 mm.); d_{25}^{25} 1.065; n_{D}^{25} 1.5665.

Anal. Calcd. for $C_{15}H_{16}O_2$: C, 78.94; H, 7.06. Found: C, 79.06; H, 7.54.

The same compound was obtained in a 70% yield by condensing 5-*tert*-butyl-2-furoyl chloride (0.1 mole), aluminum chloride (0.1 mole) and 100 cc. of benzene.

The 5-*tert*-butyl-2-furoyl chloride was obtained (51% yield) by refluxing 5-*tert*-butyl-2-furoic acid with thionyl chloride; b. p. 220°; d_{25}^{25} 1.108; n_{D}^{25} 1.5091.

Anal. Calcd. for $C_9H_{11}O_2Cl$: Cl, 19.03. Found: Cl, 19.37.

2-Furfural and Isopropyl Chloride.—In an experiment with 0.5 mole of furfural, 0.5 mole of isopropyl chloride, and 0.6 mole of aluminum chloride in carbon disulfide no external cooling was applied. There was a marked evolution of hydrogen chloride, and but very little charring was noted. Subsequent to hydrolysis of the reaction mixture, the carbon disulfide layer was washed first with water and then with sodium acetate. Then 200 cc. of a saturated solution of sodium acetate was added, and the resulting aldehyde steam distilled. This aqueous distillate was extracted with the carbon disulfide which first distilled over, washed with sodium bicarbonate, dried over sodium sulfate, and the aldehyde, after removing carbon disulfide, was distilled under reduced pressure.

The yield was 8 g. of aldehyde distilling at 101–103° (21 mm.); d_{25}^{25} 1.023; n_{D}^{25} 1.5041. The constitution of this aldehyde has not yet been established, but it appears to be a dihydrofuran derivative.

Anal. Calcd. for $C_8H_{12}O_2$: C, 68.52; H, 8.64. Found: C, 69.49; H, 8.38.

The aldehyde is relatively unstable and darkens on atmospheric exposure. When oxidized by alkaline silver oxide it gives a carboxylic acid which is unlike 5-isopropyl-2-furoic acid.[7] This new acid, which may be a dihydro-isopropylfuroic acid or a ring scission product, melts at 76–77° when crystallized from 40% ethyl alcohol. In an orienting experiment the supposed dihydroisopropylfuroic acid was heated with phosphorus pentachloride to remove two hydrogens and give the known 5-isopropyl-2-furoic acid; however, the original acid was recovered after alkaline hydrolysis. *Neutralization equivalent.* Calcd., 156; found, 155.

Anal. Calcd. for $C_8H_{12}O_3$: C, 61.49; H, 7.75. Found: C, 61.71; H, 7.45.

The semicarbazone of the aldehyde melts at 174–176° when crystallized from 30% alcohol, and its analysis agrees for a dihydro derivative.

Anal. Calcd. for $C_9H_{15}O_2N_3$: C, 54.79; H, 7.66. Found: C, 54.65; H, 7.42.

The unknown aldehyde was condensed with sodium acetate and acetic anhydride to give a 40% yield of an acid which analyzes for a dihydroisopropylfurylacrylic acid. This acid melts at 102–103° when crystallized from water and alcohol. *Neutralization equivalent.* Calcd., 182.1; found, 180.

Anal. Calcd. for $C_{10}H_{14}O_3$: C, 65.89; H, 7.74. Found: C, 65.93 and 65.93; H, 7.75 and 7.66.

Furan and Acid Chlorides.—To 26.6 g. (0.2 mole) of aluminum chloride in 250 cc. of carbon disulfide contained in a three-necked flask provided with a mechanical stirrer was added 0.2 mole of the acid chloride. The flask and contents were then chilled with an ice-bath. Furan (0.2 mole), prepared in accordance with recent directions,[10] contained in 50 cc. of carbon disulfide was added dropwide over a twenty-five minute period;

---

(10) Gilman and Lousinian, *Rec. trav. chim.*, 52, 156 (1933).

the mixture turned dark brown, and after about one-third of the furan had been added copious quantities of hydrogen chloride were evolved. Stirring was continued for fifteen minutes in the ice-bath, and then for ten minutes at room temp., after which the mixture was poured upon 300 g. of cracked ice, and steam distilled; the distillate was made alkaline with potassium hydroxide, extracted with ether, dried over sodium sulfate, and the alkyl 2-furyl ketone distilled under reduced pressure. The data are given in Table I.

[a] These semicarbazones were prepared and analyzed by Asahina and Murayama.[6] [b] The yield of methyl 5-isopropyl-2-furoate from isopropyl chloride was 42%. [c] From 12.6 g. (0.1 mole) of methyl furoate, 0.1 mole of *tert*-butyl chloride, 0.12 mole of ferric chloride in place of aluminum chloride and 100 cc. of carbon disulfide there was isolated but two fractions: one of these (8 g.) was recovered methyl furoate and the other a 41.3% yield of methyl 5-*tert*-butyl-2-furoate. The yield of methyl 5-*tert*-butyl-2-furoate from isobutyl bromide was 66%; from *sec*-butyl bromide, 1.6%; and from *tert*-butyl bromide, 46%.

The several ketones were also prepared by interaction of 2-furyl-mercuric chloride and the appropriate acid chloride, in accordance with recent directions.[11] The ketones
